The problems most often overlooked are maintenance access and risk to the collection from disruptions and leaks from overhead or decentralized equipment. Water or steam pipes over and in collection areas present the possibility of leaks, as do air-handling units. Some systems can provide full control without running any pipes to the zones, but others require two to six pipes to each zone, which often must be run over or in collection areas and are, unfortunately, the pipes most likely to leak. Leaks and maintenance can prevent effective use of spaces and result in lost space efficiency.

Central air-handling stations keep filtration, dehumidification, humidification, maintenance, and monitoring away from the collection. The investment in added space and the expense of the more elaborate duct system provide major returns in reduced disruption to the collection spaces and a dramatically extended service life for the distribution system. Unlike most commercial projects, space turnover in museums is low and rezoning is rarely needed. In some museums, 60-year-old multizone duct systems have been reused. Renovating the old system is economical, with most renovations confined entirely to the mechanical rooms. This is in comparison to common duct distribution systems (e.g., terminal reheat, dual-duct, and variable-air-volume), where renovations often require a new duct system and terminal equipment, involving major expense from demolishing the old ducts, installing the new duct system, and reinstalling architectural finishes.

Constant-Volume Reheat. A constant-volume reheat system can present problems if improperly applied. In many institutions, terminal reheat with steam or hot-water coils located near or over collection spaces cause chronic problems from steam and water leaks. Efficient zone-level humidification often suggests placing the humidifier downstream from the reheat coil; if the reheat coil is located near or over collection spaces, preventive maintenance on humidifiers further complicates maintenance problems. Constant-volume reheat systems are very effective when reheat coils and humidifiers are installed entirely within the mechanical space, instead of at the terminal, feeding through what is effectively a multizone distribution system.

Multizone System. A multizone air handler with zone reheat and zone humidification can be a stable and relatively energy-efficient solution. However, multizone systems without individual zone reheat and individual zone humidification have proved problematic in many institutions, requiring retrofit of zone equipment for stable humidity control. With proper layout and equipment complement, a multizone system can reduce the amount of reheat and be very energy efficient.

Bovill (1988, Figure 10) shows preferences for constant-volume and multizone systems in collection spaces. Without the need for many temperature control zones, but with the need for high air quality, the choices are constant-volume, multizone with bypass, and dual-duct. When air handlers are outside collection areas (as recommended), the best choices are constant-volume and multizone with bypass, and dual-duct. When other systems are used, the client must be made fully aware of the possible compromises in performance, cost, and serviceability.

Dehumidification Coil. An important feature of multizone and dual-duct air handlers is a separate dehumidification coil upstream of both the hot and cold decks. This separate cooling coil, distinct from the one in the cold deck, is used during dehumidification demand. Air can be cooled to dew point even if it eventually flows through the hot deck. Without this feature, moist return air could be warmed in the hot deck and delivered back to the room without being dehumidified. An alternative is to locate a single cooling coil upstream of both decks, where the cold deck simply bypasses the hot deck, although this configuration can increase energy use.

Fan-Coil Units. Fan-coil units have been problematic when placed in and above collection areas. Fan-coil units expand and decentralize maintenance, requiring maintenance in collection areas and a net increase in overall facility maintenance. Because they cool locally, they need condensate drains, which can leak or back up over time. As all-water systems, they require four pressurized-water pipes to each unit, increasing the chance of piping leaks in collection areas.

Variable Air Volume (VAV). VAV, though appropriate for other types of buildings, tends to be inappropriate for collection housing because of poor humidity control, inadequate airflow, maintenance disruption, leaks in the collection spaces, and inflexibility to meet environmental needs. A VAV system may be chosen because of space and budget constraints, but almost always the cost and space required for a properly designed VAV system (full filtration, local humidification, local dehumidification, minimum air volume settings, well-planned piping and maintenance access, well-documented operating instructions) give no advantages over constant-volume systems. VAV systems can save energy compared to constant-volume systems, but usually at the collection's expense.

If used, a VAV system should look much like a constant-volume reheat system, with the minimum airflow to prevent mold growth, contamination buildup, and uneven conditions in the conditioned space. Terminal equipment should include reheat for each zone and be located in mechanical rooms or other spaces where access and service do not endanger a collection. If VAV performance becomes a problem, it can be easily converted to a constant-volume reheat system with only an adjustment of controls.

Fan-Powered Mixing Boxes. These are usually inappropriate for these facilities. Although fan-powered mixing boxes can help ensure air circulation to suppress mold growth, they do not allow effective air filtration for particles and gases. These fans also increase local maintenance requirements and present an added fire risk. If they include reheat, there is an added risk from leaks (with water or steam reheat) or fire (with electric reheat).

Energy and Operating Costs

Operating a preservation environment is often costly, but it is often necessary for long-term protection of a valuable collection. In

most cases, the increase in usable life of a collection easily justifies the annual energy and operating costs to maintain the special environmental conditions. For institutions with small or limited operating budgets that cannot afford a major increase in annual energy cost, some compromises might be warranted or some initial capital investments made to reduce recurring annual costs. Careful commissioning using multiple instruments is helpful, and postconstruction tuning and off-hours volume reduction can reduce fan energy.

Scope of Special Environments. One of the best ways to reduce operating costs is to treat as little of the building as possible with the special environments. Spaces not needing preservation conditions should be on separate air systems that operate only when occupied.

Energy Efficiency. Using condenser heat to provide reheat for dehumidification can increase efficiency and can substantially reduce dehumidification energy cost. Although an air-side economizer can cause problems, a water-side economizer can allow efficient winter cooling using condenser water. Because load varies between day and night operations, particularly in museums, night cooling loads are sometimes best met with a smaller off-hours chiller. Similarly, primary-secondary pumping with two-way control valves can be useful as loads vary over the day and across areas.

Daylighting. Using natural light is often proposed. Ayres et al. (1990) noted that this feature is always a net energy penalty. If used, the daylighting aperture should be minimized, and avoided as much as possible in and over collection areas. For lower risk of leaks and better-managed lighting, clerestories are preferred over skylights.

Humidistatically Controlled Heating. This specialized approach has limited application and must include safety controls, but is sometimes the only option that can handle envelope limitations in cold climates. In this approach, the heating system is controlled by a humidistat rather than a thermostat (LaFontaine and Michalski 1984); cold, damp air is heated until the relative humidity drops to 50%. Where interior temperatures drop consistently below 50°F, it solves the problem of humidity in a building that does not have an adequate envelope. Obviously, humidity-controlled heating does not provide human comfort in winter, but many small museums, historic buildings, and reserve collection buildings are essentially unoccupied in winter. A high-limit thermostat is necessary to stop overheating during warm weather, and a low-limit thermostat is optional if water pipe freezing is a concern. This approach has been used in Canada (LaFontaine 1982; Marcon 1987), the United States (Conrad 1994; Kerschner 1992, 2006), and in many historic buildings in Britain (Staniforth 1984). Maekawa and Toledo (2001) successfully applied humidistatic control in hot, humid climates to minimize microbial growth.

Some cautions apply. Foundations in a previously heated building may heave if the ground is waterlogged before freezing. Improving drainage, insulating the ground near the footings, and heating the basement reduce this risk. Problems have occurred in buildings with dense object storage and a very low infiltration rate, such as a specially sealed storage space (Padfield and Jensen 1996); a very slow supply of dehumidified air to the space can be helpful.

This approach is cost-effective in seasonal museums (especially for low-mass wood-frame buildings) in colder climates like the northern United States and Canada, and in maritime regions. Humidistat control does not work in warm, humid weather: without a high-limit thermostat it can heat hot, humid conditions to dangerous temperatures. In this case, domestic dehumidifiers can supplement humidistat control.

Hybrid (Load-Sharing) HVAC Systems. This approach involves enhancing preservation in museums and libraries by an optimum collocation of radiant and forced-convection systems. Most of the sensible loads are assigned to radiant panel systems, whereas latent loads and the remaining sensible loads are assigned to forced-convection systems. Decoupling the HVAC functions primarily into sensible and latent heat transfer components enables the

designer to select better function-oriented HVAC components and to ensure higher accuracy and precision in control. Additionally, hybrid HVAC seems to satisfactorily balance the needs of preservation and human comfort, while keeping operating costs low. For example, in a library, human comfort could be maintained primarily by thermal radiation, while lowered air temperature increased the expected half-life of the books, with required fan power reduced by almost 50% (Kilkis et al. 1995). Moreover, because the forced-convection system is freed from satisfying most of the sensible heating and cooling loads, more accurate humidity control and faster response to humidity changes may be achieved. Multizoning in a hybrid HVAC system may be easier. Latent and sensible systems can also be integrated into a single HVAC unit called a **hybrid panel** (Kilkis 2002). When hydronic radiant panels, which require piping fluids into exhibition areas, are used, associated risks of damage from liquid leaks and the greater maintenance challenges must be balanced against expected savings. Liquid leakage risk might be minimized by using capillary tubing operated under negative pressure. To eliminate liquid leakage risks, all-air hybrid HVAC systems may be used. More information about panel heating and cooling and hybrid HVAC systems can be found in Chapter 6 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*.

Maintenance and Ease of Operation. A common failing of designs is not accounting for ongoing operation and maintenance. Most designs work if properly adjusted and maintained, but many institutions do not have the staff, budget, or expertise to give the system the attention it needs. Maintenance needs for any system should be matched against the institution's staff capabilities. For large projects in larger cities, code-required staffing for the plant should be considered; sometimes, smaller reciprocating chillers can be used at night to preclude the licensed engineer needed to operate larger chillers. Small projects without HVAC maintenance staff may need packaged equipment that does not require daily attention.

Effects of maintenance activities on the collection must always be taken into account. For example, testing or accidental activation of a smoke removal system can radically change the collection environment. Transitions between winter and summer modes on economizers cause many operational problems. Tools and ladders in gallery and storage areas are a threat to the collection and special precautions need to be taken.

Contaminated air conveyance components (e.g., microbiological growth and other buildup) can contribute to pollution levels, lead to premature component failure, and affect heat transfer efficiency, resulting in higher utility costs. Regular inspection and cleaning is an important part of preventative maintenance.

---	--

THE design of plant and animal housing is complicated because many environmental factors affect the production and well-being of living organisms. The financial constraint that equipment must repay costs through improved economic productivity must be considered by the designer. The engineer must balance costs of modifying the environment against economic losses of a plant or animal in a less-than-ideal environment.

Thus, design of plant and animal housing is affected by (1) economics, (2) concern for both workers and the care and well-being of animals, and (3) regulations on pollution, sanitation, and health assurance.

1. DESIGN FOR ANIMAL ENVIRONMENTS

Typical animal production plants modify the environment, to some degree, by housing or sheltering animals year-round or for parts of a year. The degree of modification is generally based on the expected increase in production. Animal sensible heat and moisture production data, combined with information on the effects of environment on growth, productivity, and reproduction, help designers select optimal equipment. Detailed information is available in a series of handbooks published by the MidWest Plan Service. These include *Mechanical Ventilating Systems for Livestock Housing* (MWPS 1990a), *Natural Ventilating Systems for Livestock Housing and Heating* (MWPS 1989), and *Cooling and Tempering Air for Livestock Housing* (MWPS 1990b). ASAE Monograph 6, *Ventilation of Agricultural Structures* (Hellickson and Walter 1983), also gives more detailed information.

Design Approach

Environmental control systems are typically designed to maintain thermal and air quality conditions within an acceptable range and as near the ideal for optimal animal performance as is practicable. Equipment is usually sized assuming steady-state energy and mass conservation equations. Experimental measurements confirm that heat and moisture production by animals is not constant and that there may be important thermal capacitance effects in livestock buildings. Nevertheless, for most design situations, the steady-state equations are acceptable.

Achieving the appropriate fresh air exchange rate and establishing the proper distribution within the room are generally the two most important design considerations. The optimal ventilation rate is selected according to the ventilation rate logic curve (Figure 1).

Fig. 1 Logic for Selecting Appropriate Ventilation Rate in Livestock Buildings
 (Adapted from Christianson and Fehr 1983)

During the coldest weather, the ideal ventilation rate is that required to maintain indoor relative humidity at or below the maximum desired, and air contaminant concentrations within acceptable ranges (Rates A and B in Figure 1). Supplemental heating is often required to prevent the temperature from dropping below optimal levels.

In milder weather, the ventilation rate required for maintaining optimal room air temperature is greater than that required for moisture and air quality control (Rates C and D in Figure 1). In hot weather, the ventilation rate is chosen to minimize the temperature rise above ambient and to provide optimal air movement over animals. Cooling is sometimes used in hot weather. The maximum rate (D) is often set at 60 air changes per hour (ach) as a practical maximum.

Temperature Control

The temperature in an animal structure is computed from the sensible heat balance of the system, usually disregarding transient effects. Nonstandard buildings with low airflow rates and/or large thermal mass may require transient analysis. Steady-state heat transfer through walls, ceiling or roof, and ground is calculated as

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment.

presented in Chapters 25 to 27 of the 2013 *ASHRAE Handbook—Fundamentals*.

Mature animals typically produce more heat per of unit floor area than do young stock. Chapter 10 of the 2005 *ASHRAE Handbook—Fundamentals* presents estimates of animal heat loads. Lighting and equipment heat loads are estimated from power ratings and operating times. Typically, the designer selects indoor and outdoor design temperatures and calculates the ventilation rate to maintain the temperature difference. Outdoor design temperatures are given in Chapter 14 of the 2013 *ASHRAE Handbook—Fundamentals*. The section on Recommended Practices by Species in this chapter presents indoor design temperature values for various livestock.

Moisture Control

Moisture loads produced in an animal building may be calculated from data in Chapter 10 of the 2005 *ASHRAE Handbook—Fundamentals*. The mass of water vapor produced is estimated by dividing the animal latent heat production by the latent heat of vaporization of water at animal body temperature. Spilled water and evaporation of fecal water must be included in the estimates of latent heat production within the building. The amount of water vapor removed by ventilation from a totally slatted (manure storage beneath floor) swine facility may be up to 40% less than the amount removed from a solid concrete floor. If the floor is partially slatted, the 40% maximum reduction is decreased in proportion to the percentage of the floor that is slatted.

Ventilation should remove enough moisture to prevent condensation but should not reduce the relative humidity so low (less than 40%) as to create dusty conditions. Design indoor relative humidity for winter ventilation is usually between 70 and 80%. The walls should have sufficient insulation to prevent surface condensation at 80% rh inside.

During cold weather, ventilation needed for moisture control usually exceeds that needed to control temperature. Minimum ventilation must always be provided to remove animal moisture. Up to a full day of high humidity may be allowed during extremely cold periods when normal ventilation rates could cause an excessive heating demand. Humidity level is not normally the controlling factor in mild or hot weather.

Air Quality Control

Contaminants. The most common and prevalent air contaminants in animal buildings are particulate matter (PM) and gases. In animal buildings, particulate matter originates mainly from feed, litter, fecal materials, and animals. Particulates include solid particles (or dust), liquid droplets, and microorganisms, can be deposited deep within the respiratory system. Particulates carry allergens that cause discomfort and health problems for workers in animal housing facilities. They also carry much of the odors in animal housing facilities, for potentially long distances from the facilities. Consequently, particulates pose major problems for animals, workers, and neighbors. Particulate levels in swine buildings have been measured to range from 0.028 to 0.43 mg/ft³. Dust has not been a major problem in dairy buildings; one two-year study found an average of only 0.014 mg/ft³ in a naturally ventilated dairy barn. Poultry building dust levels average around 0.057 to 0.20 mg/ft³, but levels up to 0.51 to 0.82 mg/ft³ have been measured during high activity.

The most common gas contaminants are ammonia, hydrogen sulfide, other odorous compounds, carbon dioxide, and carbon monoxide. High moisture levels can also aggravate other contaminant problems. Ammonia, which results from decomposition of manure, is the most important chronically present contaminant gas. Typical ammonia levels measured have been 10 to 50 ppm in poultry units, 0 to 20 ppm in cattle buildings, 5 to 30 ppm in swine units with liquid manure systems, and 10 to 50 ppm in swine units with

solid floors (Ni et al. 1998a). Up to 200 ppm have been measured in swine units in winter. Ammonia should be maintained below 25 ppm and, ideally, below 10 ppm.

Maghirang et al. (1995) and Zhang et al. (1992) found ammonia levels in laboratory animal rooms to be negligible, but concentrations could reach 60 ppm

in cages. Weiss et al. (1991) found ammonia levels in rat cages of up to 350 ppm with four male rats per cage and 68 ppm with four female rats per cage. Hasenau et al. (1993) found that ammonia levels varied widely among various mouse microisolation cages; ammonia ranged from negligible to 520 ppm nine days after cleaning the cage.

Hydrogen sulfide, a by-product of microbial decomposition of stored manure, is the most important acute gas contaminant. During normal operation, hydrogen sulfide concentration is usually insignificant (i.e., below 1 ppm). A typical level of hydrogen sulfide in swine buildings is around 150 to 350 ppb (Ni et al. 1998b). However, levels can reach 200 to 330 ppm, and possibly up to 1000 to 8000 ppm during in-building manure agitation.

Odors from animal facilities are an increasing concern, both in the facilities and in the surrounding areas. Odors result from both gases and particulates; particulates are of primary concern because odorous gases can be quickly diluted below odor threshold concentrations in typical weather conditions, whereas particulates can retain odor for long periods. Methods that control particulate and odorous gas concentrations in the air also reduce odors, but controlling odor generation at the source appears to be the most promising method of odor control.

Barber et al. (1993), reporting on 173 pig buildings, found that carbon dioxide concentrations were below 3000 ppm in nearly all instances when the external temperature was above 32°F but almost always above 3000 ppm when the temperature was below 32°F. The report indicated that there was a very high penalty in heating cost in cold climates if the maximum allowed carbon dioxide concentration was less than 5000 ppm. Air quality control based on carbon dioxide concentrations was suggested by Donham et al. (1989). They suggested a carbon dioxide concentration of 1540 ppm as a threshold level, above which symptoms of respiratory disorders occurred in a population of swine building workers. For other industries, a carbon dioxide concentration of 5000 ppm is suggested as the time-weighted threshold limit value for 8 h of exposure (ACGIH 1998).

Other gas contaminants can also be important. Carbon monoxide from improperly operating unvented space heaters sometimes reaches problem levels. Methane is another occasional concern.

Control Methods. Three standard methods used to control air contaminant levels in animal facilities are

1. Reduce contaminant production at the sources.
2. Remove contaminants from the air by air cleaning.
3. Reduce contaminant concentration by dilution (ventilation).

The first line of defense is to reduce release of contaminants from the source, or at least to intercept and remove them before they reach workers and animals. Animal feces and urine are the largest sources of contaminants, but feed, litter, and the animals themselves are also a major source of contaminants, especially particulates. Successful operations effectively collect and remove all manure from the building within three days, before it decomposes enough to produce large quantities of contaminants. Removing ventilation air uniformly from manure storage or collection areas helps remove contaminants before they reach animal or worker areas.

Ammonia production can be minimized by removing wastes from the room and keeping floor surfaces or bedding dry. Immediately covering manure solids in gutters and pits with water also reduces ammonia, which is highly soluble in water. Because adverse effects of hydrogen sulfide on production begin to occur at 20 ppm, ventilation systems should be designed to maintain hydrogen sulfide levels

below 20 ppm during agitation. When manure is agitated and removed from the storage, the building should be well ventilated and all animals and occupants evacuated to avoid potentially fatal concentrations of gases.

For laboratory animals, changing the bedding frequently and keeping the bedding dry with lower relative humidities and appropriate cage ventilation can reduce ammonia release. Individually ventilated laboratory animal cages or placing cages in mass air displacement units reduce contaminant production by keeping litter drier. Using localized contaminant containment work stations for dust-producing tasks such as cage changing may also help. For poultry or laboratory animals, the relative humidity of air surrounding the litter should be kept between 50 and 75% to reduce particulate and gas contaminant release. Relative humidities between 40 and 75% also reduce the viability of pathogens in the air. A moisture content of 25 to 30% (wet basis) in the litter or bedding keeps dust to a minimum. Adding 0.5 to 2% of edible oil or fat can significantly reduce dust emission from the feed. Respirable dust (smaller than 10 μm), which is most harmful to the health and comfort of personnel and animals, is primarily from feces, animal skins, and dead microorganisms. Respirable dust concentration should be kept below 0.0065 mg/ft³. Some dust control technologies are available. For example, sprinkling oil at 0.12 gal per 1000 ft² of floor area per day can reduce dust concentration by more than 80%. High animal activity levels release large quantities of particulates into the air, so management strategies to reduce agitation of animals are helpful.

Methods of removing contaminants from the air are essentially limited to particulate removal, because gas removal methods are often too costly for animal facilities. Some animal workers wear personal protection devices (appropriate masks) to reduce inhaled particulates. Room air filters reduce animal disease problems, but they have not proven practical for large animal facilities because of the large quantity of particulates and the difficulty in drawing particulates from the room and through a filter. Air scrubbers can remove gases and particulates, but the initial cost and maintenance make them impractical. Aerodynamic centrifugation is showing promise for removing the small particulates found in animal buildings.

Ventilation is the most prevalent method used to control gas contaminant levels in animal facilities. It is reasonably effective in removing gases, but not as effective in removing particulates. Pockets in a room with high concentrations of particulate contaminants are common. These polluted pockets occur in dead air spots or near large contaminant sources. Providing high levels of ventilation can be costly in winter, can create drafts on the animals, and can increase the release of gas contaminants by increasing air velocity across the source.

Disease Control

Airborne microbes can transfer disease-causing organisms among animals. For some situations, typically with young animals where there are low-level infections, it is important to minimize air mixing among animal groups. It is especially important to minimize air exchange between different animal rooms, so buildings need to be fairly airtight.

Poor thermal environments and air contaminants can increase stress on the animals, which can make them more susceptible to disease. Therefore, a good environmental control system is important for disease control.

Air Distribution

Air speed should be maintained below 50 fpm for most animal species in both cold and mild weather. Animal sensitivities to draft are comparable to those of humans, although some animals are more sensitive at different stages. Riskowski and Bundy (1988) documented that air velocities for optimal rates of gain and feed

Fig. 2 Response of Swine to Air Velocity

efficiencies can be below 25 fpm for young pigs at thermoneutral conditions.

Increased air movement during hot weather increases growth rates and improves heat tolerance. There are conflicting and limited data defining optimal air velocity in hot weather. Bond et al. (1965) and Riskowski and Bundy (1988) determined that both young and mature swine perform best when air speed is less than 200 fpm (Figure 2). Mount and Start (1980) did not observe performance penalties at air speeds increased to a maximum of 150 fpm.

Degree of Shelter

Livestock, especially young animals, need some protection from adverse climates. On the open range, mature cattle and sheep need protection during severe winter conditions. In winter, dairy cattle and swine may be protected from precipitation and wind with a three-sided, roofed shelter open on the leeward side. The windward side should also have approximately 10% of the wall surface area open to prevent negative pressure inside the shelter, which could cause rain and snow to be drawn into the building on the leeward side. These shelters do not protect against high temperature or high humidity.

In warmer climates, shades often provide adequate shelter, especially for large, mature animals such as dairy cows. Shades are commonly used in Arizona; research in Florida has shown an approximate 10% increase in milk production and a 75% increase in conception efficiency for shaded versus unshaded cows. The benefit of shades has not been documented for areas with less severe summer temperatures. Although shades for beef cattle are also common practice in the southwestern United States, beef cattle are somewhat less susceptible to heat stress, and extensive comparisons of various shade types in Florida have detected little or no differences in daily weight gain or feed conversion.

The energy exchange between an animal and various areas of the environment is illustrated in Figure 3. A well-designed shade makes maximum use of radiant heat sinks, such as the cold sky, and gives maximum protection from direct solar radiation and high surface temperature under the shade. Good design considers geometric orientation and material selection, including roof surface treatment and insulation material on the lower surface.

An ideal shade has a top surface that is highly reflective to solar energy and a lower surface that is highly absorptive to solar radiation reflected from the ground. A white-painted upper surface reflects solar radiation, yet emits infrared energy better than aluminum. The undersurface should be painted a dark color to prevent multiple reflection of shortwave energy onto animals under the shade.

Fig. 3 Energy Exchange Between Farm Animal and Surroundings in Hot Environment

1.1 COOLING AND HEATING

Air Velocity

Increasing air velocity helps to facilitate the cooling of mature animals. It is especially beneficial when combined with skin wetting evaporative cooling. Mature swine benefit most with air velocities up to 200 fpm; cattle around 300 fpm; and poultry around 600 fpm. Air velocity can be increased with air circulation fans that blow air horizontally in circular patterns around the room, paddle fans that blow air downward, or tunnel cooling that moves air horizontally along the length of the building.

Evaporative Cooling

Supplemental cooling of animals in intensive housing conditions may be necessary during heat waves to prevent heat prostration, mortality, or serious losses in production and reproduction. Evaporative cooling, which may reduce ventilation air to 80°F or lower in most of the United States, is popular for poultry houses, and is sometimes used for swine and dairy housing.

Evaporative cooling is well suited to animal housing because the high air exchange rates effectively remove odors and ammonia, and increase air movement for convective heat relief. Initial cost, operating expense, and maintenance problems are all relatively low compared to other types of cooling systems. Evaporative cooling works best in areas with low relative humidity, but significant benefits can be obtained even in the humid southeastern United States.

Design. The pad area should be sized to maintain air velocities between 200 and 275 fpm through the pads. For most pad systems, these velocities produce evaporative efficiencies between 75 and 85%; they also increase pressures against the ventilating fans from 0.04 to 0.12 in. of water, depending on pad design.

The building and pad system must be airtight because air leaks caused by the negative-pressure ventilation reduce airflow through the pads, and hence reduce cooling effectiveness.

The most serious problem encountered with evaporative pads for agricultural applications is clogging by dust and other airborne particles. Whenever possible, fans should exhaust away from pads on adjacent buildings. Regular preventive maintenance is essential. Water bleed-off and the addition of algacides to the water are recommended. When pads are not used in cool weather, they should be sealed to prevent dusty inside air from exhausting through them.

High-pressure fogging with water pressure of 500 psi is preferred to pad coolers for cooling air in broiler houses with built-up litter. The high pressure creates a fine aerosol, causing minimal litter wetting. Timers and/or thermostats control the cooling. Evaporative efficiency and installation cost are about one-half those of a well-designed evaporative pad. Foggers can also be used with naturally

ventilated, open-sided housing. Low-pressure systems are not recommended for poultry, but may be used during emergencies.

Nozzles that produce water mist or spray droplets to wet animals directly are used extensively during hot weather in swine confinement facilities with solid concrete or slatted floors. Currently, misting or sprinkling systems with larger droplets that directly wet the skin surface of the animals (not merely the outer portion of the hair coat) are preferred. Timers that operate periodically, (e.g., 2 to 3 min on a 15 to 20 min cycle) help to conserve water.

Mechanical Refrigeration

Mechanical refrigeration can be designed for effective animal cooling, but it is considered uneconomical for most production animals. Air-conditioning loads for dairy housing may require 2.5 kW or more per cow. Recirculation of refrigeration air is usually not feasible because of high contaminant loads in the air in the animal housing. Sometimes, zone cooling of individual animals is used instead of whole-room cooling, particularly in swine farrowing houses, where a lower air temperature is needed for sows than for unweaned piglets. It is also beneficial for swine boars and gestating sows. Refrigerated air, 18 to 36°F below ambient temperature, is supplied through insulated ducts directly to the head and face of the animal. Air delivery rates are typically 20 to 40 cfm per animal for snout cooling, and 60 to 80 cfm per sow for zone cooling.

Earth Tubes

Some livestock facilities obtain cooling in summer and heating in winter by drawing ventilation air through tubing buried 6 to 13 ft below grade. These systems are most practical in the north central United States for animals that benefit from both cooling in summer and heating in winter.

MWPS (1990b) details design procedures for this method. A typical design uses 50 to 150 ft of 8 in. diameter pipe to provide 300 cfm of tempered air. Soil type and moisture, pipe depth, airflow, climate, and other factors affect the efficiency of buried pipe heat exchangers. The pipes must slope to drain condensation, and must not have dips that could plug with condensation.

Heat Exchangers

Ventilation accounts for 70 to 90% of the heat losses in typical livestock facilities during winter. Heat exchangers can reclaim some of the heat lost with the exhaust ventilating air. However, predicting fuel savings based on savings obtained during the coldest periods overestimates yearly savings from a heat exchanger. Estimates of energy savings based on air enthalpy can improve the accuracy of the predictions.

Heat exchanger design must address the problems of condensate freezing and/or dust accumulation on the heat-exchanging surfaces. If unresolved, these problems result in either reduced efficiency and/or the inconvenience of frequent cleaning.

Supplemental Heating

For poultry weighing 3.3 lb or more, for pigs heavier than 50 lb, and for other large animals such as dairy cows, body heat of animals at recommended space allocations is usually sufficient to maintain moderate temperatures (i.e., above 50°F) in a well-insulated structure. Combustion-type heaters are used to supplement heat for baby chicks and pigs. Supplemental heating also increases the moisture-holding capacity of the air, which reduces the quantity of air required for moisture removal. Various types of heating equipment may be included in ventilation, but they need to perform well in dusty and corrosive atmospheres.

Fig. 4 Climatic Zones

(Reprinted with permission from ASAE Standard S401.2)

Insulation Requirements

The amount of building insulation required depends on climate, animal space allocations, and animal heat and moisture production. Refer to Figure 4 and Table 1 for selecting insulation levels. In warm weather, ventilation between the roof and insulation helps reduce the radiant heat load from the ceiling. Insulation in warm climates can be more important for reducing radiant heat loads in summer than reducing building heat loss in winter.

Cold buildings have indoor conditions about the same as outdoor conditions. Examples are free-stall barns and open-front livestock buildings. Minimum insulation is frequently recommended in the roofs of these buildings to reduce solar heat gain in summer and to reduce condensation in winter.

Modified environment buildings rely on insulation, natural ventilation, and animal heat to remove moisture and to maintain the inside within a specified temperature range. Examples are warm free-stall barns, poultry production buildings, and swine finishing units.

Supplementary heated buildings require insulation, ventilation, and extra heat to maintain the desired inside temperature and humidity. Examples are swine farrowing and nursery buildings.

1.2 VENTILATION

Mechanical Ventilation

Mechanical ventilation uses fans to create a static pressure difference between the inside and outside of a building. Farm buildings use either positive pressure, with fans forcing air into a building, or negative pressure, with exhaust fans. Some ventilation systems use a combination of positive pressure to introduce air into a building and separate fans to remove air. These zero-pressure systems are particularly appropriate for heat exchangers.

Positive-Pressure Ventilation. Fans blow outdoor air into the ventilated space, forcing humid air out through any planned outlets and through leaks in walls and ceilings. If vapor barriers are not complete, moisture can condense within the walls and ceiling during cold weather. Condensation causes deterioration of building materials and reduces insulation effectiveness. The energy used by fan motors and rejected as heat is added to the building (an advantage in winter, but a disadvantage in summer).

Negative-Pressure Ventilation. Fans exhaust air from the ventilated space while drawing outdoor air in through planned inlets and leaks in walls, in ceilings, and around doors and windows. Air distribution in negative-pressure ventilation is often less complex and costly than positive- or neutral-pressure systems. Simple openings and baffled slots in walls control and distribute air in the build-

Table 1 Minimum Recommended Overall Coefficients of Heat Transmission *U* for Insulated Assemblies^{a,b}

Climatic Zone ^d	Recommended Minimum <i>U</i> , Btu/h·ft ² ·°F ^c					
	Cold		Modified Environment		Supplementally Heated	
	Walls	Ceiling	Walls	Ceiling	Walls	Ceiling
1	—	0.17 ^e	0.17 ^e	0.071	0.071	0.045
2	—	0.17	0.17	0.059	0.071	0.040
3	—	0.17	0.083	0.040	0.050	0.030

^aUse assembly *U*-factors that include framing effects, air spaces, air films, linings, and sidings. Determine assembly *U*-factors by testing the full assembly in accordance with ASTM Standard C1363 or calculate by the procedures presented in the 2013 ASHRAE Handbook—Fundamentals.

^bValues shown are not the values necessary to provide a heat balance between heat produced by products or animals and heat transferred through the building.

^cCurrent practice for poultry growout buildings uses a *U* of 0.11 to 0.14 Btu/h·ft²·°F in the roof and walls.

^dRefer to Figure 4.

^eWhere ambient temperature and radiant heat load are severe, *U* = 0.83 Btu/h·ft²·°F.

ing. However, at low airflow rates, negative pressure ventilation may not distribute air uniformly because of air leaks and wind pressure effects. Supplemental air mixing may be necessary.

Allowances should be made for reduced fan performance caused by dust, guards, and corrosion of louver joints (Person et al. 1979). Totally enclosed fan motors are protected from exhaust air contaminants and humidity. Periodic cleaning helps prevent overheating. Negative-pressure ventilation is more commonly used than positive-pressure ventilation.

Ventilation should always be designed so that manure gases are not drawn into the building from manure storages connected to the building by underground pipes or channels.

Neutral-Pressure Ventilation. Neutral-pressure (push/pull) ventilation typically uses supply fans to distribute air down a distribution duct to room inlets, and exhaust fans to remove air from the room. Supply and exhaust fan capacities should be matched.

Neutral-pressure systems are often more expensive, but they achieve better control of the air. They are less susceptible to wind effects and to building leakage than positive- or negative-pressure systems. Neutral-pressure systems are most frequently used for young stock and for animals most sensitive to environmental conditions, primarily where cold weather is a concern.

Natural Ventilation

Either natural or mechanical ventilation is used to modify environments in livestock shelters. Natural ventilation is most common for mature animal housing, such as free-stall dairy, poultry growing, and swine finishing houses. Natural ventilation depends on pressure differences caused by wind and temperature differences. Well-designed natural ventilation keeps temperatures reasonably stable, if automatic controls regulate ventilation openings. Usually, a design includes an open ridge (with or without a rain cover) and openable sidewalls, which should cover at least 50% of the wall for summer operation. Ridge openings are about 2 in. wide for each 10 ft of house width, with a minimum ridge width of 6 in. to avoid freezing problems in cold climates. Upstand baffles on each side of the ridge opening greatly increase airflow (Riskowski et al. 1998). Small screens and square edges around sidewall openings can significantly reduce airflow through vents.

Openings can be adjusted automatically, with control based on air temperature. Some designs, referred to as flex housing, include a combination of mechanical and natural ventilation usually dictated by outdoor air temperature and/or the amount of ventilation required.

1.3 VENTILATION MANAGEMENT

Air Distribution

Pressure differences across walls and inlet or fan openings are usually maintained between 0.04 and 0.06 in. of water. (The exhaust fans are usually sized to provide proper ventilation at pressures up to 0.12 in. to compensate for wind effects.) This pressure difference creates inlet velocities of 600 to 1000 fpm, sufficient for effective air mixing, but low enough to cause only a small reduction in fan capacity. A properly planned inlet system distributes fresh air equally throughout the building. Negative pressure ventilation that relies on cracks around doors and windows does not distribute fresh air effectively. Inlets require adjustment, since winter airflow rates are typically less than 10% of summer rates. Automatic controllers and inlets are available to regulate inlet areas.

Positive pressure ventilation, with fans connected directly to perforated air distribution tubes, may combine heating, circulation, and ventilation in one system. Air distribution tubes or ducts connected to circulating fans are sometimes used to mix the air in negative pressure ventilation. Detailed design procedures for perforated ventilation tubes are described by Zhang (1994). However, dust in the ducts is of concern when air is recirculated, particularly when cold incoming air condenses moisture in the tubes.

Inlet Design. Inlet location and size most critically affect air distribution within a building. Continuous or intermittent inlets can be placed along the entire length of one or both outer walls. Building widths narrower than 20 ft may need only a single inlet along one wall. The total inlet area may be calculated by the system characteristic technique, which follows. Because the distribution of the inlet area is based on the geometry and size of the building, specific recommendations are difficult.

System Characteristic Technique. This technique determines the operating points for the ventilation rate and pressure difference across inlets. Fan airflow rate as a function of pressure difference across the fan should be available from the manufacturer. Allowances must be made for additional pressure losses from fan shutters or other devices such as light restriction systems or cooling pads.

Inlet flow characteristics are available for hinged baffle and center-ceiling flat baffle slotted inlets (Figure 5). Airflow rates can be calculated for the baffles in Figure 5 by the following:

For Case A:

$$Q = 285Wp^{0.5} \quad (1)$$

For Case B:

$$Q = 183Wp^{0.5} \quad (2)$$

For Case C (total airflow from sum of both sides):

$$Q = 320Wp^{0.5}(D/T)^{0.08}e^{(-0.867W/T)} \quad (3)$$

where

- Q = airflow rate, cfm per foot length of slot opening
- W = slot width, in.
- p = pressure difference across the inlet, in. of water
- D = baffle width, in.
- T = width of slot in ceiling, in.

Zhang and Barber (1995) measured infiltration rates of five rooms in a newly built swine building at 0.12 cfm/ft² of surface area at 0.08 in. of water. Surface area included the area of walls and ceiling enclosing the room. It is important to include this infiltration rate into the ventilation design and management. For example, at 0.12 cfm/ft² of surface area, the infiltration represents 1.4 ach. In the heating season, the minimum ventilation is usually about 3 ach. Thus, large infiltration rates greatly reduce the airflow from the controlled inlet and adversely affect the air distribution.

Fig. 5 Typical Livestock Building Inlet Configurations

Room Air Velocity. The average air velocity inside a slot-ventilated structure relates to the inlet air velocity, inlet slot width (or equivalent continuous length for boxed inlets), building width, and ceiling height. Estimates of air velocity within a barn, based on air exchange rates, may be very low because of the effects of jet velocity and recirculation. Conditions are usually partially turbulent, and there is no reliable way to predict room air velocity at animal level. General design guidelines keep the throw distance less than 20 ft from slots and less than 10 ft from perforated tubes.

Fans

Fans should not exhaust against prevailing winds, especially for cold-weather ventilation. If structural or other factors require installing fans on the windward side, fans rated to deliver the required capacity against at least 0.12 in. of water static pressure and with a relatively flat power curve should be selected. The fan motor should withstand a wind velocity of 30 mph, equivalent to a static pressure of 0.4 in. of water, without overloading beyond its service factor. Wind hoods on the fans or windbreak fences reduce the effects of wind.

Third-party test data should be used to obtain fan performance and energy efficiencies for fan selection (BESS Lab 1997). Fans

should be tested with all accessories (e.g., louvers, guards, hoods) in place, just as they will be installed in the building. The accessories have a major effect on fan performance.

Flow Control. Because the numbers and size of livestock and climatic conditions vary, means to modulate ventilation rates are often required beyond the conventional off/on thermostat switch. The minimum ventilation rate to remove moisture, reduce air contaminant concentrations, and keep water from freezing should always be provided. Methods of modulating ventilation rates include (1) intermittent fan operation (fans operate for a percentage of the time controlled by a percentage timer with a 10 min cycle); (2) staging of fans using multiple units or fans with high/low-exhaust capability; (3) using multispeed fans [larger fans (1/2 hp and up) with two flow rates, the lower being about 60% of the maximum rate]; and (4) using variable-speed fans [split-capacitor motors designed to modulate fan speed smoothly from maximum down to 10 to 20% of the maximum rate (the controller is usually thermostatically adjusted)].

Generally, fans are spaced uniformly along the winter leeward side of a building. Maximum distance between fans is 115 to 165 ft. Fans may be grouped in a bank if this range is not exceeded. In housing with side curtains, exhaust fans that can be reversed or removed and placed inside the building in the summer are sometimes installed to increase air movement in combination with doors, walls, or windows being opened for natural ventilation.

Thermostats

Thermostats should be placed where they respond to a representative temperature as sensed by the animals. Thermostats need protection and should be placed to prevent potential physical or moisture damage (i.e., away from animals, ventilation inlets, water pipes, lights, heater exhausts, outer walls, or any other objects that will unduly affect performance). Thermostats also require periodic adjustment based on accurate thermometer readings taken in the immediate proximity of the animal.

Emergency Warning

Animals housed in a high-density, mechanically controlled environment are subject to considerable risk of heat prostration if a failure of power or ventilation equipment occurs. To reduce this danger, an alarm and an automatic standby electric generator are highly recommended. Many alarms detect failure of the ventilation. These alarms range from inexpensive power-off alarms to ones that sense temperature extremes and certain gases. Automatic telephonedialing systems are effective as alarms and are relatively inexpensive. Building designs that allow some side wall panels (e.g., 25% of wall area) to be removed for emergency situations are also recommended.

1.4 RECOMMENDED PRACTICES BY SPECIES

Mature animals readily adapt to a broad range of temperatures, but efficiency of production varies. Younger animals are more temperature sensitive. Figure 6 illustrates animal production response to temperature.

Relative humidity has not been shown to influence animal performance, except when accompanied by thermal stress. Relative humidity consistently below 40% may contribute to excessive dustiness; above 80%, it may increase building and equipment deterioration. Disease pathogens also appear to be more viable at either low or high humidity. Relative humidity has a major influence on the effectiveness of skin-wetting cooling methods.

Dairy Cattle

Dairy cattle shelters include confinement stall barns, free stalls, and loose housing. In a stall barn, cattle are usually confined to stalls approximately 4 ft wide, where all chores, including milking

and feeding, are conducted. Such a structure requires environmental modification, primarily through ventilation. Total space requirements are 50 to 75 ft² per cow. In free-stall housing, cattle are not confined to stalls but can move freely. Space requirements per cow are 75 to 100 ft². In loose housing, cattle are free to move within a fenced lot containing resting and feeding areas. Space required in sheltered loose housing is similar to that in free-stall housing. Shelters for resting and feeding areas are generally open-sided and require no air conditioning or mechanical ventilation, but supplemental air mixing is often beneficial during warm weather. The milking area is in a separate area or facility and may be fully or partially enclosed, thus requiring some ventilation.

For dairy cattle, climate requirements for minimal economic loss are broad, and range from 35 to 75°F with 40 to 80% rh. Below 35°F, production efficiency declines and management problems increase. However, the effect of low temperature on milk production is not as extreme as are high temperatures, where evaporative coolers or other cooling methods may be warranted.

Ventilation Rates for Each 1100 lb Cow

Winter	Spring/Fall	Summer
36 to 47 cfm	142 to 190 cfm	230 to 470 cfm

Required ventilation rates depend on specific thermal characteristics of individual buildings and internal heating load. The relative humidity should be maintained between 50 and 80%.

Both loose housing and stall barns require an additional milk room to cool and hold the milk. Sanitation codes for milk production contain minimum ventilation requirements. The market being supplied should be consulted for all applicable codes. Some state codes require positive-pressure ventilation of milk rooms. Milk rooms are usually ventilated with fans at rates of 4 to 10 ach to satisfy requirements of local milk codes and to remove heat from milk coolers. Most milk codes require ventilation in the passageway (if any) between the milking area and the milk room.

Beef Cattle

Beef cattle ventilation requirements are similar to those of dairy cattle on a unit weight basis. Beef production facilities often provide only shade and wind breaks.

Swine

Swine housing can be grouped into four general classifications:

1. Farrowing pigs, from birth to 30 lb, and sows
2. Nursery pigs, from 30 to 75 lb
3. Growing/finishing pigs, from 75 lb to market weight
4. Breeding and gestation

In farrowing barns, two environments must be provided: one for sows and one for piglets. Because each requires a different temperature, zone heating and/or cooling is used. The environment within the nursery is similar to that within the farrowing barn for piglets. The requirements for growing barns and breeding stock housing are similar.

Currently recommended practices for **farrowing houses**:

- Temperature: 50 to 68°F, with small areas for piglets warmed to 82 to 90°F by brooders, heat lamps, or floor heat. Avoid cold drafts and extreme temperatures. Hovers are sometimes used. Provide supplemental cooling for sows (usually drippers or zone cooling) in extreme heat.
- Relative humidity: Up to 70% maximum
- Ventilation rate: 20 to 500 cfm per sow and litter (about 400 lb total weight). The low rate is for winter; the high rate is for summer temperature control.

Fig. 6 Critical Ambient Temperatures and Temperature Zone for Optimum Performance and Nominal Performance Loss in Farm Animals

(Adapted from Hahn 1985, in *Stress Physiology in Livestock*, Vol. II, CRC Press)

- Space: 35 ft² per sow and litter (stall); 65 ft² per sow and litter (pens)
Recommendations for **nursery barns**:
- Temperature:
80°F for first week after weaning. Lower room temperature 3°F per week to 72°F. Provide warm, draft-free floors. Provide supplemental cooling for extreme heat (temperatures 85°F and above).
- Ventilation rate:
2 to 2.5 cfm per pig, 12 to 30 lb each
3 to 35 cfm per pig, 30 to 75 lb each
- Space:
2 to 2.5 ft² per pig, 12 to 30 lb each
3 to 4 ft² per pig, 30 to 75 lb each
Recommendations for **growing and gestation barns**:
- Temperature:
55 to 72°F preferred. Provide supplemental cooling (sprinklers or evaporative coolers) for extreme heat.

- Relative humidity:
75% maximum in winter; no established limit in summer
- Ventilation rate:
Growing pig (75 to 150 lb), 7 to 75 cfm
Finishing pig (150 to 220 lb), 10 to 120 cfm
Gestating sow (325 lb), 12 to 150 cfm
Boar/breeding sow (400 lb), 14 to 300 cfm
- Space:
6 ft² per pig, 75 to 150 lb each
8 ft² per pig, 150 to 220 lb each
14 to 24 ft² per sow, 240 to 500 lb each

Poultry

In broiler and brooder houses, growing chicks require changing environmental conditions, and heat and moisture dissipation rates increase as the chicks grow older. Supplemental heat, usually from brooders, is used until sensible heat produced by the birds is adequate to maintain an acceptable air temperature. At early stages of growth, moisture dissipation per bird is low. Consequently, low

ventilation rates are recommended to prevent excessive heat loss. Litter is allowed to accumulate over 3 to 5 flock placements. Lack of low-cost litter material may justify the use of concrete floors. After each flock, caked litter is removed and fresh litter is added.

Housing for poultry may be open, curtain-sided or totally enclosed. Mechanical ventilation depends on the type of housing used. For open-sided housing, ventilation is generally natural airflow in warm weather, supplemented with stirring fans, and by fans with closed curtains in cold weather or during the brooding period. Mechanical ventilation is used in totally enclosed housing. Newer houses have smaller curtains and well-insulated construction to accommodate both natural and mechanical ventilation operation.

Recommendations for **broiler houses**:

- Room temperature: 60 to 80°F
- Temperature under brooder hover: 86 to 91°F, reducing 5°F per week until room temperature is reached
- Relative humidity: 50 to 80%
- Ventilation rate: Sufficient to maintain house within 2 to 4°F of outdoor air conditions during summer. Generally, rates are about 0.1 cfm per lb live weight during winter and 1 to 2 cfm per lb for summer conditions.
- Space: 0.6 to 1.0 ft² per bird (for the first 21 days of brooding, only 50% of floor space is used)
- Light: Minimum of 10 lx or 1 footcandle to 28 days of age; 1 to 20 lx or 0.1 to 2 footcandles for growout (in enclosed housing).

Recommendations for **breeder houses** with birds on litter and slatted floors:

- Temperature: 50 to 86°F maximum; consider evaporative cooling if higher temperatures are expected.
- Relative humidity: 50 to 75%
- Ventilation rate: Same as for broilers on live weight basis.
- Space: 2 to 3 ft² per bird

Recommendations for **laying houses** with birds in cages:

- Temperature, relative humidity, and ventilation rate: Same as for breeders.
- Space: 50 to 65 in² per hen minimum
- Light: Controlled day length using light-controlled housing is generally practiced (January through June).

Laboratory Animals

The well-being and experimental response of laboratory animals depend greatly on the design of the facilities. Cage type, noise levels, light levels, air quality, and thermal environment can affect animal well-being and, in many cases, affect how the animal responds to experimental treatments (Clough 1982; Lindsey et al. 1978; McPherson 1975; Moreland 1975). If any of these factors vary across treatments or even within treatments, it can affect the validity of experimental results, or at least increase experimental error. Consequently, laboratory animal facilities must be designed and maintained to expose the animals to appropriate levels of these environmental conditions and to ensure that all animals in an experiment are in a uniform environment. See Chapter 16 for additional information on laboratory animal facilities.

In the United States, recommended environmental conditions within laboratory animal facilities are usually dictated by ILAR (1996). Temperature recommendations vary from 61 to 84°F, depending on the species being housed. The acceptable range for relative humidity is 30 to 70%. For animals in confined spaces, daily temperature fluctuations should be minimized. Relative humidity must also be controlled, but not as precisely as temperature.

Ventilation recommendations are based on room air changes; however, cage ventilation rates may be inadequate in some cages

and excessive in other cages, depending on cage and facility design. ILAR (1996) recommendations for room ventilation rates of 10 to 15 ach are an attempt to provide adequate ventilation for the room and cages. This recommendation is based on the assumption that adequate ventilation in the macroenvironment (room) provides sufficient ventilation to the microenvironment (cage). This may be a reasonable assumption when cages have a top of wire rods or mesh. However, several studies have shown that covering cages with filter tops, which provide a protective barrier for rodents and reduce airborne infections and diseases, especially neonatal diarrhea, can create significant differences in microenvironmental conditions.

Maghirang et al. (1995) and Riskowski et al. (1996) surveyed room and cage environmental conditions in several laboratory animal facilities and found that the animal's environmental needs may not be met even though the facilities were designed and operated according to ILAR (1996). The microenvironments were often considerably poorer than the room conditions, especially in micro-isolator cages. For example, ammonia levels in cages were up to 60 ppm even though no ammonia was detected in a room. Cage temperatures were up to 7°F higher than room temperature and relative humidities up to 41% higher.

Furthermore, cage microenvironments in the same room were found to have significant variation (Riskowski et al. 1996): ammonia levels varied from 0 to 60 ppm, air temperature varied from 1 to 7°F higher than room temperature, relative humidity varied from 1 to 30% higher than room humidity, and average light levels varied from 2 to 337 lx. This survey found three identical rooms that had room ventilation rates from 4.4 to 12.5 ach but had no differences in room or cage environmental parameters.

A survey of laboratory animal environmental conditions in seven laboratory rat rooms was conducted by Zhang et al. (1992). They found that room air ammonia levels were under 0.5 ppm for all rooms, even though room airflow varied from 11 to 24 ach. Air exchange rates in the cages varied from less than 0.1 to 2.5 cfm per rat, and ammonia levels ranged from negligible to 60 ppm. Riskowski et al. (1996) measured several environmental parameters in rat shoebox cages in full-scale room mockups with various room and ventilation configurations. Significant variations in cage temperature and ventilation rates within a room were also found. Varying room ventilation rate from 5 to 15 ach did not have large effects on cage environmental conditions. These studies verify that designs based only on room air changes do not guarantee desired conditions in the animal cages.

In order to analyze the ventilation performance of different laboratory animal research facilities, Memarzadeh (1998) used **computational fluid dynamics** (CFD) to undertake computer simulation of over 100 different room configurations. CFD is a three-dimensional mathematical technique used to compute the motion of air, water, or any other gas or liquid. However, all conditions must be correctly specified in the simulation to produce accurate results. Empirical work defined inputs for such parameters as heat dissipation and surface temperature as well as the moisture, CO₂, and NH₃ mass generation rates for mice.

This approach compared favorably with experimentally measured temperatures and gas concentrations in a typical animal research facility. To investigate the relationships between room configuration parameters and the room and cage environments in laboratory animal research facilities, the following parameters were varied:

- Supply air diffuser type and orientation, air temperature, and air moisture content
- Room ventilation rate
- Exhaust location and number
- Room pressurization
- Rack layout and cage density

- Change station location, design, and status
- Leakage between the cage lower and upper moldings
- Room width

Room pressurization, change station design, and room width had little effect on ventilation performance. However, other factors found to affect either the macroenvironment or microenvironment or both led to the following observations:

- Ammonia production depends on relative humidity. Ten days after the last change of bedding, a high-humidity environment produced ammonia at about three times the rate of cages in a low-humidity environment.
- Acceptable room and cage ammonia concentrations after 5 days without changing cage bedding are produced by room supply air-flow rates of around 0.85 cfm per 100 g of body mass of mice. This is equivalent to 5 ach for the room with single-density racks considered in this study, and 10 ach for the room with double-density racks. The temperature of the supply air must be set appropriately for the heat load in the room. The room with single-density racks contained 1050 mice with a total mass of 21 kg and the room with double-density racks contained 2100 mice with a total mass of 42 kg.
- Increasing the room ventilation rate does not have a large effect on the cage ventilation. Increasing the supply airflow from 5 to 20 ach around single-density racks parallel to the walls reduces the CO₂ concentration from 1764 to 1667 ppm, a reduction of only 6%. For the double-density racks perpendicular to the walls, the reduction is larger, but still only from about 2300 to 1800 ppm (around 20%)
- Both the cage and the room ammonia concentrations can be reduced by increasing the supply air temperatures. This reduces the relative humidity for a given constant moisture content in the air, and the lower relative humidity leads to lower ammonia generation. Raising the supply discharge temperature from 66 to 72°F at 15 ach raises the room temperature by 5°F to around 73°F and the cages by 4°F to around 77°F. This can reduce ammonia concentrations by up to 50%.
- Using 72°F as the supply discharge temperature at 5 ach (the lowest flow rate considered) for double-density racks produces a room temperature around 79°F, with cage temperatures only slightly higher. Although this higher temperature provides a more comfortable environment for the mice (Gordon et al. 1997), the high room temperature may be unacceptable to the scientists working in the room.
- Ceiling or high-level exhausts tend to produce lower room temperatures (for a given supply air temperature, all CFD models were designed to have 72°F at the room exhaust) when compared to low-level exhausts. This indicates that low-level exhausts are less efficient at cooling the room.
- Low-level exhausts appear to ventilate the cages slightly better (up to 27% for the radial diffuser; much less for the slot diffuser) than ceiling or high-level exhausts when the cages are placed parallel to the walls, near the exhausts. Ammonia concentration in the cages decreased even further, although this is because of the higher temperatures in the low-level exhaust cases when compared to the ceiling and high-level exhausts. The room concentrations of CO₂ and ammonia do not show that any type of supply or exhaust is significantly better or worse than the other type.

2. DESIGN FOR PLANT FACILITIES

Greenhouses, plant growth chambers, and other facilities for indoor crop production overcome adverse outdoor environments and provide conditions conducive to economical crop production. The basic requirements of indoor crop production are (1) adequate light; (2) favorable temperatures; (3) favorable air or gas content;

Fig. 7 Structural Shapes of Commercial Greenhouses

(4) protection from insects and disease; and (5) suitable growing media, substrate, and moisture. Because of their lower cost per unit of usable space, greenhouses are preferred over plant growth chambers for protected crop production.

This section covers greenhouses and plant growth facilities. Figure 7 shows the structural shapes of typical commercial greenhouses. Other greenhouses may have Gothic arches, curved glazing, or simple lean-to shapes. Glazing, in addition to traditional glass, now includes both film and rigid plastics. High light transmission by the glazing is usually important; good location and orientation of the house are important in providing desired light conditions. Location also affects heating and labor costs, exposure to plant disease and air pollution, and material handling requirements. As a general rule in the northern hemisphere, a greenhouse should be placed at a distance of at least 2.5 times the height of the object closest to it in the eastern, western, and southern directions.

2.1 GREENHOUSES

Site Selection

Sunlight. Sunlight provides energy for plant growth and is often the limiting growth factor in greenhouses of the central and northern areas of North America during the winter. When planning greenhouses that are to be operated year-round, a designer should design for the greatest sunlight exposure during the short days of midwinter. The building site should have an open southern exposure, and if the land slopes, it should slope to the south.

Soil and Drainage. When plants are to be grown in the soil covered by the greenhouse, a growing site with deep, well-drained, fertile soil, preferably sandy loam or silt loam, should be chosen. Even though organic soil amendments can be added to poor soil, fewer problems occur with good natural soil. However, when good soil is not available, growing in artificial media should be considered. The greenhouse should be level, but the site can and often should be sloped and well-drained to reduce salt build-up and insufficient soil aeration. A high water table or a hardpan may produce water-saturated soil, increase greenhouse humidity, promote diseases, and prevent effective use of the greenhouse. If present, these problems can be alleviated by tile drains under and around the greenhouse. Ground beds should be level to prevent water from concentrating in low areas. Slopes within greenhouses also increase temperature and humidity stratification and create additional environmental problems.

Sheltered Areas. Provided they do not shade the greenhouse, surrounding trees act as wind barriers and help prevent winter heat loss. Deciduous trees are less effective than coniferous trees in midwinter, when the heat loss potential is greatest. In areas where snowdrifts occur, windbreaks and snowbreaks should be 100 ft or more from the greenhouse to prevent damage.

Orientation. Generally, in the northern hemisphere, for single-span greenhouses located north of 35° latitude, maximum transmission during winter is attained by an east-west orientation. South of 35° latitude, orientation is not important, provided headhouse

Fig. 8 Transmittance of Solar Radiation Through Glazing Materials for Various Angles of Incidence

structures do not shade the greenhouse. North-south orientation provides more light on an annual basis.

Gutter-connected or ridge-and-furrow greenhouses are oriented preferably with the ridge line north-south regardless of latitude. This orientation allows the shadow pattern caused by the gutter superstructure to move from the west to the east side of the gutter during the day. With an east-west orientation, the shadow pattern would remain north of the gutter, and the shadow would be widest and create the most shade during winter when light levels are already low. Also, the north-south orientation allows rows of tall crops, such as roses and staked tomatoes, to align with the long dimension of the house (an alignment that is generally more suitable to long rows and the plant support methods preferred by many growers).

The slope of the greenhouse roof is a critical part of greenhouse design. If the slope is too flat, a greater percentage of sunlight is reflected from the roof surface (Figure 8). A slope with a 1:2 rise-to-run ratio is the usual inclination for a gable roof.

Heating

Structural Heat Loss. Estimates for heating and cooling a greenhouse consider conduction, infiltration, and ventilation energy exchange. In addition, the calculations must consider solar energy load and electrical input, such as light sources, which are usually much greater for greenhouses than for conventional buildings. Generally, conduction q_c plus infiltration q_i are used to determine the peak requirements q_t for heating.

$$q_t = q_c + q_i \tag{4}$$

$$q_c = UA(t_i - t_o) \tag{5}$$

$$q_i = 0.018VN(t_i - t_o) \tag{6}$$

where

- U = overall heat loss coefficient, Btu/h·ft²·°F (Tables 2 and 3)
- A = exposed surface area, ft²
- t_i = inside temperature, °F
- t_o = outdoor temperature, °F

Table 2 Suggested Heat Transmission Coefficients

		U , Btu/h·ft ² ·°F
Glass		
	Single glazing	1.13
	Double glazing	0.70
	Insulating	Manufacturers' data
Plastic film		
	Single film ^a	1.20
	Double film, inflated	0.70
	Single film over glass	0.85
	Double film over glass	0.60
Corrugated glass fiber		
	Reinforced panels	1.20
Plastic structured sheet ^b		
	16 mm thick	0.58
	8 mm thick	0.65
	6 mm thick	0.72

^aInfrared barrier polyethylene films reduce heat loss; however, use this coefficient when designing heating systems because the structure could occasionally be covered with non-IR materials.

^bPlastic structured sheets are double-walled, rigid plastic panels.

Table 3 Construction U-Factor Multipliers

Metal frame and glazing system, 16 to 24 in. spacing	1.08
Metal frame and glazing system, 48 in. spacing	1.05
Fiberglass on metal frame	1.03
Film plastic on metal frame	1.02
Film or fiberglass on wood	1.00

Table 4 Suggested Design Air Changes (N)

New Construction	
Single glass lapped (unsealed)	1.25
Single glass lapped (laps sealed)	1.0
Plastic film covered	0.6 to 1.0
Structured sheet	1.0
Film plastic over glass	0.9
Old Construction	
Good maintenance	1.5
Poor maintenance	2 to 4

V = greenhouse internal volume, ft³

N = number of air exchanges per hour (Table 4)

Type of Framing. The type of framing should be considered in determining overall heat loss. Aluminum framing and glazing systems may have the metal exposed to the exterior to a greater or lesser degree, and the heat transmission of this metal is higher than that of the glazing material. To allow for such a condition, the U-factor of the glazing material should be multiplied by the factors shown in Table 3.

Infiltration. Equation (6) may be used to calculate heat loss by infiltration. Table 4 suggests values for air changes N .

Radiation Energy Exchange. Solar gain can be estimated using the procedures outlined in Chapter 18 of the 2013 *ASHRAE Handbook—Fundamentals*. As a guide, when a greenhouse is filled with a mature crop of plants, one-half the incoming solar energy is converted to latent heat, and one-quarter to one-third, to sensible heat. The rest is either reflected out of the greenhouse or absorbed by the plants and used in photosynthesis.

Radiation from a greenhouse to a cold sky is more complex. Glass admits a large portion of solar radiation but does not transmit long-wave thermal radiation in excess of approximately 5000 nm. Plastic films transmit more of the thermal radiation but, in general, the total heat gains and losses are similar to those of glass. Newer

Fig. 9 Temperature Profiles in a Greenhouse Heated with Radiation Piping along the Sidewalls

plastic films containing infrared (IR) inhibitors reduce the thermal radiation loss. Plastic films and glass with improved radiation reflection are available at a somewhat higher cost. Some research greenhouses use a retractable horizontal heat curtain to reduce the effect of night sky losses. Normally, radiation energy exchange is not considered in calculating the design heat load.

Heating Systems. Greenhouses may have a variety of heaters. One is a convection heater that circulates hot water or steam through plain or finned pipe. The pipe is most commonly placed along walls and occasionally beneath plant benches to create desirable convection currents. A typical temperature distribution pattern created by perimeter heating is shown in Figure 9. More uniform temperatures can be achieved when about one-third the total heat comes from pipes spaced uniformly across the house. These pipes can be placed above or below the crop, but temperature stratification and shading are avoided when they are placed below. Outdoor weather conditions affect temperature distribution, especially on windy days in loosely constructed greenhouses. Manual or automatic overhead pipes are also used for supplemental heating to prevent snow build-up on the roof. In a gutter-connected greenhouse in a cold climate, a heat pipe should be placed under each gutter to prevent snow accumulation.

An overhead tube heater consists of a unit heater that discharges into 12 to 30 in. diameter plastic film tubing perforated to provide uniform air distribution. The tube is suspended at 6 to 10 ft intervals and extends the length of the greenhouse. Variations include a tube and fan receiving the discharge of several unit heaters. The fan and tube system is used without heat to recirculate the air and, during cold weather, to introduce ventilation air. However, tubes sized for heat distribution may not be large enough for effective ventilation during warm weather.

Perforated tubing, 6 to 10 in. in diameter, placed at ground-level (underbench) heaters can also improve heat distribution. Ideally, the ground-level tubing should draw air from the top of the greenhouse for recirculation or heating. Tubes on or near the floor have the disadvantage of being obstacles to workers and reducing usable floor space.

Underfloor heating can supply up to 25% or more of the peak heating requirements in cold climates. A typical underfloor system uses 0.75 in. plastic pipe spaced 12 to 16 in. on center, and covered with 4 in. of gravel or porous concrete. Hot water, not exceeding 104°F, circulates at a rate of 2 to 2.5 gpm per loop. Pipe loops should generally not exceed 400 ft in length. This can provide 16 to 20 Btu/h·ft² from a bare floor, and about 75% as much when potted plants or seedling flats cover most of the floor.

Similar systems can heat soil directly, but root temperature must not exceed 77°F. When used with water from solar collectors or other heat sources, the underfloor area can store heat. This storage consists of a vinyl swimming pool liner placed on top of insulation

and a moisture barrier at a depth of 8 to 12 in. below grade, and filled with 50% void gravel. Hot water from solar collectors or other clean sources enters and is pumped out on demand. Some heat sources, such as cooling water from power plants, cannot be used directly but require closed-loop heat transfer to avoid fouling the storage and the power plant cooling water.

Greenhouses can also be bottom-heated with 0.25 in. diameter EPDM tubing (or variations of that method) in a closed loop. The tubes can be placed directly in the growing medium of ground beds or under plant containers on raised benches. The best temperature uniformity is obtained by flow in alternate tubes in opposite directions. This method can supply all the greenhouse heat needed in mild climates.

Bottom heat, underfloor heating, and underbench heating are, because of the location of the heat source, more effective than overhead or peripheral heating, and can reduce energy loss by 20 to 30%.

Unless properly located and aimed, overhead unit heaters, whether hydronic or direct fired, do not give uniform temperature at the plant level and throughout the greenhouse. Horizontal blow heaters positioned so that they establish a horizontal airflow around the outside of the greenhouse offer the best distribution. The airflow pattern can be supplemented with the use of horizontal blow fans or circulators.

When direct combustion heaters are used in the greenhouse, combustion gases must be adequately vented to the outdoors to minimize danger to plants and humans from products of combustion. One manufacturer recommends that combustion air must have access to the space through a minimum of two permanent openings in the enclosure, one near the bottom. A minimum of 1 in² of free area per 1000 Btu/h input rating of the unit, with a minimum of 100 in² for each opening, whichever is greater, is recommended. Unvented direct-combustion units should not be used inside the greenhouse.

Many greenhouses combine overhead and perimeter heating. Regardless of the type of heating, it is common practice to calculate overall heat loss first, and then to calculate the individual elements such as the roof, sidewalls, and gables. It is then simple to allocate the overhead portion to the roof loss and the perimeter portions to the sides and gables, respectively.

The annual heat loss can be approximated by calculating the design heat loss and then, in combination with the annual degree-day tables using the 65°F base, estimating an annual heat loss and computing fuel usage on the basis of the rating of the particular fuel used. If a 50°F base is used, it can be prorated.

Heat curtains for energy conservation are becoming more important in greenhouse construction. Although this energy savings may be considered in the annual energy use, it should not be used when calculating design heat load; the practice is to open the heat curtains during snowstorms to facilitate snow melting, thereby nullifying its contribution to the design heat loss value.

Air-to-air and water-to-air heat pumps have been used experimentally on small-scale installations. Their usefulness is especially sensitive to the availability of a low-cost heat source.

Radiant (Infrared) Heating. Radiant heating is used in some limited applications for greenhouse heating. Steel pipes spaced at intervals and heated to a relatively high temperature by special gas heaters serve as the source of radiation. Because the energy is transmitted by radiation from a source of limited size, proper spacing is important to completely cover the heated area. Further, heavy-foilage crops can shade the lower parts of the plants and the soil, thus restricting the radiation from warming the root zone, which is important to plant growth.

Cogenerated Sources of Heat. Greenhouses have been built near or adjacent to power plants to use the heat and electricity generated by the facility. Although this energy may cost very little, an

adequate standby energy source must be provided, unless the power supplier can assure that it will supply a reliable, continuous source of energy.

Cooling

Solar radiation is a considerable source of sensible heat gain; even though some of this energy is reflected from the greenhouse, some of it is converted into latent heat as the plants transpire moisture, and some is converted to plant material by photosynthesis. Natural ventilation, mechanical ventilation, shading, and evaporative cooling are common methods used to remove this heat. Mechanical refrigeration is seldom used to air-condition greenhouses because the cooling load and resulting cost is so high.

Natural Ventilation. Most older greenhouses and many new ones rely on natural ventilation with continuous roof sashes on each side of the ridge and continuous sashes in the sidewalls. The roof sashes are hinged at the ridge, and the wall sashes are hinged at the top of the sash. During much of the year, vents admit enough ventilating air for cooling without the added cost of running fans.

The principles of natural ventilation are explained in Chapter 16 of the 2013 *ASHRAE Handbook—Fundamentals*. Ventilation air is driven by wind and thermal buoyancy forces. Proper vent openings take advantage of pressure differences created by wind. Thermal buoyancy caused by the temperature difference between the inside and the outside of the greenhouse is enhanced by the area of the vent opening and the stack height (vertical distance between the center of the lower and upper opening). Within the limits of typical construction, the larger the vents, the greater the ventilating air exchanged. For a single greenhouse, the combined area of the sidewall vents should equal that of the roof vents. In ranges of several gutter-connected greenhouses, the sidewall area cannot equal the roof vent area.

Mechanical (Forced) Ventilation. Exhaust fans provide positive ventilation without depending on wind or thermal buoyancy forces. The fans are installed in the side or end walls of the greenhouse and draw air through vents on the opposite side or end walls. Air velocity through the inlets should not exceed 400 fpm.

Air exchange rates between 0.75 and 1 change per minute effectively control the temperature rise in a greenhouse. As shown in Figure 10, the temperature inside the greenhouse rises rapidly at lower airflow rates. At higher airflow rates, the reduction of the temperature rise is small, fan power requirements are increased, and plants may be damaged by the high air speed.

Shading. Shading compounds can be applied in varying amounts to the exterior of the roof of the greenhouse to achieve up to 50% shading. Durability of these compounds varies; ideally, the compound wears away during the summer and leaves the glazing clean in the fall, when shading is no longer needed. In practice, some physical cleaning is needed. Compounds used formerly usually contained lime, which corrodes aluminum and attacks some caulking. Most compounds used currently are formulated to avoid this problem.

Mechanically orated shade cloth systems with a wide range of shade levels are also available. They are mounted inside the greenhouse to protect them from the weather. Not all shading compounds or shade cloths are compatible with all plastic glazings, so the manufacturers' instructions and precautions should be followed.

Evaporative Cooling.

Fan-and-Pad Systems. Fans for fan-and-pad evaporative cooling are installed in the same manner as fans used for mechanical ventilation. Pads of cellulose material in a honeycomb form are installed on the inlet side. The pads are kept wet continuously when evaporative cooling is needed. As air is drawn through the pads, the water evaporates and cools the air. New pads cool the air by about 80% of the difference between the outdoor dry- and wet-bulb temperatures, or to 3 to 4°F above the wet-bulb tem-

perature. The principles of applying evaporative cooling are explained in Chapter 41 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* and in Chapter 52 of this volume.

The empirical base rate of airflow is 8 cfm per square foot of floor area. This flow rate is modified by multiplying it by factors for elevation (F_e), maximum interior light intensity (F_l), and allowable temperature rise between the pad and fans (F_t). These factors are listed in Table 5. The overall factor for the house is given by the following equation:

$$F_h = F_e F_l F_t \tag{7}$$

The maximum fan-to-pad distance should be kept to 175 ft, although some greenhouses with distances of 225 ft have shown no serious reduction in effectiveness. With short distances, the air velocity becomes so low that the air feels clammy and stuffy, even though the airflow is sufficient for cooling. Therefore, a velocity factor F_v listed in Table 6 is used for distances less than 100 ft. For distance less than 100 ft, F_v is compared to F_h . The factor that gives

Table 5 Multipliers for Calculating Airflow for Fan-and-Pad Cooling

60	1.29		

the greatest airflow is used to modify the empirical base rate. For fan-to-pad distances greater than 100 ft, F_v can be ignored.

For best performance, pads should be installed on the windward side, and fans spaced within 25 ft of each other. Fans should not blow toward pads of an adjacent house unless it is at least 50 ft away. Fans in adjacent houses should be offset if they blow toward each other and are within 15 ft of each other.

Recommended air velocities through commonly used pads are listed in Table 7. Water flow and sump capacities are shown in Table 8. The system should also include a small, continuous bleed-off of water to reduce the build-up of dirt and other impurities.

Unit Evaporative Coolers. This equipment contains the pads, water pump, sump, and fan in one unit. Unit coolers are primarily used for small compartments. They are mounted 15 to 20 ft apart on the sidewall and blow directly into the greenhouse. They cool a distance of up to 50 ft from the unit. A side sash on the outside opposite wall is the best outlet, but roof vents may also work. The roof vent on the same side as the unit should be slightly open for better air distribution. If the roof vent on the opposite side is opened instead, air may flow directly out the vent and not cool the opposite side of the greenhouse.

Fog. In a direct-pressure atomizer, a high-pressure pump forces water at 800 to 1000 psi through a special fog nozzle. Fog is considered to be a water droplet smaller than 40 μm in diameter. The direct-pressure atomizer generates droplets of 35 μm or less. This requires a superior filter to minimize clogging of the very small nozzle orifices.

A line of nozzles placed along the top of the vent opening can cool the entering air nearly to its wet-bulb temperature. Additional lines in the greenhouse continue to cool the air as it absorbs heat in the space.

Fogging cools satisfactorily with less airflow than fan-and-pad systems, but the fan capacity must still be based on one air change per minute to ventilate the greenhouse when the cooler will be used without fog.

Other Environmental Controls

Humidity Control. At various times during the year, humidity may need to be controlled in the greenhouse. When the humidity is too high at night, it can be reduced by adding heat and ventilating simultaneously. When the humidity is too low during the day, it can be increased by turning on a fog or mist nozzle.

Winter Ventilation. During the winter, houses are normally closed tightly to conserve heat, but photosynthesis by the plants may lower the carbon dioxide level to such a point that it slows plant growth. Some ventilation helps maintain inside carbon dioxide levels. A normal rate of airflow for winter ventilation is 2 to 3 cfm per square foot of floor area.

Air Circulation. Continuous air circulation within the greenhouse reduces still-air conditions that favor plant diseases. Recirculating fans, heaters that blow air horizontally, and fans attached to polyethylene tubes are used to circulate air. The amount of

Table 7 Recommended Air Velocity Through Various Pad Materials

Pad Type and Thickness	Air Face Velocity Through Pad,* fpm
Corrugated cellulose, 4 in. thick	250
Corrugated cellulose, 6 in. thick	350

*Speed may be increased by 25% where construction is limiting.

Table 8 Recommended Water Flow and Sump Capacity for Vertically Mounted Cooling Pad Materials

Pad Type and Thickness	Minimum Water Rate per Linear Foot of Pad, gpm	Minimum Sump Capacity per Unit Pad Area, gal/ft ²
Corrugated cellulose, 4 in. thick	0.5	0.8
Corrugated cellulose, 6 in. thick	0.8	1.0

recirculation has not been well defined, except that some studies have shown high air velocities (greater than 200 fpm) can harm plants or reduce growth.

Insect Screening. Insect screening is being used to cover vent inlets and outlets. These fine-mesh screens increase resistance to airflow, which must be considered when selecting ventilation fans. The screen manufacturer should provide static pressure data for its screens. The pressure drop through the screen can be reduced by framing out from the vent opening to increase the area of the screen.

Carbon Dioxide Enrichment. Carbon dioxide is added in some greenhouse operations to increase growth and enhance yields. However, CO₂ enrichment is practical only when little or no ventilation is required for temperature control. Carbon dioxide can be generated from solid CO₂ (dry ice), bottled CO₂, and misting carbonated water. Bulk or bottled CO₂ gas is usually distributed through perforated tubing placed near the plant canopy. Carbon dioxide from dry ice is distributed by passing greenhouse air through an enclosure containing dry ice. Air movement around the plant leaf increases the efficiency with which the plant absorbs whatever CO₂ is available. One study found an air speed of 100 fpm to be equivalent to a 50% enrichment in CO₂ without forced air movement.

Radiant Energy. Light is normally the limiting factor in greenhouse crop production during the winter. North of the 35th parallel (in the northern hemisphere), light levels are especially inadequate or marginal in fall, winter, and early spring. Artificial light sources, usually high-intensity discharge (HID) lamps, may be added to greenhouses to supplement low natural light levels. High-pressure sodium (HPS), metal halide (MH), low-pressure sodium (LPS), and, occasionally, mercury lamps coated with a color-improving phosphor are currently used. Because differing irradiance or illuminance ratios are emitted by the various lamp types, the incident radiation is best described as radiant flux density (W/ft²) between 400 and 850 nm, or as photon flux density between 400 and 700 nm, rather than in photometric terms of lux or footcandles.

To assist in relating irradiance to more familiar illuminance values, Table 9 shows constants for converting illuminance (lux) and photon flux density [$\mu\text{mol}/(\text{s}\cdot\text{m}^2)$] of HPS, MH, LPS, and other lamps to the irradiance (W/m²). One footcandle is approximately 10 lux.

Table 10 gives values of suggested irradiance at the top of the plant canopy, duration, and time of day for supplementing natural light levels for specific plants.

HID lamps in luminaires developed specifically for greenhouse use are often placed in a horizontal position, which may decrease both the light output and the life of the lamp. These drawbacks may be balanced by improved horizontal and vertical uniformity as compared to industrial parabolic reflectors.

Table 9 Constants to Convert to W/m²

Light Source	klx	μmol/(s·m ²)
400 to 700 nm		
Incandescent (INC)	3.99	0.20
Fluorescent cool white (FCW)	2.93	0.22
Fluorescent warm white (FWW)	2.81	0.21
Discharge clear mercury (HG)	2.62	0.22
Metal halide (MH)	3.05	0.22
High-pressure sodium (HPS)	2.45	0.20
Low-pressure sodium (LPS)	1.92	0.20
Daylight	4.02	0.22

Photoperiod Control. Artificial light sources are also used to lengthen the photoperiod during the short days of winter. Photoperiod control requires much lower light levels than those needed for photosynthesis and growth. Photoperiod illuminance needs to be only 0.6 to 1.1 W/ft². The incandescent lamp is the most effective light source for this purpose because of its higher far-red component. Lamps such as 150 W (PS-30) silverneck lamps spaced 10 to 13 ft on centers and 13 ft above the plants provide a cost-effective system. Where a 13 ft height is not practical, 60 W extended service lamps on 6.5 ft centers are satisfactory. One method of photoperiod control is to interrupt the dark period by turning the lamps on at 2200 and off at 0200. The 4 h interruption, initially based on chrysanthemum response, induces a satisfactory long-day response in all photoperiodically sensitive species. Many species, however, respond to interruptions of 1 h or less. Demand charges can be reduced in large installations by operating some sections from 2000 to 2400 and others from 2400 to 0400. The biological response to these schedules, however, is much weaker than with the 2200 to 0200 schedule, so some varieties may flower prematurely. If the 4 h interruption period is used, it is not necessary to keep the light on throughout the interruption period. Photoperiod control of most plants can be accomplished by operating the lamps on light and dark cycles with 20% on times; for example, 12 s/min. The length of the dark period in the cycle is critical, and the system may fail if the dark period exceeds about 30 min. Demand charges can be reduced by alternate scheduling of the on times between houses or benches without reducing the biological effectiveness of the interruption.

Plant displays in places such as showrooms or shopping malls require enough light for plant maintenance and a spectral distribution that best shows the plants. Metal halide lamps, with or without incandescent highlighting, are often used for this purpose. Fluorescent lamps, frequently of the special phosphor plant-growth type, enhance color rendition, but are more difficult to install in aesthetically pleasing designs.

Design Conditions

Plant requirements vary from season to season and during different stages of growth. Even different varieties of the same species of plant may vary in their requirements. State and local cooperative extension offices are a good source of specific information on design conditions affecting plants. These offices also provide current, area-specific information on greenhouse operations.

Alternative Energy Sources and Energy Conservation

Limited progress has been achieved in heating commercial greenhouses with solar energy. Collecting and storing the heat requires a volume at least one-half the volume of the entire greenhouse. Passive solar units work at certain times of the year and, in a few localities, year-round.

If available, reject heat is a possible source of winter heat. Winter energy and solar (photovoltaic) sources are possible future energy

Table 10 Suggested Radiant Energy, Duration, and Time of Day for Supplemental Lighting in Greenhouses

Plant and Stage of Growth	W/ft ²	Duration

sources for greenhouses, but the development of such systems is still in the research stage.

Energy Conservation. A number of energy-saving measures (e.g., thermal curtains, double glazing, and perimeter insulation) have been retrofitted to existing greenhouses and incorporated into new construction. Sound maintenance is necessary to keep heating system efficiency at a maximum level.

Automatic controls, such as thermostats, should be calibrated and cleaned at regular intervals, and heating-ventilation controls should interlock to avoid simultaneous operation. Boilers that can burn more than one type of fuel allow use of the most inexpensive fuel available.

Modifications to Reduce Heat Loss

Film covers that reduce heat loss are used widely in commercial greenhouses, particularly for growing foliage plants and other species that grow under low light levels. Irradiance (intensity) is reduced 10 to 15% per layer of plastic film.

One or two layers of transparent 4 or 6 mil continuous-sheet plastic is stretched over the entire greenhouse (leaving some vents uncovered), or from the ridge to the sidewall ventilation opening. When two layers are used, (outdoor) air at a pressure of 0.2 to 0.25 in. of water is introduced continuously between the layers of film to maintain the air space between them. When a single layer is used, an air space can be established by stretching the plastic over the glazing bars and fastening it around the edges, or a length of polyethylene tubing can be placed between the glass and the plastic and inflated (using outdoor air) to stretch the plastic sheet.

Double-Glazing Rigid Plastic. Double-wall panels are manufactured from acrylic and polycarbonate plastics, with walls separated by about 0.4 in. Panels are usually 48 in. wide and 96 in. or longer. Nearly all types of plastic panels have a high thermal expansion coefficient and require about 1% expansion space (0.12 in./ft). When a panel is new, light reduction is roughly 10 to 20%. Moisture accumulation between the walls of the panels must be avoided.

Double-Glazing Glass. The framing of most older greenhouses must be modified or replaced to accept double glazing with glass.

Light reduction is 10% more than with single glazing. Moisture and dust accumulation between glazings increases light loss. As with all types of double glazing, snow on the roof melts slowly and increases light loss. Snow may even accumulate enough to cause structural damage, especially in gutter-connected greenhouses.

Silicone Sealants. Transparent silicone sealant in the glass overlaps of conventional greenhouses reduces infiltration and may produce heat savings of 5 to 10% in older structures. There is little change in light transmission.

Precautions. The preceding methods reduce heat loss by reducing conduction and infiltration. They may also cause more condensation, higher relative humidity, lower carbon dioxide concentration, and an increase in ethylene and other pollutants. Combined with the reduced light levels, these factors may cause delayed crop production, elongated plants, soft plants, and various deformities and diseases, all of which reduce the marketable crop.

Thermal Blankets. Thermal blankets are any flexible material that is pulled from gutter to gutter and end to end in a greenhouse, or around and over each bench, at night. Materials ranging from plastic film to heavy cloth, or laminated combinations, have successfully reduced heat losses by 25 to 35% overall. Tightness of fit around edges and other obstructions is more important than the kind of material used. Some films are vaportight and retain moisture and gases. Others are porous and allow some gas exchange between the plants and the air outside the blanket. Opaque materials can control crop day length when short days are part of the requirement for that crop. Condensation may drip onto and

collect on the upper sides of some blanket materials to such an extent that they collapse.

Multiple-layer blankets, with two or more layers separated by air spaces, have been developed. One such design combines a porous-material blanket and a transparent film blanket; the latter is used for summer shading. Another design has four layers of porous, aluminum foil-covered cloths, with the layers separated by air.

Thermal blankets may be opened and closed manually as well as automatically. The decision to open or close should be based on irradiance level and whether it is snowing, rather than on time of day. Two difficulties with thermal blankets are the physical problems of installation and use in greenhouses with interior supporting columns, and the loss of space from shading by the blanket when it is not in use during the day.

Other Recommendations. Although the foundation can be insulated, the insulating materials must be protected from moisture, and the foundation wall should be protected from freezing. All or most of the north wall can be insulated with opaque or reflective-surface materials. The insulation reduces the amount of diffuse light entering the greenhouse and, in cloudy climates, causes reduced crop growth near the north wall.

Ventilation fan cabinets should be insulated, and fans not needed in winter should be sealed against air leaks. Efficient management and operation of existing facilities are the most cost-effective ways to reduce energy use.

2.2 PLANT GROWTH ENVIRONMENTAL FACILITIES

Controlled-environment rooms (CERs), also called plant growth chambers, include all controlled or partially controlled environmental facilities for growing plants, except greenhouses. CERs are indoor facilities. Units with floor areas less than 50 ft² may be moveable with self-contained or attached refrigeration units. CERs usually have artificial light sources, provide control of temperature and, in some cases, control relative humidity and CO₂ level.

CERs are used to study all aspects of botany. Some growers use growing rooms to increase seedling growth rate, produce more uniform seedlings, and grow specialized, high-value crops. The main components of the CER are (1) an insulated room or an insulated box with an access door; (2) a heating and cooling mechanism with associated air-moving devices and controls; and (3) a lamp module at the top of the insulated box or room. CERs are similar to walk-in cold storage rooms, except for the lighting and larger refrigeration system needed to handle heat produced by the lighting.

Location

The location for a CER must have space for the outer dimensions of the chamber, refrigeration equipment, ballast rack, and control panels. Additional space around the unit is necessary for servicing the various components of the system and, in some cases, for substrate, pots, nutrient solutions, and other paraphernalia associated with plant research. The location requires electricity, water, compressed air, and ventilation and exhaust air systems. For planning purposes, electrical densities of up to 140 W/ft² of controlled environment space) are possible, or 95 W/ft² of total space housing CERs.

Construction and Materials

Wall insulation should have a thermal conductance of less than 0.026 Btu/h · ft² · °F. Materials should resist corrosion and moisture. The interior wall covering should be metal, with a high-reflectance white paint, or specular aluminum with a reflectivity of at least 80%. Reflective films or similar materials can be used, but require periodic replacement.

Floors and Drains

Floors that are part of the CER should be corrosion-resistant. Tar or asphalt waterproofing materials and volatile caulking compounds should not be used because they are likely to release phytotoxic gases into the chamber atmosphere. The floor must have a drain to remove spilled water and nutrient solutions. The drains should be trapped and equipped with screens to catch plant and substrate debris.

Plant Benches

Three bench styles for supporting the pots and other plant containers are normally encountered in plant growth chambers: (1) stationary benches; (2) benches or shelves built in sections that are adjustable in height; and (3) plant trucks, carts, or dollies on casters, which are used to move plants between chambers, greenhouses, and darkrooms. The bench supports containers filled with moist sand, soil, or other substrate, and is usually rated for loads of at least 50 lb/ft². The bench or truck top should be constructed of nonferrous, perforated metal, wire, or metal mesh to allow free passage of air around the plants and to let excess water drain from the containers to the floor and subsequently to the floor drain.

Normally, benches, shelves, or truck tops are adjustable in height so that small plants can be placed close to the lamps and thus receive a greater amount of light. As the plants grow, the shelf or bench is lowered so that the tops of the plants continue to receive the original radiant flux density.

Control

Environmental chambers require complex controls to provide the following:

- Automatic transfer from heating to cooling with 2°F or less dead zone and adjustable time delay.
- Automatic daily switching of the temperature set point for different day and night temperatures (setback may be as much as 10°F).
- Protection of sensors from radiation. Ideally, the sensors are located in a shielded, aspirated housing, but satisfactory performance can be attained by placing them in the return air duct.
- Control of the daily duration of light and dark periods. Ideally, this control should be programmable to change the light period each day to simulate the natural progression of day length. Photoperiod control, however, is normally accomplished with mechanical time clocks, which must have a control interval of 5 min or less for satisfactory timing.
- Protective control to prevent the chamber temperature from going more than a few degrees above or below the set point. Control should also prevent short-cycling of the refrigeration system, especially when condensers are remotely located.
- Control of the CO₂ level in enriched environment chambers.
- Audible and visual alarms to alert personnel of malfunctions.
- Maintenance of relative humidity to prescribed limits.

Data loggers, recorders, or recording controllers are recommended for monitoring daily operation. Solid-state, microprocessor-based controls are widely used for programming, controlling, and monitoring the CER conditions. Host systems are also used to program and monitor larger numbers of units in a common facility, and most offer remote access functions. Host systems tend to be vendor-specific in their use and application.

Heating, Air Conditioning, and Airflow

When the lights are on, cooling will normally be required, and the heater will rarely be called on to operate. When the lights are off, however, both heating and cooling may be needed. Conventional refrigeration is generally used with some modification. Direct-expansion units usually operate with a hot-gas bypass to prevent numerous on/off cycles, and secondary coolant may use aqueous

ethylene glycol rather than chilled water. Heat is usually provided by electric heaters, but other energy sources can be used, including hot gas from the refrigeration.

The plant compartment is the heart of the growth chamber. The primary design objective, therefore, is to provide the most uniform, consistent, and regulated environmental conditions possible. Thus, airflow must be adequate to meet specified psychrometric conditions, but it is limited by the effects of high air speed on plant growth. As a rule, the average air speed in CERs is restricted to about 100 fpm.

To meet the uniform conditions required by a CER, conditioned air is normally moved through the space from bottom to top, although some CERs use top-to-bottom airflow. There is no apparent difference in plant growth between horizontal, upward, or downward airflow when the speed is less than 175 fpm. Regardless of the method, a temperature gradient is certain to exist, and should be kept as small as possible. Uniform airflow is more important than the direction of flow; thus, selection of properly designed diffusers or plenums with perforations is essential for achieving it.

The ducts or false sidewalls that direct air from the evaporator to the growing area should be small, but not so small that the noise increases appreciably more than acceptable building air duct noise. CER design should include some provision for cleaning the interior of the air ducts.

Air-conditioning equipment for relatively standard chambers provides temperatures that range from 45 to 90°F. Specialized CERs that require temperatures as low as -5°F need low-temperature refrigeration equipment and devices to defrost the evaporator without increasing the growing area temperature. Other chambers that require temperatures as high as 115°F need high-temperature components. The air temperature in the growing area must be controlled with the least possible variation about the set point. Temperature variation about the set point can be held to 0.5°F using solid-state controls, but in older facilities, the variation is 1 to 2°F.

The relative humidity in many CERs is simply an indicator of the existing psychrometric conditions and is usually between 50 and 80%, depending on the temperature. Relative humidity in the chamber can be increased by steam injection, misting, hot-water evaporators, and other conventional humidification methods. Steam injection causes the least temperature disturbance, and sprays or misting cause the greatest disturbance. Complete control of relative humidity requires dehumidification as well as humidification.

A typical humidity control includes a cold evaporator or steam injection to adjust the chamber air dew point. The air is then conditioned to the desired dry-bulb temperature by electric heaters, a hot-gas bypass evaporator, or a temperature-controlled evaporator. A dew point lower than about 40°F cannot be obtained with a cold-plate dehumidifier because of icing. Dew points lower than 40°F usually require a chemical dehumidifier in addition to the cold evaporator.

Lighting Environmental Chambers

The type of light source and number of lamps used in CERs are determined by the desired plant response. Traditionally, cool-white fluorescent plus incandescent lamps that produce 10% of the fluorescent illuminance are used. Nearly all illumination data are based on either cool-white or warm-white fluorescent, plus incandescent lamps. A number of fluorescent lamps have special phosphors hypothesized to be the spectral requirements of the plant. Some of these lamps are used in CERs, but there is little data to suggest that they are superior to cool-white and warm-white lamps. In recent years, high-intensity discharge lamps have been installed in CERs, either to obtain very high radiant flux densities, or to reduce the electrical load while maintaining a light level equal to that produced by the less efficient fluorescent-incandescent systems.

Table 11 Input Power Conversion of Light Sources

Lamp Identification		Total Input Power, W	Radiation (400-700 nm), %	Radiation (400-850 nm), %	Other Radiation, %	Conduction and Convection, %	Ballast Loss, %

Note: Conversion efficiency is for lamps without luminaires. Values compiled from manufacturers' data, published information, and unpublished test data by R.W. Thimijan.

Table 12 Approximate Mounting Height and Spacing of Luminaires in Greenhouses

Lamp and Wattage	Irradiation, W/ft ²			
	0.6	1.1	2.2	4.4
Height and Spacing, in.				
HPS (400 W)	118	90	63	39
LPS (180 W)	94	67	47	31
MH (400 W)	106	79	55	35

One method to design lighting for biological environments is to base light source output recommendations on photon flux density $\mu\text{mol}/(\text{s} \cdot \text{m}^2)$ between 400 and 700 nm, or, less frequently, as radiant flux density between 400 and 700 nm, or 400 and 850 nm. Rather than basing illuminance measurements on human vision, this allows comparisons between light sources as a function of plant photosynthetic potential. Table 9 shows constants for converting various measurement units to W/m^2 . However, instruments that measure the 400 to 850 nm spectral range are generally not available, and some controversy exists about the effectiveness of 400 to 850 nm as compared to the 400 to 700 nm range in photosynthesis. The power conversion of various light sources is listed in Table 11.

The design requirements for plant growth lighting differ greatly from those for vision lighting. Plant growth lighting requires a greater degree of horizontal uniformity and, usually, higher light levels than vision lighting. In addition, plant growth lighting should have as much vertical uniformity as possible (a factor rarely important in vision lighting). Horizontal and vertical uniformity are much easier to attain with linear or broad sources, such as fluorescent lamps, than with point sources, such as HID lamps. Tables 12 and 13 show the type and number of lamps, mounting height, and spacing required to obtain several levels of incident energy. Because the data were taken directly under lamps with no reflecting wall surfaces nearby, the incident energy is perhaps one-half of what the plants would receive if the lamps had been placed in a small chamber with highly reflective walls.

Extended-life incandescents, which have a much longer life, lower lamp replacement requirements. These lamps have lower lumen output, but are nearly equivalent in the red portion of the spectrum. For safety, porcelain lamp holders and heat-resistant lamp wiring should be used. Lamps used for CER lighting include fluorescent lamps (usually 1500 mA), 250, 400, and occasionally 1000 W HPS and MH lamps, 180 W LPS lamps, and various sizes of incandescent lamps. In many installations, the abnormally short life of incandescent lamps is caused by vibration from the lamp loft ventilation or from cooling fans. Increased incandescent lamp life

under these conditions can be attained by using lamps constructed with a C9 filament.

Energy-saving lamps have approximately equal or slightly lower irradiance per input watt. Because the irradiance per lamp is lower, there is no advantage to using these lamps, except in tasks that can be accomplished with low light levels. Light output of all lamps declines with use, except perhaps for low-pressure sodium (LPS) lamps, which appear to maintain approximately constant output but require an increase in input power during use.

Fluorescent and metal halide designs should be based on 80% of the initial light level. Most CER lighting systems have difficulty maintaining a relatively constant light level over considerable periods of time. Combinations of MH and HPS lamps compound the problem, because the lumen depreciation of the two light sources is significantly different. Thus, over time, the spectral energy distribution at plant level shifts toward the HPS. Lumen output can be maintained in two ways: (1) individual lamps, or a combination of lamps, can be switched off initially and activated as the lumen output decreases; and (2) the oldest 25 to 33% of the lamps can be replaced periodically. Solid-state dimmer systems are commercially available only for low-wattage fluorescent lamps and for mercury lamps.

To maintain a constant distance from plant to light source, light fixtures in many CERs are mounted on movable, counterbalanced light banks. This design requirement precludes separation of the lamps from the plant chamber.

Large rooms, especially those constructed as an integral part of the building and retrofitted as CERs, rarely separate the lamps from the growing area with a transparent barrier. Rooms designed as CERs (at the time a building is constructed) and freestanding rooms or chambers usually separate the lamp from the growing area with a barrier of glass or rigid plastic. Light output from fluorescent lamps is a function of the temperature of the lamp. Thus, the barrier serves a twofold purpose: (1) to maintain optimum lamp temperature when the growing area temperature is higher or lower than optimum, and (2) to reduce the thermal radiation entering the growing area. Fluorescent lamps should operate in an ambient temperature and airflow environment that maintains the tube wall temperature at 104°F. Under most conditions, the light output of HID lamps is not affected by ambient temperature. The heat must be removed, however, to prevent high thermal radiation from causing adverse biological effects (Figure 11).

Transparent glass barriers remove nearly all radiation from about 350 to 2500 nm. Rigid plastic is less effective than glass; however, the lighter weight and lower breakage risk of plastic makes it a popular barrier material. Ultraviolet is also screened by both glass and plastic (more by plastic). Special UV-transmitting plastic (which

Fig. 11 Cooling Lamps in Growth Chambers

degrades rapidly) can be obtained if the biological process requires UV light. When irradiance is very high, especially from HID lamps or large numbers of incandescent lamps or both, rigid plastic can soften from the heat and fall from the supports. Furthermore, very high irradiance and the resulting high temperatures can darken plastic, which can increase the absorptivity and temperature enough to destroy it. Under these conditions, heat-resistant glass may be necessary. The lamp compartment and barrier absolutely require positive ventilation regardless of the light source, and the lamp loft should have limit switches to shut down the lamps if the temperature rises to a critical level.

Phytotrons

A phytotron is a botanical laboratory comprising a series of chambers reproducing any condition of temperature, humidity, illumination, or other plant growth factor. They are typically found in plant-based research buildings. These facilities require substantial electrical and mechanical systems to generate light required for plant growth as well as to remove heat generated by lights and CER cooling systems.

Electrical Requirements. If the exact number and size of units is unknown, an electrical consumption of 0.2 kW/ft² may be

assumed for lighting input to the CERs. If the CERs have a built-in refrigeration system, the compressor input is typically 80% of lighting input, because the units are designed to maintain the chamber at 50°F with lights on, creating a high latent load on the compressor at an inefficient operating point. Remote condensing units and remote air-cooled condensers require a separate electrical feed and interconnecting control wiring.

Heat Rejection. Most of the electrical input to the CERs is converted to heat. The heat rejection system must be able to remove that heat from the phytotron; this can be done in a number of ways.

If the CERs are primarily self-contained air-cooled units, the room can be ventilated at a rate that maintains acceptable working conditions in the space (see Chapter 14). Because of the high ventilation rates needed, ensure that air returned to the space is properly filtered to limit the introduction of dust, pollen, insects, and bacteria from the outdoors.

Self-contained CERs with water-cooled condensing units typically use a condenser water loop connected to a cooling tower or fluid cooler to reject heat. Chapter 13 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* describes selection and design of these systems. Because phytotron facilities operate all year, operation of fluid coolers and cooling towers at ambient temperatures below freezing in cold climates must be considered. Sediment must also be removed from the condenser water, because the condenser on the CER is a relatively low-velocity point in the loop and will plug up with these solids.

Locations of remote condensing units or remote air-cooled condensers should be easily accessible, because they require servicing at all times of the year. Ensure good airflow around all air-cooled condensers so that discharge air from one unit is not reentrained into adjacent units. Locate equipment away from laboratory exhaust systems that could accelerate corrosion of metal on the units. Refrigerant piping must be carefully designed, sized, and installed to ensure proper oil return and long-term operation of the compressors. Chapter 1 of the 2014 *ASHRAE Handbook—Refrigeration* details these requirements.

Central chilled water can be used for the CERs. The primary consideration is the chilled-water temperature to be provided to each unit. In practice, most CERs operate at internal temperatures between 68 to 77°F when lights are on. As a result, standard chilled-water supply temperatures of 45°F can be used successfully. When lights are off, temperatures of 50°F can be achieved using the same chilled-water temperature. Chambers that require cooler daytime temperatures can use water-cooled condensing units and reject their heat to the chilled-water loop. Some phytotrons use chilled-water supply temperatures of 14°F, but with a high failure rate on the compressors because of low suction temperatures and poor oil return.

Energy Conservation. Because of CERs' very high energy consumption and the predictable day/night cycle of the lighting load, consider balancing the units' schedule to limit electrical demand. Most plants require a 12 to 16 h daily photoperiod. By adjusting the day/night schedule, it is possible to reduce the phytotron's electrical demand by up to 25%.

Chilled-water CERs can have the lowest total energy consumption because of the economy of scale available by using large-capacity chillers versus small compressors. Large laboratory facilities can reject heat from the phytotron to preheat laboratory makeup air. In cold climates, chilled water can be produced without mechanical cooling at ambient temperatures below 28°F. If exposing chilled water to ambient air that could be below freezing, use an appropriate concentration of suitable antifreeze.

Condenser water can also be used to preheat fresh air or, because of its higher temperature, other process loads, such as domestic hot water.

Operating Considerations. CERs with self-contained compressors generate noise. When a large number of units are placed in

a room, consideration should be given to attenuating this sound. Chilled-water and remote-condensing-unit CERs provide the quietest environment for workers, because the compressors are remotely located. The total installed cost of these systems may be higher because of the extra cost to remotely locate and energize the cooling systems.

Plants require CO₂ to grow. Many CERs in phytotrons have a central exhaust system to exhaust any chemicals used inside the chambers and to pull in a constant supply of air. Because the units are under a slight negative pressure, makeup air entering the unit must be filtered to limit uncontrolled spread of pollen, insect pests, and bacteria. The flow rate from units depends on the type of crop being grown. A normal rate of ventilation is 2 to 3 cfm per square foot of plant growth area.

Water is required for humidification, plant watering, and cleaning. This often means that three totally separate systems are used. High-purity water is often available in laboratory buildings, and can be used to directly humidify the chambers without introducing waterborne minerals into the chamber. Water for plants should be tempered to avoid root shock. A tempered-water loop with provision for introducing chemical fertilizer, supplied to designated hose stations in the phytotron, is common in larger installations, but normal municipal water supplies are all that is required. Cleaning of these areas is important.

CERs require drainage of cooling coil condensate and plant over-watering. It is important to provide good drainage near the units without excess use of drain lines running exposed across the floor. Similarly, any piping or ducts that operate below the room design dew-point temperature should be insulated to prevent condensation on those lines. These puddles of water are prime breeding grounds for plant pests, and could cause slip hazards for staff.

Keeping the phytotron clean is important for plants' health. Phytotrons typically have separate potting areas and harvest rooms, both of which generate a lot of dust and dirt. Potting areas must remain sanitary to minimize contamination of seedlings and plants. In harvest rooms, mature plants may host insects that can damage young plants. Ventilation systems should keep harvest rooms at negative pressure relative to the cleaner potting areas and phytotron.

Genetically modified plants must be autoclaved once the plant is harvested. Provision should be made for an autoclave next to the harvest room, with a supply of steam or electricity. Odors and steam from the autoclave should be exhausted out of the building.

2.3 OTHER PLANT ENVIRONMENTAL FACILITIES

Plants may be held or processed in warehouse-type structures prior to sale or use in interior landscaping. Required temperatures range from slightly above freezing for cold storage of root stock and cut flowers, to 68 to 77°F for maintaining growing plants, usually in pots or containers. Provision must be made for venting fresh air to avoid CO₂ depletion.

Light duration must be controlled by a time clock. When they are in use, lamps and ballasts produce almost all the heat required in an insulated building. Ventilation and cooling may be required. Illumination levels depend on plant requirements. Table 14 shows approximate mounting heights for two levels of illumination. Luminaires mounted on chains permit lamp height to be adjusted to compensate for varying plant height.

The main concerns for interior landscape lighting are how it renders the color of plants, people, and furnishings, as well as how it meets the minimum irradiation requirements of plants. The temperature required for human occupancy is normally acceptable for plants. Light level and duration determine the types of plants that can be grown or maintained. Plants grow when exposed to

Table 14 Mounting Height for Luminaires in Storage Areas

	Survival = 0.3 W/ft ²		Maintenance = 0.8 W/ft ²	
	Distance, ft	lux	Distance, ft	lux
Fluorescent (F)				
FCW two 40 W	3.0	1000	2.5	3000

FCW two 215 W	9.2	1000	5.2	3000
Discharge (HID)				
MH 400 W	10.8	800	6.6	2400
HPS 400 W	14.8	800	8.2	2400
LPS 180 W	11.2	1300	3.9	4000
Incandescent (INC)				
INC 160 W	4.3	350	1.0	1000
INC-HG 160 W	3.9	500	5.2	1500
DL	—	500	—	1500

higher levels, but do not survive below the suggested minimum. Plants may be grouped into three levels based on the following of irradiances:

Low (survival): A minimum light level of 0.07 W/ft² and a preferred level of 0.3 W/ft² irradiance for 8 to 12 h daily.

Medium (maintenance): A minimum of 0.3 W/ft² and a preferred level of 0.8 W/ft² irradiance for 8 to 12 h daily.

High (propagation): A minimum of 0.8 W/ft² and a preferred level of 2.2 W/ft² irradiance for 8 to 12 h daily.

Fluorescent (warm-white), metal halide, or incandescent lighting is usually chosen for public places. Table 13 lists the irradiance of various light sources.

CHAPTER 25

DRYING AND STORING SELECTED FARM CROPS

<i>DRYING</i>	25.2
<i>Drying Equipment and Practices</i>	25.2
<i>Shallow-Layer Drying</i>	25.3
<i>Deep-Bed Drying</i>	25.4
<i>DRYING SPECIFIC CROPS</i>	25.7
<i>Soybeans</i>	25.7
<i>Hay</i>	25.8
<i>Cotton</i>	25.8
<i>Peanuts</i>	25.9
<i>Rice</i>	25.9
<i>STORAGE PROBLEMS AND PRACTICES</i>	25.9
<i>Moisture Migration</i>	25.9
<i>Grain Aeration</i>	25.10
<i>SEED STORAGE</i>	25.12

CONTROL of moisture content and temperature during storage is critical to preserving the nutritional and economic value of farm crops as they move from the field to the market. Fungi (mold) and insects feed on poorly stored crops and reduce crop quality. Relative humidity and temperature affect mold and insect growth, which is reduced to a minimum if the crop is kept cooler than 50°F and if the relative humidity of the air in equilibrium with the stored crop is less than 60%.

Mold growth and spoilage are a function of elapsed storage time, temperature, and moisture content above critical values. Approximate allowable storage life for cereal grains is shown in Table 1. For example, corn at 60°F and 20% wet basis (w.b.) moisture has a storage life of about 25 days. If it is dried to 18% w.b. after 12 days, half of its storage life has elapsed. Thus, the remaining storage life at 60°F and 18% w.b. moisture content is 25 days, not 50 days.

Insects thrive in stored grain if the moisture content and temperature are not properly controlled. At low moisture contents and temperatures below 50°F, insects remain dormant or die.

Most farm crops must be dried to, and maintained at, a suitable moisture content. For most grains, a suitable moisture content is in the range of 12 to 15% w.b., depending on the specific crop, storage temperature, and length of storage. Oilseeds such as peanuts, sunflower seeds, and flaxseeds must be dried to a moisture content of 8 to 9% w.b. Grain stored for more than a year, grain that is damaged,

and seed stock should be dried to a lower moisture content. Moisture levels above these critical values lead to the growth of fungi, which may produce toxic compounds such as aflatoxin.

The maximum yield of dry matter can be obtained by harvesting when the corn has dried in the field to an average moisture content of 26% w.b. However, for quality-conscious markets, the minimum damage occurs when corn is harvested at 21 to 22% w.b. Wheat can be harvested when it has dried to 20% w.b., but harvesting at these moisture contents requires expensive mechanical drying. Although field drying requires less expense than operating drying equipment, total cost may be greater because field losses generally increase as the moisture content decreases.

The price of grain to be sold through commercial market channels is based on a specified moisture content, with price discounts for moisture levels above the specified amount. These discounts compensate for the weight of excess water, cover the cost of water removal, and control the supply of wet grain delivered to market. Grain dried to below the base moisture content set by the market (15.0% w.b. for corn, 13.0% w.b. for soybeans, and 13.5% w.b. for wheat) is not generally sold at a premium; thus, the seller loses the opportunity to sell water for the price of grain.

Grain Quantity

The **bushel** is the common measure used for marketing grain in the United States. Most dryers are rated in bushels per hour for a specified moisture content reduction. The use of the bushel as a measure causes considerable confusion. A bushel is a volume measure equal to 1.244 ft³. The bushel is used to estimate the holding capacity of bins, dryers, and other containers.

For buying and selling grain, for reporting production and consumption data, and for most other uses, the bushel weight is used. For example, the legal weight of a bushel is 56 lb for corn and 60 lb for wheat. When grain is marketed, bushels are computed as the load weight divided by the bushel weight. So, 56,000 lb of corn (regardless of moisture content) is 1000 bushels. Rice, grain sorghum, and sunflower are more commonly traded on the basis of the hundred-weight (100 lb), a measure that does not connote volume. The relationship between bushel by volume and market bushel is the **bulk density** (listed for some crops in Table 2). For some crops, the market has defined a test weight parameter, lb/bu. Test weight is essentially the bulk density, with bushels and cubic feet related by the definition of 1 bushel = 1.244 cubic feet.

The terms **wet bushel** and **dry bushel** sometimes refer to the mass of grain before and after drying. For example, 56,000 lb of 25% moisture corn may be referred to as 1000 wet bushels or simply 1000 bushels. When the corn is dried to 15.5% moisture content (m.c.), only 49,704 lb or 49,704/56 = 888 bushels remain. Thus, a dryer rated on the basis of wet bushels (25% m.c.) shows a capacity 12.6% higher than if rated on the basis of dry bushels (15.5% m.c.).

The percent of weight lost due to water removed may be calculated by the following equation:

Table 1 Approximate Allowable Storage Time (Days) for Cereal Grains

Moisture Content, % w.b. ^a	Temperature, °F					
	30	40	50	60	70	80
14	*	*	*	*	200	140
15	*	*	*	240	125	70
16	*	*	230	120	70	40
17	*	280	130	75	45	20
18	*	200	90	50	30	15
19	*	140	70	35	20	10
20	*	90	50	25	14	7
22	190	60	30	15	8	3
24	130	40	15	10	6	2
26	90	35	12	8	5	2
28	70	30	10	7	4	2
30	60	25	5	5	3	1

Based on composite of 0.5% maximum dry matter loss calculated on the basis of USDA research; *Transactions of ASAE* 333-337, 1972; and "Unheated Air Drying," Manitoba Agriculture Agdex 732-1, rev. 1986.

^aGrain moisture content calculated as percent wet basis: (weight of water in a given amount of wet grain ÷ weight of the wet grain) × 100.

*Approximate allowable storage time exceeds 300 days.

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment.

**Table 2 Calculated Densities of Grains and Seeds
Based on U.S. Department of Agriculture Data**

	Bulk Density, lb/ft ³
Alfalfa	48.0
Barley	38.4
Beans, dry	48.0
Bluegrass	11.2 to 24.0
Canola	40.2 to 48.2
Clover	48.0
Corn*	
Ear, husked	28.0
Shelled	44.8
Cottonseed	25.6
Oats	25.6
Peanuts, unshelled	
Virginia type	13.6
Runner, Southeastern	16.8
Spanish	19.8
Rice, rough	36.0
Rye	44.8
Sorghum	40.0
Soybeans	48.0
Sudan grass	32.0
Sunflower	
Nonoil	19.3
Oilseed	25.7
Wheat	48.0

*70 lb of husked ears of corn yield 1 bushel, or 56 lb of shelled corn. 70 lb of ears of corn occupy 2 volume bushels (2.5 ft³).

$$\text{Moisture shrink, \%} = \frac{M_o - M_f}{100 - M_f} \times 100$$

where

M_o = original or initial moisture content, wet basis

M_f = final moisture content, wet basis

Applying the formula to drying a crop from 25% to 15%,

$$\text{Moisture shrink} = \frac{25 - 15}{100 - 15} \times 100 = 11.76\%$$

In this case, the moisture shrink is 11.76%, or an average 1.176% weight reduction for each percentage point of moisture reduction. The moisture shrink varies depending on the final moisture content. For example, the average shrink per point of moisture when drying from 20% to 10% is 1.111.

Economics

Producers generally have the choice of drying their grain on the farm before delivering it to market, or delivering wet grain with a price discount for excess moisture. The expense of drying on the farm includes both fixed and variable costs. Once a dryer is purchased, the costs of depreciation, interest, taxes, and repairs are fixed and minimally affected by volume of crops dried. The costs of labor, fuel, and electricity vary directly with the volume dried. Total drying costs vary widely, depending on the volume dried, the drying equipment, and fuel and equipment prices. Energy consumption depends primarily on dryer type. Generally, the faster the drying speed, the greater the energy consumption (Table 3).

1. DRYING

1.1 DRYING EQUIPMENT AND PRACTICES

Contemporary crop-drying equipment depends on mass and energy transfer between the drying air and the product to be dried.

Table 3 Estimated Corn Drying Energy Requirement

Dryer Type	Btu/lb of Water Removed
Unheated air	1000 to 1200
Low temperature	1200 to 1500
Batch-in-bin, continuous-flow in-bin	1500 to 2000
High temperature	
Air recirculating	1800 to 2200
Without air recirculating	2000 to 3000
Combination drying, dryeration	1400 to 1800

Note: Includes all energy requirements for fans and heat.

The drying rate is a function of the initial temperature and moisture content of the crop, the air-circulation rate, the entering condition of the circulated air, the length of flow path through the products, and the time elapsed since the beginning of the drying operation. Outdoor air is frequently heated before it is circulated through the product. Heating increases the rate of heat transfer to the product, increases its temperature, and increases the vapor pressure of the product moisture. For more information on crop responses to drying, see Chapter 11 of the 2005 *ASHRAE Handbook—Fundamentals*.

Most crop-drying equipment consists of (1) a fan to move the air through the product, (2) a controlled heater to increase the ambient air temperature to the desired level, and (3) a container to distribute the drying air uniformly through the product. The exhaust air is vented to the atmosphere. Where climate and other factors are favorable, unheated air is used for drying, and the heater is omitted.

Fans

The fan selected for a given drying application should meet the same requirements important in any air-moving application. It must deliver the desired amount of air against the static resistance of the product in the bin or column, the resistance of the delivery system, and the resistance of the air inlet and outlet.

Foreign material in the grain can significantly change the required air pressure in the following ways:

- Foreign particles larger than the grain (straw, plant parts, and larger seeds) reduce airflow resistance. The airflow rate may be increased by 60% or more.
- Foreign particles smaller than the grain (broken grain, dust, and small seeds) increase the airflow resistance. The effect may be dramatic, decreasing the airflow rate by 50% or more.
- The method used to fill the dryer or the agitation or stirring of the grain after it is placed in the dryer can increase pressure requirements by up to 100%. In some grain, high moisture causes less pressure drop than does low moisture.

Vaneaxial fans are normally recommended when static pressures are less than 3 in. of water. Backward-curved centrifugal fans are commonly recommended when static pressures are higher than 4 in. of water. Low-speed centrifugal fans operating at 1750 rpm perform well up to about 7 in. of water, and high-speed centrifugal fans operating at about 3500 rpm have the ability to develop static pressure up to about 10 in. of water. The in-line centrifugal fan consists of a centrifugal fan impeller mounted in the housing of an axial flow fan. A bell-shaped inlet funnels the air into the impeller. The in-line centrifugal fan operates at about 3450 rpm and has the ability to develop pressures up to 10 in. of water with 7.5 hp or larger fans.

After functional considerations are made, the initial cost of the dryer fan should be taken into account. Drying equipment has a low percentage of annual use in many applications, so the cost of dryer ownership per unit of material dried is sometimes greater than the energy cost of operation. The same considerations apply to other components of the dryer.

Heaters

Most crop dryer heaters are fueled by either natural gas, liquefied petroleum gas, or fuel oil, though some electric heaters are used. Dryers using coal, biomass (e.g., corn cobs, stubble, or wood), and solar energy have also been built.

Fuel combustion in crop dryers is similar to combustion in domestic and industrial furnaces. Heat is transferred to the drying air either indirectly, by means of a heat exchanger, or directly, by combining the combustion gases with the drying air. Direct combustion heating is generally limited to natural gas or liquefied petroleum (LP) gas heaters. Most grain dryers use direct combustion. Indirect heating is sometimes used in drying products such as hay because of its greater fire hazard.

Controls

In addition to the usual temperature controls for drying air, all heated air units must have safety controls similar to those found on space-heating equipment. These safety controls shut off the fuel in case of flame failure and stop the burner in case of overheating or excessive drying air temperatures. All controls should be set up to operate the machinery safely in the event of power failure.

1.2 SHALLOW-LAYER DRYING

Batch Dryers

The batch dryer cycles through the loading, drying, cooling, and unloading of the grain. Fans force hot air through columns (typically 12 in. wide) or layers (2 to 5 ft thick) of grain. Drying time depends on the type of grain and the amount of moisture to be removed. Some dryers circulate and mix the grain to prevent significant moisture content gradients from forming across the column. A circulation rate that is too fast or a poor selection of handling equipment may cause undue damage and loss of market quality. Batch dryers are suitable for farm operations and are often portable.

Continuous-Flow Dryers

This type of self-contained dryer passes a continuous stream of grain through the drying chamber. Some dryers use a second chamber to cool the hot, dry grain before storage. Handling and storage equipment must be available at all times to move grain to and from the dryers. These dryers have cross-flow, concurrent flow, or counterflow designs.

Cross-Flow Dryers. A cross-flow dryer is a column dryer that moves air perpendicular to the grain movement. These dryers commonly consist of two or more vertical columns surrounding the drying and cooling air plenums. The columns range in thickness from 8 to 16 in. Airflow rates range from 40 to 160 cfm per cubic foot of grain. The thermal efficiency of the drying process increases as column width increases and decreases as airflow rate increases. However, moisture uniformity and drying capacity increase as airflow rate increases and as column width decreases. Dryers are designed to obtain a desirable balance of airflow rate and column width for the expected moisture content levels and drying air temperatures. Performance is evaluated in terms of drying capacity, thermal efficiency, and dried product moisture uniformity.

As with the batch dryer, a moisture gradient forms across the column because the grain nearest the inside of the column is exposed to the driest air during the complete cycle. Several methods minimize the problem of uneven drying.

One method uses turnflow devices that split the grain stream and move the inside half of the column to the outside and the outside half to the inside. Although effective, turnflow devices tend to plug if the grain is trashy. Under these conditions, a scalper/cleaner should be used to clean the grain before it enters the dryer.

Another method is to divide the drying chamber into sections and duct the hot air so that its direction through the grain is reversed in alternate sections. This method produces about the same effect as the turnflow method.

A third method is to divide the drying chamber into sections and reduce the drying air temperature in each section consecutively. This method is the least effective.

Rack-Type Dryers. In this special type of cross-flow dryer, grain flows over alternating rows of heated air supply ducts and air exhaust ducts (Figure 1). This action mixes the grain and alternates exposure to relatively hot drying air and air cooled by previous contact with the grain, promoting moisture uniformity and equal exposure of the product to the drying air.

Concurrent-Flow Dryers. In the concurrent-flow dryer, grain and drying air move in the same direction in the drying chamber. The drying chamber is coupled to a counterflow cooling section. Thus, the hottest air is in contact with the wettest grain, allowing the use of higher drying air temperatures (up to 450°F). Rapid evaporative cooling in the wettest grain prevents the grain temperature from reaching excessive levels. Because higher drying air temperatures are used, the energy efficiency is better than that obtained with a conventional cross-flow dryer. In the cooling section, the coolest air initially contacts the coolest grain. The combination of drying and cooling chambers results in lower thermal stresses in the grain kernels during drying and cooling and, thus, a higher-quality product.

Counterflow Dryers. The grain and drying air move in opposite directions in the drying chamber of this dryer. Counterflow is common for in-bin dryers. Drying air enters from the bottom of the bin and exits from the top. The wet grain is loaded from overhead, and floor sweep augers can be used to bring the hot, dry grain to a center sump, where it is removed by another auger. The travel of the sweep is normally controlled by moisture- or temperature-sensing elements.

A drying zone exists only in the lower layers of the grain mass and is truncated at its lower edge so that the grain being removed is not overdried. As a part of the counterflow process, the warm, saturated or near-saturated air leaving the drying zone passes through the cool incoming grain. Some energy is used to heat the cool grain, but some moisture may condense on the cool grain if the bed is deep and the initial grain temperature is low.

Reducing Energy Costs

Recirculation. In most commercially available continuous-flow dryers, optional ducting systems recycle some of the exhaust air from the drying and cooling chambers back to the inlet of the drying chamber (Figure 2). Systems vary, but most make it possible to

Fig. 1 Rack-Type Continuous-Flow Grain Dryer with Alternate Rows of Air Inlet and Outlet Ducts

recirculate all of the air from the cooling chamber and from the lower two-thirds of the drying chamber. The relative humidity of this recirculated air for most cross-flow dryers is less than 50%. Energy savings of up to 30% can be obtained from a well-designed system.

Dryeration. This is another means of reducing energy consumption and improving grain quality. In this process, hot grain with a moisture content one or two percentage points above that desired for storage is removed from the dryer (Figure 3). The hot grain is placed in a dryeration bin, where it tempers without airflow for at least 4 to 6 h. After the first grain delivered to the bin has tempered, the cooling fan is turned on as additional hot grain is delivered to the bin. The air cools the grain and removes 1 to 2% of its moisture before the grain is moved to final storage. If the cooling rate equals the filling rate, cooling is normally completed about 6 h after the last hot grain is added. The crop cooling rate should equal the filling rate of the dryeration bin. A faster cooling rate cools the grain before it has tempered. A slower rate may result in spoilage, since the allowable storage time for hot, damp grain may be only a few days. The required airflow rate is based on dryer capacity and crop density. An airflow rate of 12 cfm for each bushel per hour (bu/h) of dryer capacity provides the cooling capacity to keep up with the dryer when it

Fig. 2 Crop Dryer Recirculation Unit
(Courtesy Farm Fans, Inc., a division of The GSI Group)

is drying corn that weighs 56 lb/bu. Recommended airflow rates for some crops are listed in Table 4.

Combination Drying. This method was developed to improve drying thermal efficiency and corn quality. First, a high-temperature dryer dries the corn to 18 to 20% moisture content. Then it is transferred to a bin, where the full-bin drying system brings the moisture down to a safe storage level.

Dryer Temperature. For energy savings, operating temperatures of batch and continuous-flow dryers are usually set at the highest level that will not damage the product for its end use.

1.3 DEEP-BED DRYING

A deep-bed drying system can be installed in any structure that holds grain. Most grain storage structures can be designed or adapted for drying if a means of distributing the drying air uniformly through the grain is provided. A perforated floor (Figure 4) and duct systems placed on the floor of the bin (Figure 5) are the two most common means.

Perforations in the floor should have a total area of at least 10% of the floor area. A perforated floor distributes air more uniformly and offers less resistance to airflow than do ducts, but a duct system is less expensive for larger floor area systems. Ducts can be removed after the grain is removed, and the structure can be cleaned and used for other purposes. Ducts should not be spaced farther apart than one-half times the depth of the grain. The amount of perforated area or the duct length will affect airflow distribution uniformity.

Air ducts and tunnels that disperse air into the grain should be large enough to prevent the air velocity from exceeding 2000 fpm; slower speeds are desirable. Sharp turns, obstructions, or abrupt changes in duct size should be eliminated, as they cause pressure loss. Operating methods for drying grain in storage bins are (1) full-bin drying, (2) layer drying, (3) batch-in-bin drying, and (4) recirculating/continuous-flow bin drying.

Full-Bin Drying

Full-bin drying is generally performed with unheated air or air heated up to 10°F above ambient. A humidistat is frequently used to sense the humidity of the drying air and turn off the heater if the weather conditions are such that heated air would cause overdrying. A humidistat setting of 55% stops drying at approximately the 12% moisture level for most farm grains, assuming that the ambient relative humidity does not go below this point.

Airflow rate requirements for full-bin drying are generally calculated on the basis of cfm of air required per cubic foot or bushel of grain. The airflow rate recommendations depend on the weather

Fig. 3 Dryeration System Schematic

Table 4 Recommended Airflow Rates for Dryeration

Crop	Weight, lb/bu	Recommended Dryeration Airflow Rate, cfm per bu/h
Barley	48	10
Corn	56	12
Durum	60	13
Edible beans	60	13
Flaxseeds	56	12
Millet	50	11

Fig. 4 Perforated Floor System for Bin Drying of Grain

conditions and on the type of grain and its moisture content. Airflow rate is important for successful drying. Because faster drying results from higher airflow rates, the highest economical airflow rate should be used. However, the cost of full-bin drying at high airflow rates may exceed the cost of using column dryers, or the electric power requirement may exceed the available capacity.

Recommendations for full-bin drying with unheated air are shown in Tables 5, 6, and 7. These recommendations apply to the principal production areas of the continental United States and are based on experience under average conditions; they may not be applicable under unusual weather conditions or even usual weather conditions in the case of late-maturing crops. Full-bin drying may not be feasible in some geographical areas.

The maximum practical depth of grain to be dried (distance of air travel) is limited by the cost of the fan, motor, air distribution system, and power required. This depth seems to be 20 ft for corn and soybeans, and about 15 ft for wheat.

To ensure satisfactory drying, heated air may be used during periods of prolonged fog or rain. Burners should be sized to raise the temperature of the drying air by no more than 10°F above ambient. The temperature should not exceed about 80°F after heating. Overheating the drying air causes the grain to overdry and dry nonuniformly; heat is recommended only to counteract adverse weather

Fig. 5 Tunnel or Duct Air Distribution System

Fig. 6 Three Zones Within Grain During Full-Bin Drying

conditions. Electric controllers can be applied to fan and heater operation to achieve the final desired grain moisture content.

Drying takes place in a drying zone, which advances upward through the grain (Figure 6). Grain above this drying zone remains at or slightly above the initial moisture content, while grain below the drying zone is at a moisture content in equilibrium with the drying air.

As the direction of air movement does not affect the rate of drying, other factors must be considered in choosing the direction. A pressure system moves the moisture-laden air up through the grain, and it is discharged under the roof. If there are insufficient roof outlets, moisture may condense on the underside of metal roofs. During pressure system ventilation, the wettest grain is near the top surface and is easy to monitor. Fan and motor waste heat enter into the airstream and contribute to drying.

A negative-pressure system moves air down through the grain. Moisture-laden air discharges from the fan to the outdoors; thus, roof condensation is not a problem. Also, the air picks up some solar heat from the roof. However, the wettest grain is near the bottom of the mass and is difficult to sample. Of the two systems, the pressure system is recommended because it is easier to manage.

The following management practices must be observed to ensure the best performance of the dryer:

1. Minimize foreign material. A scalper-cleaner is recommended for cleaning the grain to reduce air pressure and energy requirements and to help provide uniform airflow for elimination of wet spots.
2. Distribute the remaining foreign material uniformly by installing a grain distributor.

Table 6 Minimum Airflow Rate for Unheated Air Low-Temperature Drying of Small Grains and Sunflower in the Northern Plains of the United States

Airflow Rate		Maximum Initial Moisture Content, % Wet Basis	
cfm/bu	cfm/ft ³	Small Grains	Sunflower
0.5	0.4	16	15
1.0	0.8	18	17
2.0	1.6	20	21

- Place the grain in layers and keep it leveled.
- Start the fan as soon as the floor or ducts are covered with grain.
- Operate the fan continuously with unheated air unless it is raining heavily or there is a dense ground fog. Once all the grain is within 1% of desired storage moisture content, run the fans only when the relative humidity is below 70%.

Layer Drying

In layer drying, successive layers of wet grain are placed on top of dry grain. When the top 6 in. has dried to within 1% of the desired moisture content, another layer is added (Figure 7). Compared to full-bin drying, layering reduces the time that the top layers of grain remain wet. Because the effective airflow rate is greater for lower layers, allowable harvest moisture content of grain in these levels can be greater than that in the upper layers. Either unheated air or air heated 10 to 20°F above ambient may be used, but using heated air controlled with a humidistat to prevent overdrying is most common. The first layer may be about 7 ft deep, with successive layers of about 3 ft.

Batch-in-Bin Drying

A storage bin adapted for drying may be used to dry several batches of grain during a harvest season, if the grain is kept to a shallow layer so that higher airflow rates and temperatures can be used. After the batch is dry, the bin is emptied, and the cycle is repeated. The drying capacity of the batch system (bu/yr) is greater than that of other in-storage drying systems. In a typical operation, batches of

corn in 3 ft depths are dried from an initial moisture content of 25% with 130°F air at the rate of about 20 cfm per cubic foot. Considerable nonuniformity of moisture content may be present in the batch after drying is stopped; therefore, the grain should be well mixed as it is placed into storage. If the mixing is done well, grain that is too wet equalizes in moisture with grain that is too dry before spoilage

Fig. 7 Example of Layer Filling of Corn

can occur. Aeration of the grain in storage will facilitate the equalization of moisture.

Grain may be cooled in the dryer to ambient temperature before it is stored. Cooling is accomplished by operating the fan without the heater for about 1 h. Some additional drying occurs during the cooling process, particularly in the wetter portions of the batch.

Grain stirring devices are used with both full-bin and batch-in-bin drying systems. Typically, these devices consist of one or more open, 2 in. diameter, standard pitch augers suspended from the bin roof and extending to near the bin floor. The augers rotate and simultaneously travel horizontally around the bin, mixing the drying grain to reduce moisture gradients and prevent overdrying of the bottom grain. The augers also loosen the grain, allowing a higher airflow rate for a given fan. Stirring equipment reduces bin capacity by about 10%. Furthermore, commercial stirring devices are available only for round storage enclosures.

Recirculating/Continuous-Flow Bin Drying

This type of drying incorporates a tapered sweep auger that removes uniform layers of grain from the bottom of the bin as it dries (Figure 8). The dry grain is then redistributed on top of the pile of grain or moved to a second bin for cooling. The sweep auger may be controlled by temperature or moisture sensors. When the desired condition is reached, the sensor starts the sweep auger, which removes a layer of grain. After a complete circuit of the bin, the sweep auger stops until the sensor determines that another layer is dry. Some drying takes place in the cooling bin. Up to two percentage points of moisture may be removed, depending on the management of the cooling bin.

2. DRYING SPECIFIC CROPS

2.1 SOYBEANS

Soybeans usually need drying only when there is inclement weather during the harvest season. Mature soybeans left exposed to rain or damp weather develop a dark brown color and a mealy or chalky texture. Seed quality deteriorates rapidly. Oil from weather-damaged beans costs more to refine and is often not of edible grade. In addition to preventing deterioration, the artificial drying of soybeans offers the advantage of early harvest, which reduces the chance of loss from bad weather and reduces natural and combine shatter loss. Soybeans harvested with a wet basis moisture content greater than 13.5% exhibit less damage.

Fig. 8 Grain Recirculators Convert Bin Dryer to High-Speed Continuous-Flow Dryer

Drying Soybeans for Commercial Use

Conventional corn-drying equipment can be used for soybeans, with some limitations on heat input. Soybeans for commercial use can be dried at 130 to 140°F; drying temperatures of 190°F reduce the oil yield. If the relative humidity of the drying air is below 40%, excessive seedcoat cracking occurs, causing many split beans in subsequent handling. Physical damage can cause fungal growth on the beans, storage problems, and a slight reduction in oil yield and quality. Flow-retarding devices should be used during handling, and beans should not be dropped more than 20 ft onto concrete floors.

Drying Soybeans for Seed and Food

The relative humidity of the drying air should be kept above 40%, regardless of the amount of heat used. The maximum drying temperature to avoid germination loss is 110°F. Natural air drying at a flow rate of 1.6 cfm per cubic foot is adequate for drying seed with an initial moisture content of up to 16% w.b.

If adding heat, raise the drying air temperature no more than 5°F above ambient. This drying method is slow, but it results in excellent quality and avoids overdrying. However, drying must be completed before spoilage occurs. At higher moisture contents, good results have been obtained using an airflow rate of 3.2 cfm per cubic foot with humidity control. Data on allowable drying time for soybeans are unavailable. Without better information, an estimate of storage life for oil crops can be made based on the values for corn, using an adjusted moisture content calculated by the following equation:

$$\text{Comparable moisture content} = \frac{\text{Oilseed moisture content}}{100 - \text{Seed oil content}} \times 100$$

A corn moisture content 2% greater than that of the soybeans should generally be used to estimate allowable drying time (e.g., 12% soybeans are comparable to 14% corn). Soybeans are dried from a lower initial moisture content than corn.

Dry high-moisture soybeans in a bin with the air temperature controlled to keep the relative humidity at 40% or higher. Airflow rates of 8.0 cfm per cubic foot are recommended, with the depth of the beans not to exceed 4 ft.

2.2 HAY

Hay normally contains 65 to 80% wet basis moisture at cutting. Field drying to 20% may result in a large loss of leaves. Alfalfa hay leaves average about 50% of the crop by weight, but they contain 70% of the protein and 90% of the carotene. The quality of hay can be increased and the risk of loss due to bad weather reduced if the hay is put under shelter when partially field dried (35% moisture content) and then artificially dried to a safe storage moisture content. In good drying weather, hay conditioned by mechanical means can be dried sufficiently in one day and placed in the dryer. Hay may be long, chopped, or baled for this operation; unheated or heated air can be used.

In-Storage Drying

Unheated air is normally used for in-storage or mow drying. Hay is dried in the field to 30 to 40% moisture content before being placed in the dryer. For unheated air drying, airflow should be at least 200 cfm per ton. The fan should be able to deliver required airflow against static pressure of 1 to 2 in. of water.

Slotted floors, with at least 50% of the area open, are generally used for drying baled hay. For long or chopped hay in mows narrower than 36 ft wide, the center duct system is the most popular. A slotted floor should be placed on each side of the duct to within 5 ft of its ends and the outer walls (Figure 9). If the mow is wider than 36 ft, it should be divided crosswise into units of 28 ft or narrower. These should then be treated as individual dryers. If the storage depth exceeds about 13 ft, vertical flues and/or additional levels of ducts may be used. If tiered ducts are used, a vertical air chamber, about 75% of the probable hay depth, should be used. The supply ducts are then connected at 7 to 10 ft vertical intervals as the mow is filled. With either of these methods, hay in total depths up to 30 ft can be dried. The duct size should be such that the air velocity is less than 1000 fpm.

The maximum depth of wet hay that should be placed on a hay-drying system at any time depends on hay moisture content, weather conditions, the physical form of the hay, and the airflow rate. The maximum drying depth is about 16 ft for long hay, 13 ft for chopped hay, and 7 small rectangular bales deep for baled hay. Baled hay should have a density of about 8 lb/ft³. For best results, bales should be stacked tightly together on edge (parallel to the stems) to ensure that no openings exist between them.

Fig. 9 Central Duct Hay-Drying System with Lateral Slatted Floor for Wide Mows

For mow drying, the fan should run continuously during the first few days. Afterward, it should be operated only during low relative humidity weather. During prolonged wet periods, the fan should be operated only enough to keep the hay cool.

Batch Wagon Drying

Batch drying can be done on a slotted floor platform; however, because this method is labor-intensive, wagon dryers are more commonly used. With a wagon dryer system, hay is baled at about 45% moisture content to a density of about 11 lb/ft³. The hay is then stacked onto a wagon with tight, high sides and a slotted or expanded metal floor. Drying is accomplished most efficiently by forcing the heated air (up to 158°F) down the canvas duct of a plenum chamber secured to the top of the wagon. After 4 or 5 h of drying, the exhaust air is no longer saturated with moisture, and about 75% of it may be recirculated or passed through a second wagon of wet hay for greater drying efficiency.

In this method, the amount of hay harvested each day is limited by the capacity of the drying wagons. In this 24 h process, the hay cut one day is stored the following day; only enough hay to load the drying wagons should be harvested each day.

The airflow rate in this method is normally much higher than when unheated air is used. About 40 cfm per square foot of wagon floor space is required. As with mow drying, the duct size should be such that the air velocity is less than 1000 fpm.

2.3 COTTON

Producers normally allow cotton to dry naturally in the field to 12% moisture content or less before harvest. Cotton harvested in this manner can be stored in trailers, baskets, or compacted stacks for extended periods with little loss in fiber or seed quality. Thus, cotton is not normally aerated or artificially dried before ginning. Cotton harvested during inclement weather and stored cotton exposed to precipitation must be dried at the cotton gin within a few days to prevent self heating and deterioration of the fiber and seed.

Though cotton may be safely stored at moisture contents as high as 12%, moisture levels near the upper limit are too high for efficient ginning and for obtaining optimum fiber grade. The cleaning efficiency of cotton is inversely proportional to its moisture content, with the most efficient level being 5% fiber moisture content. However, fiber quality is best preserved when the fiber is separated from the seed at moisture contents between 6.5 and 8%. Therefore, if cotton comes into the system below this level, it can be cleaned, but moisture should be added before separating the fiber from the seed to improve the ginning quality. Dryers in the cotton gins are capable of drying the cotton to the desired moisture level.

The tower dryer is the most commonly used among several types of commercially available dryers. This device operates on a parallel flow principle: 14 to 24 cfm of drying air per pound of cotton also serves as the conveying medium. As it moves through the dryer's serpentine passages, cotton impacts on the walls. This action agitates the cotton for improved drying and lengthens its exposure time. Drying time depends on many variables, but total exposure seldom exceeds 15 s. For extremely wet cotton, two stages of drying are needed for adequate moisture control.

Wide variations in initial moisture content dictate different drying amounts for each load of cotton. Rapid changes in drying requirements are accommodated by automatically controlling drying air temperature in response to moisture measurements taken before or after drying. These control systems prevent overdrying and reduce energy requirements. For safety and to preserve fiber quality, drying air temperature should not exceed 350°F in any portion of the drying system.

If the internal cottonseed temperature does not exceed 140°F, germination is unimpaired by drying. This temperature is not exceeded in a tower dryer; however, the moisture content of the seed after drying may be above the 12% level recommended for safe long-term storage. Wet cottonseed is normally processed immediately at a cottonseed oil mill. Cottonseed under the 12% level is frequently stored for several months before milling or delinting and treatment at a seed processing plant. The aeration that cools deep beds of stored cottonseed effectively maintains viability and prevents an increase in free fatty acid content. For aeration, ambient air is normally drawn downward through the bed at a rate of at least 0.025 cfm per cubic foot of oil mill seed and 0.125 cfm per cubic foot of planting seed.

2.4 PEANUTS

Peanuts normally have a moisture content of about 50% at the time of digging. Allowing the peanuts to dry on the vines in the windrow for a few days removes much of this water. However, peanuts usually contain 20 to 30% moisture when removed from the vines, and some artificial drying is necessary. Drying should begin within 6 h after harvesting to keep the peanuts from self heating. Both the maximum temperature and the rate of drying must be carefully controlled to maintain quality.

High temperatures result in an off flavor or bitterness. Drying too rapidly without high temperatures results in blandness or nuts that do not develop flavor during roasting. High temperatures, rapid drying, or excessive drying cause the skin to slip easily and the kernels to become brittle. These conditions result in high damage rates in the shelling operation but can be avoided if the moisture removal rate does not exceed 0.5% per hour. Because of these limitations, continuous-flow drying is not usually recommended for peanuts.

Peanuts can be dried in bulk bins using unheated air or air with supplemental heat. Under poor drying conditions, unheated air may cause spoilage, so supplemental heat is preferred. Air should be heated no more than 13 or 14°F to a maximum temperature of 95°F. An airflow rate of 10 to 25 cfm per cubic foot of peanuts should be used, depending on the initial moisture content.

The most common method of drying peanuts is bulk wagon drying. Peanuts are dried in depths of 5 to 6 ft, using airflow rates of 10 to 15 cfm per cubic foot of peanuts and air heated 11 to 14°F above ambient. This method retains quality and usually dries the peanuts in three to four days. Wagon drying reduces handling labor but may require additional investment in equipment.

2.5 RICE

Of all grains, rice is probably the most difficult to process without quality loss. Rice containing more than 13.5% moisture cannot be safely stored for long periods, yet the recommended harvest moisture content for best milling and germination ranges from 20 to 26%. When rice is harvested at this moisture content, drying must be started promptly to prevent souring. Normally, heated air is used in continuous-flow dryers, where large volumes of air are forced through 4 to 10 in. layers of rice. Temperatures as high as 130°F may be used, if (1) the temperature drop across the rice does not exceed 20 to 30°F, (2) the moisture reduction does not exceed two percentage points in a 0.5 h exposure, and (3) the rice temperature does not exceed 100°F. During the tempering period following drying, the rice should be aerated to ambient temperature before the next pass through the dryer. This removes additional moisture and eliminates one to two dryer passes. It is estimated that full use of aeration following dryer passes could increase the maximum daily drying capacity by about 14%.

Unheated air or air with a small amount of added heat (13°F above ambient, but not exceeding 95°F) should be used for deep-bed rice drying. Too much heat overdries the bottom, resulting in checking

(cracking), reduced milling qualities, and possible spoilage in the top. Because unheated air drying requires less investment and attention than supplemental heat drying, it is preferred when conditions permit. In the more humid rice-growing areas, supplemental heat is desirable to ensure that the rice dries. The time required for drying varies with weather conditions, moisture content, and airflow rate. In California, the recommended airflow rate is 0.2 to 2.4 cfm per cubic foot. Because of less favorable drying conditions in Arkansas, Louisiana, and Texas, greater airflow rates are recommended (e.g., a minimum of 2.0 cfm per cubic foot is recommended in Texas). Whether unheated air or supplemental heat is used, the fan should be turned on as soon as rice uniformly covers the air distribution system. The fan should then run continuously until the moisture content in the top 1 ft of rice is reduced to about 15%. At this point, the supplemental heat should be turned off. The rice can then be dried to a safe storage level by operating the fan only when the relative humidity is below 75%.

3. STORAGE PROBLEMS AND PRACTICES

3.1 MOISTURE MIGRATION

Redistribution of moisture generally occurs in stored grain when grain temperature is not controlled (Figure 10). Localized spoilage can occur even when the grain is stored at a safe moisture level. Grain placed in storage in the fall at relatively high temperatures cools nonuniformly through contact with the outer surfaces of the storage bin as winter approaches. Thus, the grain near the outer walls and roof may be at cool outdoor temperatures while the grain nearer the center is still nearly the same temperature it was at harvest. These temperature differentials induce air convection currents that flow downward along the outer boundaries of the porous grain mass and upward through the center. When the cool air from the outer regions contacts the warm grain in the interior, the air is heated and its relative humidity is lowered, increasing its capacity to absorb moisture from the grain. When the warm, humid air reaches the cool grain near the top of the bin, it cools again and transfers vapor to the grain. Under extreme conditions, water condenses on the grain. The moisture concentration near the center of the grain surface causes significant spoilage if moisture migration is uncontrolled. During spring and summer, the temperature gradients are reversed. The grain moisture content increases most at depths of 2 to 4 ft below the surface. Daily variations in temperature do not cause significant moisture migration. Aside from seasonal temperature variations, the size of the grain mass is the most important factor in fall and winter moisture migration. In storages containing less than 1200 ft³, there is less trouble with moisture migration. The problem becomes critical in large storages and is aggravated by incomplete cooling of artificially dried grain. Artificially dried grain should be cooled to near ambient temperature soon after drying.

3.2 GRAIN AERATION

Aeration by mechanically moving ambient air through the grain mass is the best way to control moisture migration. Aeration systems are also used to cool grain after harvest, particularly in warmer climates where grain may be placed in storage at temperatures exceeding 100°F. After the harvest heat is removed, aeration may be continued in cooler weather to bring the grain to a temperature within 20°F of the coldest average monthly temperature. The temperature must be maintained below 50°F.

Aeration systems are not a means of drying because airflow rates are too low. However, in areas where the climate is favorable, carefully controlled aeration may be used to remove small amounts of moisture. Commercial storages may have pockets of higher-moisture grain if, for example, some batches of grain are delivered after a rain shower or early in the morning. Aeration can control heating damage in the higher-moisture pockets.

Aeration Systems Design

Aeration systems include fans capable of delivering the required amount of air at the required static pressure, suitable ducts or floors to distribute the air into the grain, and controls to regulate the operation of the fan. The airflow rate determines how many hours are required to cool the crop (Table 8). Most aeration systems are designed with airflow rates between 0.05 and 0.2 cfm/bu.

Stored grain is aerated by forcing air up or down through the grain. Upward airflow is more common because it is easier to observe when the cooling front has moved through the entire grain mass. In large, flat storages with long ducts, upward airflow results in more uniform air distribution than downdraft systems.

During aeration, a warming or cooling front moves through the crop (Figure 11); it is important to run the fan long enough to move the front completely through the crop.

Static pressure for an aeration system can be determined using the airflow resistance information in Chapter 11 of the 2005 *ASHRAE Handbook—Fundamentals*. All common types of fans are used in aeration systems. Attention should be given to noise levels with fans that are operated near residential areas or where people work for extended periods. The supply ducts connecting the fan to the distribution ducts in the grain should be designed and constructed according to the standards of good practice for any air-moving application. A maximum air velocity of 2500 fpm may be used, but 1600 to 2000 fpm is preferred. In large systems, one large fan may be attached to a manifold duct leading to several distribution ducts in one or more storages, or smaller individual fans may serve individual distribution ducts. Where a manifold is used, valves or dampers should be installed at each takeoff to allow adjustment or closure of airflow when part of the aerator is not needed.

Distribution ducts are usually perforated sheet metal with a circular or inverted U-shaped cross section, although many functional arrangements are possible. The area of the perforations should be at least 10% of the total duct surface. The holes should be uniformly spaced and small enough to prevent the passage of the grain into the duct (e.g., 0.1 in. holes or 0.08 in. wide slots do not pass wheat).

Since most problems develop in the center of the storage, and the crop cools naturally near the wall, the aeration system must provide good airflow in the center. Flush floor systems work well in storages with sweep augers and unloading equipment. Ducts should be easily removable for cleaning. Duct spacing should not exceed the depth of the crop; the distance between the duct and storage structure wall should not exceed one-half the depth of the crop for bins and flat storages. Common duct patterns for round bins are shown in Figure 12. Duct spacing for flat storages is shown in Figure 13.

When designing the distribution duct system for any type of storage, the following should be considered: (1) the cross-sectional area and length of the duct, which influences both the air velocity within the duct and the uniformity of air distribution; (2) the duct surface area, which affects the static pressure losses in the grain surrounding the duct; and (3) the distance between ducts, which influences the uniformity of airflow.

For upright storages where distribution ducts are relatively short, duct velocities up to 2000 fpm are permissible. Maximum recommended air velocities in ducts for flat storages are shown in Table 9. Furthermore, these velocities should not be exceeded in the air outlets from the storage; therefore, an air outlet area at least equal to the duct cross-sectional area should be provided.

The duct surface area that is perforated or otherwise open for air distribution must be great enough that the air velocity through the grain surrounding the duct is low enough to avoid excessive pressure loss. When a semicircular perforated duct is used, the entire surface area is effective; only 80% of the area of a circular duct resting on the floor is effective. For upright storages, the air velocity through the grain near the duct (duct face velocity) should be limited to 30 fpm or less; in flat storages, to 20 fpm or less.

Duct strength and anchoring are important. If ducts placed directly on the floor are to be held in place by the crop, the crop flow should be directly on top of the ducts to prevent movement and damage. Distribution ducts buried in the grain must be strong enough to withstand the pressure the grain exerts on them. In tall, upright storages, static grain pressures may reach 10 psi. When ducts are located in the path of the grain flow, as in a hopper, they may be subjected to many times this pressure during grain unloading.

Fig. 12 Common Duct Patterns for Round Grain Bins

Operating Aeration Systems

The operation of aeration systems depends largely on the objectives to be attained and the locality. In general, cooling should be carried out any time the outdoor air temperature is about 15°F cooler than the grain. Stored grain should not be aerated when the air humidity is much above the equilibrium humidity of the grain because moisture will be added. The fan should be operated long enough to cool the crop completely, but it should then be shut off and covered, thus limiting the amount of grain that is rewetted.

Aeration to cool the grain should be started as soon as the storage is filled, and cooling air temperatures are available. Aeration to prevent moisture migration should be started whenever the average air temperature is 10 to 15°F below the highest grain temperature. Aeration is usually continued as weather permits until the grain is uniformly cooled to within 20°F of the average temperature of the coldest month, or to 30 to 40°F.

Grain temperatures of about 32 to 50°F are desirable. In the northern corn belt, aeration may be resumed in the spring to equalize the grain temperature and raise it to between 40 and 50°F. This

Table 9 Maximum Recommended Air Velocities Within Ducts for Flat Storages

Grain	Airflow Rate, cfm/bu	Air Velocity (fpm) within Ducts for Grain Depths of				
		10 ft	20 ft	30 ft	40 ft	50 ft

(A) IS SHORTEST AIR PATH
MAKE (B) OR (C) NO MORE THAN 1.5 TIMES (A)

Fig. 13 Duct Arrangements for Large Flat Storages

reduces the risk of localized heating from moisture migration. Storage problems are the only reason to aerate when air temperatures are above 60°F. Aeration fans and ducts should be covered when not in use.

In storages where fans are operated daily in fall and winter months, automatic controls work well when air is not too warm or humid. One thermostat usually prevents fan operation when the air temperature is too high, and another prevents operation when the air is too cold. A humidistat allows operation when the air is not too humid. Fan controllers that determine the equilibrium moisture content of the crop based on existing air conditions can regulate the fan based on entered information.

4. SEED STORAGE

Seed must be stored in a cool, dry environment to maintain viability. Most seed storages have refrigeration equipment to maintain a storage environment of 45 to 55°F. Seed storage conditions must be achieved before mold and insect damage occur.

CHAPTER 26

AIR CONDITIONING OF WOOD AND PAPER PRODUCT FACILITIES

<i>General Wood Product Operations</i>	26.1
<i>Pulp and Paper Operations</i>	26.2

THIS chapter covers some of the standard requirements for air conditioning of facilities that manufacture finished wood products as well as for pulp and paper product process operations.

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

1. GENERAL WOOD PRODUCT OPERATIONS

In wood product manufacturing facilities, ventilation can be considered a part of the process. Metal ductwork should be used and grounded to prevent a buildup of static electricity. Hoods should be made of spark-free, noncombustible material. A pneumatic conveying system should be furnished to reduce the accumulation of wood dust in the collecting duct system. The airflow rate and velocity should be able to maintain the air-dust mixture below the minimum explosive

concentration level. If dampers are unavoidable in the system, they should be firmly fastened after balancing work. Dust collectors should be located outside the building. Fans or blowers should be placed downstream of the dust collector and air-cleaning equipment, and should be interlocked with the wood-processing equipment. When the fan or blower stops, the wood process should stop immediately and forward a signal to the alarm system.

Deflagration venting and suppression should be furnished for wood-processing workshops and wood-processing equipment such as vessels, reactors, mixers, blenders, mills, dryers, ovens, filters, dust collectors, storage equipment, material-handling equipment, and aerosol areas. The deflagration suppression system must be disarmed before performing any maintenance work to avoid possible injury from discharging the suppressant. Warning signs should be displayed prominently at all maintenance access points.

Finished lumber products to be used in heated buildings should be stored in areas that are heated 10 to 20°F above ambient. This provides sufficient protection for furniture stock, interior trim, cabinet material, and stock for products such as ax handles and glue-laminated beams. Air should be circulated within the storage areas. Lumber that is kiln-dried to a moisture content of 12% or less can be kept within a given moisture content range through storage in a heated shed. The moisture content can be regulated either manually or automatically by altering the dry-bulb temperature (Figure 1).

Some special materials require close control of moisture content. For example, musical instrument stock must be dried to a given moisture level and maintained there because the moisture content of

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Fig. 1 Relationship of Temperature, Relative Humidity, and Vapor Pressure of Air and Equilibrium Moisture Content of Wood

the wood affects the harmonics of most stringed wooden instruments. This control may require air conditioning, heating, and/or humidification, with or without reheating.

Process Area Air Conditioning

Temperature and humidity requirements in wood product process areas vary according to product, manufacturer, and governing code. For example, in match manufacturing, the match head must be cured (i.e., dried) after dipping. This requires careful control of humidity and temperature to avoid a temperature near the ignition point. Any process involving application of flammable substances should follow the ventilation recommendations of the National Fire Protection Association, the National Fire Code, and the U.S. Occupational Safety and Health Act.

Finished Product Storage

Finished lumber to be made into furniture, equipment parts, musical instruments, architectural woodwork, or other wood products of value is stored and/or manufactured under controlled temperature and humidity to maintain proper wood dryness. Improper drying can cause laminated or glued joints to fail. Finished wood that has changed dimension because of excess moisture gain or loss can cause fitting problems. Cracking, splitting, checking, warping, and discoloring are other problems with improperly dried and/or stored wood.

Green, rough, cut lumber is stacked end to end in layers, each layer being separated by wood strips to allow air circulation. Lumber can be stacked and left to dry naturally in open-sided sheds. Enclosed, heated kilns with steam coils and/or direct steam injection, forced air circulation, makeup air, and exhaust air vents could be used where faster, controlled drying is preferred. Drying (or addition of moisture) can be accomplished by HVAC systems using dehumidifying coils and/or desiccants, heating/reheat coils, humidifiers, makeup and exhaust air, distribution air ducts, and automatic controls. An insulated dehumidifying/humidifying room could be constructed and finished to minimize moisture migration from higher-humidity areas. Lumber can also be dried by solar kilns, microwaves, dielectric heating, superheated steam, and vacuum.

Wood is composed of natural fibers and its moisture content varies according to its environment. Samples from the wood being dried must be tested for moisture content at predetermined time intervals to prevent overdrying and defects. Drying rates are determined by the wood species. Final moisture content depends upon the wood's ultimate use.

The formula for determining moisture content is

$$\frac{\left[\left(\text{Weight of sample when cut} \right) - \left(\text{Weight of oven-dried sample} \right) \right] \times 100}{\text{Weight of oven-dried sample}} = \text{Moisture content, \%}$$

Lumber/wood drying using HVAC systems can be accomplished with factory- or field-assembled systems. The quantity of lumber/wood to be dried, wood species, rate of drying, total moisture removal, drying room construction, economics (cost and rate of return on investment), fire and safety codes, maintenance, and ease of use influence the type of HVAC system to be installed.

2. PULP AND PAPER OPERATIONS

The papermaking process comprises two basic steps: (1) wood is reduced to pulp (i.e., wood fibers), and (2) the pulp is converted to paper. Wood can be pulped by either mechanical action (e.g., grinding in a groundwood mill), chemical action (e.g., kraft pulping), or a combination of both.

Many different types of paper can be produced from pulp, ranging from the finest glossy finish to newsprint to bleached board to

fluff pulp for disposable diapers. To make newsprint, a mixture of mechanical and chemical pulps is fed into the paper machine. To make kraft paper (e.g., grocery bags, corrugated containers), however, only unbleached chemical pulp is used. Disposable diaper material and photographic paper require bleached chemical pulp with a very low moisture content of 6 to 9%.

Paper Machine Area

In papermaking, extensive air systems are required to support and enhance the process (e.g., by preventing condensation) and to provide reasonable comfort for operating personnel. Radiant heat from steam and hot-water sources and mechanical energy dissipated as heat can result in summer temperatures in the machine room as high as 120°F. In addition, high paper machine operating speeds of 2000 to 4500 fpm and a stock temperature near 122°F produce warm vapor in the machine room.

Outdoor air makeup units and process exhausts absorb and remove room heat and water vapor released from the paper as it is dried (Figure 2). Makeup air is distributed to working areas above and below the operating floor. Part of the air delivered to the basement migrates to the operating floor through hatches and stairwells. Motor-cooling equipment distributes cooler basement air to the paper machine drive motors.

Wet and basement exhaust should be installed inside the room. Outdoor air intakes with insulated adjustable louvers should be installed on the outside wall to supplement the mechanical air supply. In facilities with no basement exterior wall, sufficient mechanical air intake should be provided. The exhaust, adjustable louver, or mechanical air intake should be furnished with modulating control. When the ambient temperature drops to near freezing, outdoor airflow must be reduced to a minimum and the appropriate heater started to prevent freezing.

The most severe ventilation demand occurs in the area between the wet-end forming section and press section and the dryer section. In the forming section, the pulp slurry, which contains about 90% water, is deposited on a traveling screen. Gravity, rolls, foils, vacuum, steam boxes, and three or more press roll nips are sequentially used to remove up to 50% of the water in the forming section and press section. The wet end is very humid because of evaporation of moisture and mechanical generation of vapor by turning rolls and cleaning showers. Baffles and a custom-designed exhaust in the forming section help control the vapor. A drive-side exhaust in the wet end removes heat from the motor vent air and removes the process generated vapor.

To prevent condensation or accumulated fiber from falling on the traveling web, a false ceiling is used with ducts connected to roof

Fig. 2 Paper Machine Area

exhausters that remove humid air not captured at a lower point. At the wet end, heated inside air is usually circulated to scrub the underside of the roof to prevent condensation in cold weather. Additional roof exhaust may also remove accumulated heat from the dryer section and the dry end during warmer periods. Ventilation in the wet end should be predominantly by roof exhaust.

The large volume of moisture and vapor generated from the wet-end process rises and accumulates under the roof. To keep condensation from forming in winter, the roof is normally exhausted and hot air is distributed under the roof. Sufficient roof insulation should be installed to keep the inside surface temperature above the dew point. Heat transfer from the room to the interior surface is

$$\frac{t_r - t_{is}}{R_{r-is}} = \frac{t_{is} - t_o}{R_{is-o}} \tag{1}$$

where

- t_r = room air temperature, °F
- t_{is} = roof interior surface temperature, °F
- t_o = outdoor air temperature, °F
- R_{r-is} = heat transfer resistance from room air to roof interior surface. In winter, $R_{r-is} = 0.61 \text{ ft}^2 \cdot \text{F} \cdot \text{h/Btu}$
- R_{is-o} = required total R-value from roof interior surface to outdoor air, $\text{ft}^2 \cdot \text{F} \cdot \text{h/Btu}$

For a given project, t_o and t_r have been determined and only t_{is} needs to be selected. For wet-end roof insulation and assuming 96% relative humidity, t_{is} can be shown on a psychrometric chart to be

$$t_{is} = t_r - 1.2^\circ\text{F} \tag{2}$$

Then Equation (1) can be simplified to find the required roof R-value as

$$R_{is-o} = \frac{0.61}{1.2} (t_r - t_o - 1.2) \tag{3}$$

In the dryer section, the paper web is dried as it travels in a serpentine path around rotating steam-heated drums. Exhaust hoods remove heat from the dryers and moisture evaporated from the paper web. Most modern machines have enclosed hoods, which reduce the airflow required to less than 50% of that required for an open-hood exhaust. The temperature inside an enclosed hood ranges from 130 to 140°F at the operating floor to 180 to 200°F in the hood exhaust plenum at 70 to 90% rh, with an exhaust rate generally ranging from 300,000 to 400,000 cfm per machine.

Where possible, pocket ventilation air (see Figure 3) and hood supply air are drawn from the upper level of the machine room to take advantage of the preheating of makeup air by process heat as it rises. The basement of the dryer section is also enclosed to control infiltration of machine room air to the enclosed hood. The hood supply and the pocket ventilation air typically operate at 200°F;

Fig. 3 Pocket Ventilation

however, some systems run as high as 250°F. Enclosed hood exhaust is typically 300 cfm per ton of machine capacity. The pocket ventilation and hood supply are designed for 75 to 80% of the exhaust, with the balance infiltrated from the basement and machine room. Large volumes of air (500,000 to 800,000 cfm) are required to balance the paper machine’s exhaust with the building air balance.

The potential for heat recovery from hood exhaust air should be evaluated. Most of the energy in steam supplied to the paper dryers is converted to latent heat in the hood exhaust as water evaporates from the paper web. Air-to-air heat exchangers are used where the air supply is located close to the exhaust. Air-to-liquid heat exchangers that recirculate water/glycol to heat remote makeup air units can also be used. Air-to-liquid systems provide more latent heat recovery, resulting in three to four times more total heat recovery than air-to-air units. Some machines use heat recovered from the exhaust air to heat process water. Ventilation in paper machine buildings in the United States ranges from 10 to 25 air changes per hour in northern mills to 20 to 50 in southern mills. In some plants, computers monitor the production rate and outdoor air temperature to optimize operation and conserve energy.

After fine, bond, and cut papers have been bundled and/or packaged, they should be wrapped in a nonpermeable material. Most papers are produced with less than 10% moisture by weight, the average being 7%. Dry paper and pulp are hygroscopic and begin to swell noticeably and deform permanently when the relative humidity exceeds 38%. Therefore, finished products should be stored under controlled conditions to maintain their uniform moisture content.

Finishing Area

To produce a precisely cut paper that stabilizes at a desirable equilibrium moisture content, the finishing areas require temperature and humidity control. Further converting operations such as printing and die cutting require optimum sheet moisture content for efficient processing. Finishing room conditions range from 70 to 75°F db and from 40 to 45% rh. Rooms should be maintained within reasonably close limits of the selected conditions. Without precise environmental control, the paper equilibrium moisture content varies, influencing dimensional stability, the tendency to curl, and further processing.

Process and Motor Control Rooms

In most pulp and paper applications, process control, motor control, and switchgear rooms are separate from the process environment. Air conditioning removes heat generated by equipment, lights, etc., and reduces the air-cleaning requirement. (See Chapter 19 for air conditioning in control rooms that include a computer, a computer terminal, or data processing equipment.) Ceiling grilles or diffusers should be located above access aisles to avoid the risk of condensation on control consoles or electrical equipment during start-up and recovery after an air-conditioning shutdown. Electrical rooms are usually maintained in the range of 75 to 80°F, with control rooms at 73°F; the humidity is maintained in the range of 45 to 55% in process control rooms and is not normally controlled in electrical equipment rooms.

Motor and electrical control rooms for process and electrical distribution control contain electronic equipment that is susceptible to corrosion. The typical pulp and paper mill environment contains both particulate and vapor-phase contaminants with sulfur- and chloride-based compounds. To protect equipment, multistage particulate and adsorbent filters should be used. They should have treated activated charcoal and potassium permanganate-impregnated alumina sections for vapor-phase contaminants, as well as fiberglass and cloth media for particulates.

To ensure normal operation of air-conditioning systems, redundancy of supply fans, fan motors, and fan power supply in air-handling units that serve process control rooms and motor control centers is strongly recommended in new-construction plants.

Switchgear and motor control centers are not as heat-sensitive as control rooms, but the moisture-laden air carries chemical residues onto the contact surfaces. Arcing, corrosion, and general deterioration can result. A minimum amount of filtered, outdoor air and air conditioning is used to protect these areas.

In most projects, the electric distribution control system (DCS) is energized before the room air conditioning is installed and started. If a temporary air conditioner is used in the DCS room, a condensate drain pan and temporary drain pipe should be installed to keep condensate from the cable channel beneath the DCS panels.

Paper Testing Laboratories

Design conditions in paper mill laboratories must be followed rigidly. The most recognized standard for testing environments for paper and paper products (paperboard, fiberboard, and containers) is TAPPI (the Technical Association of the Pulp and Paper Industry) *Standard* T402. Other standards include ASTM E171 and ISO/TC 125.

Standard pulp and paper testing laboratories have three environments: preconditioning, conditioning, and testing. The physical properties of a sample are different if it is brought to the testing humidity from a high humidity than if it is brought from a lower humidity. Preconditioning at lower relative humidity tends to eliminate hysteresis. For a preconditioning atmosphere, TAPPI *Standard* T402 recommends 10 to 35% rh and 72 to 104°F db. Samples are usually conditioned in a controlled, conditioned cabinet.

Conditioning and testing atmospheres should be maintained at $50 \pm 2.0\%$ rh and $73 \pm 2^\circ\text{F}$ db. However, a change of 2°F db at 73°F without starting a humidifier causes the relative humidity to fluctuate as much as 3%. A dry-bulb temperature tolerance of $\pm 1^\circ\text{F}$ must be held to maintain a $\pm 2\%$ rh. A well-designed temperature and humidity control system should be provided.

Miscellaneous Areas

The pulp digester area contains many components that release heat and contribute to dusty conditions. For batch digesters, the chip feeders are a source of dust and need hooded exhaust and makeup air. The wash and screen areas have numerous components with hooded exhausts that require considerable makeup air. Good ventilation controls fumes and humidity. The lime kiln feed-end releases extremely large amounts of heat and requires high ventilation rates or air conditioning.

Recovery-boiler and power-boiler buildings have conditions similar to those of power plants; the ventilation rates are also similar. The control rooms are generally air conditioned. The grinding

motor room, in which groundwood is made, contains many large motors that require ventilation to keep the humidity low.

System Selection

The system and equipment selected for air conditioning a pulp and paper mill depends on many factors, including the plant layout and atmosphere, geographic location, roof and ceiling heights (which can exceed 100 ft), and degree of control desired. Chilled-water systems are economical and practical for most pulp and paper operations, because they have both the large cooling capacity needed by mills and the precision of control to maintain the proper temperature and humidity in laboratories and finishing areas. In the bleach plant, the manufacture of chlorine dioxide is enhanced by using water with a temperature of 45°F or lower; this water is often supplied by the chilled-water system. If clean plant or process water is available, water-cooled chillers are satisfactory and may be supplemented by water-cooled direct-expansion package units for small, remote areas. However, if plant water is not clean enough, a separate cooling tower and condenser water system should be installed for the air conditioning.

Most manufacturers prefer water-cooled over air-cooled systems because of the gases and particulates present in most paper mills. The most prevalent contaminants are chlorine gas, caustic soda, borax, phosphates, and sulfur compounds. With efficient air cleaning, the air quality in and about most mills is adequate for properly placed air-cooled chillers or condensing units that have properly applied coil and housing coatings. Phosphor-free brazed coil joints are recommended in areas where sulfur compounds are present.

Heat is readily available from processing operations and should be recovered whenever possible. Most plants have good-quality hot water and steam, which can be used for unit heater, central station, or reheat quite easily. Evaporative cooling should be considered. Newer plant air-conditioning methods, using energy conservation techniques such as temperature destratification and stratified air conditioning, have application in large structures. Absorption systems should be considered for pulp and paper mills because they provide some degree of energy recovery from the high-temperature steam processes.

--	---

THIS chapter discusses HVAC systems for industrial facilities for the production of process heat and power and for electrical generating stations and transmission facilities. Not every type of power plant is specifically covered, but the process areas addressed normally correspond to similar process areas in any plant. For example, wood-fired boilers are not specifically discussed, but the requirements for coal-fired boilers generally apply. Aspects of HVAC system design unique to nuclear power plants are covered in Chapter 28.

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), the American National Standards Institute (ANSI), the facility’s insurance carriers, and authorities having jurisdiction (AHJs). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

1. GENERAL DESIGN CRITERIA

Space-conditioning systems in power plant buildings are designed to maintain an environment for reliable operation of power generation systems and equipment and for the convenience and safety of plant personnel. A balance is achieved between the cost of the process systems designed to operate in a specified environment and the cost of providing HVAC to modify or condition the environment.

Environmental criteria for personnel safety and comfort are governed by several sources. The U.S. Occupational Safety and Health Administration (OSHA) defines noise, thermal environment, and air contaminant exposure limits. Chapters 14 and 31 of this volume and *Industrial Ventilation* by the American Conference of Governmental Industrial Hygienists (ACGIH 2013) also provide guidance for safety in work spaces, primarily in the areas of industrial ventilation and worker-related heat stress. Worker comfort is somewhat subjective and more difficult to quantify. The plant owner or operator ordinarily establishes the balance between cost and worker comfort.

Exhaust vents are subject to regulation of the plant’s air quality permit and local air pollution control board’s requirements. For this reason, all exhaust vent locations should be properly identified and classified, and coordinated with the plant’s environmental compliance permits. Treatment of exhaust streams is discussed in Chapter

30 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*.

Criteria should be clearly defined at the start of design, because they document an understanding between the process designer and the HVAC system engineer that is fundamental to achieving the environment required for the various process areas. Typical criteria for a coal-fired power plant are outlined in Table 1. Review criteria for compliance with local codes, the plant operator’s experience and preferences, and the facility’s overall financial objectives. Additional discussion of criteria may be found in the sections on specific areas.

Temperature and Humidity

Selection of outdoor design temperatures is based on the operating expectations of the plant. If the power production facility is critical and must operate during severe conditions, then the effect of local extreme high and low temperatures on the systems should be evaluated. Electrical power consumption is usually highest under extreme outdoor conditions, so critical areas of the plant should be designed to operate when needed the most. Other noncritical-area temperature ranges, indicated in Table 1, may be more appropriately less stringent. A starting point for establishing design weather conditions for extreme conditions (typically defined on a 5, 10, or 20 year recurrence interval) and design (99.6% and 0.4% conditions) can be found in Chapter 14 of the 2013 *ASHRAE Handbook—Fundamentals* and on the CD accompanying that volume.

Indoor temperatures should match the specified operating temperatures of the equipment. Electrical equipment, such as switchgear, motor control centers, and motors, typically determines the design temperature limits in the plant; common temperature ratings are 104 or 122°F. Other areas such as elevator machine rooms may include electronic equipment with temperature restrictions.

In plant areas where compressed-gas containers are stored, the design temperature is according to the gas supplier. Typically, the minimum temperature should be high enough that the gas volume can be effectively released from the containers. If the gas is hazardous (e.g., chlorine), the minimum temperature does not apply during personnel occupancy periods, when high dilution ventilation rates are needed.

Practical ventilation rates for fuel-fired power plants provide indoor conditions 10 to 20°F above the outdoor ambient. Therefore, ventilation design criteria establish a temperature rise above the design outdoor temperature to produce an expected indoor temperature that matches the electrical equipment ratings. For example, an outdoor extreme design temperature of 112°F with a ventilation system designed for a 10°F rise would meet the requirements of 122°F-rated plant equipment. Because excursions above selected design outdoor air temperature are often brief (e.g., 2 to 3 h), the effect on room temperature is minimal. In addition, the electrical equipment

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

^hLower criteria should be considered for occupied substations.

temperature ratings are associated with design life, not sudden failures. Carefully evaluate extreme temperatures for their duration and discuss them with the electrical system designer before adopting the design. In hot climates where outdoor temperatures may cause indoor temperatures to exceed electrical equipment ratings for extended periods, evaporative cooling or air conditioning of electrical equipment areas may be required to hold temperatures below the equipment design values. When high area temperatures are possible, the environment for plant maintenance workers should also be considered. Velocity (spot) cooling may be necessary in some areas to support work activities.

Low temperatures may affect plant reliability because of the potential for freezing. Selection of the low design temperature should be balanced by selection of the heating design margin. If the record low temperature is used in the design, indoor design temperatures of 35 to 40°F may be used. In the heating system design, credit is generally not taken for heat generated from operating equipment.

The selection of outdoor design humidity levels affects the selection of cooling towers and evaporative cooling processes and the sizing of air-conditioning coils for outdoor air loads. When values from Chapter 14 of the 2013 *ASHRAE Handbook—Fundamentals* are used for design, the mean coincident wet bulb is appropriate. If extreme dry-bulb temperatures are selected for the design basis, the use of extreme wet bulbs is too restrictive because the extremes are not coincident. It is prudent to use the wet bulb associated with the 1% dry bulb when extreme dry-bulb temperatures are used for the design.

Indoor design humidity is not a factor in ventilated areas unless the plant is in a harsh, corrosive environment. In this case, lower humidity reduces the potential for corrosion. In air-conditioned areas for personnel or electronic equipment, ASHRAE *Standard* 62.1, Instrumentation, Systems, and Automation Society (ISA) *Standard* 71.04, and manufacturers' recommendations dictate the humidity criteria.

Ventilation Rates

Ventilation within plant structures provides heat removal and dilution of potentially hazardous gases. Ventilation rates for heat removal are calculated during HVAC system design to meet summer indoor design temperatures.

The numbers in Table 1 for air change rates are for estimating approximate ventilation needs. Actual heat emission rates should be obtained from equipment manufacturers, White and Piescorovsky (2010), or from the engineer's experience. American Boiler Manufacturer's Association (ABMA) heat loss curves (Stultz and Kitto 2005) can be used to approximate heat loads from boiler casings if better information is not available.

The ventilation rate for room heat removal is

$$Q = \frac{q}{(t_r - t_o)(60\rho c_p)} \quad (1)$$

where

- Q = ventilation rate, cfm
- q = room heat, Btu/h
- t_r = suggested room temperature from Table 1, °F
- t_o = outdoor air temperature, °F
- ρ = air density, lb_m/ft³
- c_p = specific heat of air = 0.24 Btu/lb_m·°F

Hazardous gases are mostly handled by the process system design functions. Natural gas and other combustible fuel gases are controlled by ignition safeties and may contain odorants for detection. Hydrogen and other gases used for generator and bus cooling are monitored for leakage by pressure loss or makeup rates. Escaped gases are diluted by outdoor air infiltration. For a building with very

tight construction (i.e., very little natural infiltration), perform an analysis to verify that dilution rates are acceptable.

Flue gas is confined to the boiler and flue gas ductwork and generally poses no hazard. In some types of boilers and associated gas ducts, however, flue gas is at a higher pressure than the surroundings and can leak into occupied areas. Also, special-treatment gases such as ammonia or sulfur compounds encountered in flue gas conditioning systems can leak into the boiler building, depending on the location of the treatment device in the flue gas stream. In these cases, gas detection monitors should be used.

Ventilation for areas with hazardous gases (e.g., chlorine) should be designed by specific gas industry standards such as *The Chlorine Manual* (CI 1997) or ACGIH (2013).

Infiltration and Exfiltration

Infiltration of outdoor air into boiler and power-generation structures or exfiltration of room air from these buildings is driven by thermal buoyancy of heated air. Both infiltration and exfiltration are beneficial; infiltration air dilutes fugitive fumes, whereas exfiltration air carries out excess heat during hot weather. However, infiltration adds to the cold-weather load on the heating system.

Filtration and Space Cleanliness

Filtration of ventilation air for process areas is usually not needed because some process areas are dirtier than the outdoor surroundings, and the process equipment is designed to operate in a dusty environment. However, the plant may be located in an area with sources of outdoor particulate contaminants that need to be managed to protect the process equipment. Power plants in dusty or sandy areas, or where there are seasonal nuisances such as airborne plant matter, may require filtration of ventilation air. Plants at industrial sites such as refineries and paper mills may need to address gaseous contaminants and corrosive gases, as well.

Indoor air cleanliness is a concern in control room HVAC system design. Even if the control center is in an independent building, remote from the boiler-turbine building, other operations such as coal transportation, coal crushing, fuel/air distribution and combustion, ash handling, fume heat recovery, fume/smoke exhaust diffusion, and so forth may contaminate the entire plant and its surroundings.

When potential outdoor contaminants are a factor, the quality of outdoor air may need to be evaluated. This may include collection of typical particulates and the use of corrosion coupons to quantify gaseous contaminants. The U.S. Environmental Protection Agency (EPA) is a good data source. Filtration requirements may include 30% dust-spot test efficiency prefilters, 65 to 90% efficiency final filters, and gas-phase filtration units.

Air-conditioned areas for people should satisfy ASHRAE *Standard* 62.1 requirements. Air-conditioned areas for control and electrical equipment should meet the requirements of the equipment manufacturer(s). Guidelines for reliability of electrical equipment are found in ISA *Standard* 71.04.

Redundancy

Maintaining design operating temperatures in the power plant is essential for reliable operation. Operating electrical equipment above its rated temperature reduces equipment life. Sensitive electronic equipment, such as in the main control center, may not function reliably at high temperatures. Low temperatures also affect plant availability; for example, low temperatures in batteries or freezing of pipes, instrument lines, or tanks could prevent normal plant operation.

The HVAC systems or components essential for plant operation should be designed with redundancy to ensure plant availability. Automatic switchover to the back-up system may be required in normally unoccupied areas. Where back-up systems are impractical,

consider using temperature monitoring and alarming systems to initiate temporary corrective measures.

HVAC systems that include multiple units (indicated as “multiplicity” in Table 1) also improve power plant reliability. A space ventilated by multiple fans, such as four at 1/4 capacity, may retain sufficient ventilation even if one fan is out of service.

Noise

Pay attention to noise levels produced by HVAC system equipment both inside and outside plant spaces, and establish indoor noise guidelines for air-conditioned areas and ventilated areas with continuous occupancies. Outdoor noise levels are established by the environmental noise pollution concerns of adjacent areas.

Air-conditioned indoor spaces should meet the normal sound level guidelines for occupancies (e.g., offices) listed in Chapter 48. Special occupancies such as control rooms should follow the guidelines in Table 1.

Ventilated areas of the plant should be treated as other industrial areas following OSHA regulations. Sound levels in Table 1 are suggested guidelines that may be appropriate in the absence of a specific engineered solution to meet the OSHA requirements. Where “background” is indicated in Table 1, noise generated by HVAC equipment is usually not a major noise source in comparison to the noise from processes or equipment such as turbine generators, motors, pumps, and relieving of process steam. In these areas, overall noise level criteria are established by the process equipment requirements.

HVAC system components contribute to the overall noise level outside the plant buildings either by generating noise or by having ventilation openings. HVAC designs for power plants in urban areas can be significantly influenced by outdoor noise level requirements. Equipment may have to include sound-absorbing materials or be located indoors in sound attenuation enclosures. Openings may require acoustical louvers.

Ductwork and Equipment Location

All outdoor HVAC equipment should be secured to foundations or structures to prevent being blown into transmission and other equipment in the event of high winds. In addition, ductwork and equipment in the room should be adequately supported and restrained to prevent collateral damage to the switching equipment by failed HVAC equipment/ductwork in the event of an earthquake or similar event, following local codes and plant design criteria. Preventing damage from dripping/overflowing condensate or other water sources should also be considered. Also, where possible, equipment and system components must meet CAN/CSA *Standard* C2.1 and NFPA *Standard* 70 guidance for minimum distance from energized transmission equipment to ensure adequate separation from energized equipment and power lines.

2. VENTILATION APPROACH

Summer ventilation can be achieved by natural draft, forced mechanical supply and exhaust, or natural and mechanical combined systems. **Natural-draft systems** use a combination of adjustable inlet louvers and open doors or windows and relieve warmed air through roof or high side-wall openings. **Mechanical systems** use fans, power roof ventilators (PRVs), or air-handling units to move air. A **combined system** typically uses lower and upper wall and roof openings for natural ventilation while using mechanical ventilation as a supplement. With any ventilation arrangement, maintain physical separation of inlet and outlet openings to minimize recirculation, as discussed in Chapter 24 of the 2013 *ASHRAE Handbook—Fundamentals*.

3. APPLICATIONS

Large plants or units with layouts containing large ducts and equipment in the ventilation airflow path, possibly with limited

separation between pieces of major equipment and/or exterior walls, imposing a pressure drop exceeding the capability of gravity ventilation systems, require mechanical assistance. The plant design may have cavities, such as the area under the boiler arch and between the casing and flue gas duct (see Figures 1 and 2), which require mechanical ventilation. Areas of the plant such as the conveyor gallery usually require mechanical assistance in the makeup air system to ensure pressurization control and proper functioning of dust collectors and associated equipment.

Natural or gravity systems are appropriate for facilities without basements and with relatively open airflow paths. The pressure drop of intake louvers, control dampers, powerhouse airflow path, and exhaust louvers/gravity vents should not exceed the minimum expected buoyancy forces. Be sure to configure the system so as not to interfere with mechanical dust collection equipment.

In any system configuration, the engineer should ensure all areas of the plant are provided airflow. Air intakes and supply ducts/fans should be located to prevent short-circuiting with relief openings. Ventilation air should be supplied to electrical boards and other equipment located in upper elevations of the plant, because these areas are usually significantly hotter than the lower elevations.

Driving Forces

Natural ventilation systems use the thermal buoyancy of the air as the motive force for air movement through a building. Equations for determining differential pressures for natural ventilation are found in Chapter 16 of the 2013 *ASHRAE Handbook—Fundamentals*. With natural ventilation, air enters the enclosed space and is heated by the plant equipment. The difference in density between the inside air and the outdoor air causes air to be drawn into the building at low elevations and relieved at high elevations.

Mechanical ventilation depends on fans (or fans and buoyancy forces) to provide required ventilation regardless of the building configuration or the temperature difference.

Air Distribution

With natural ventilation, small differential pressures drive air movement. Accordingly, air is drawn into the building at low velocities; it penetrates a short distance into the building and then disperses.

Mechanical ventilation supplied from the walls or roof can distribute air more effectively throughout the structure.

A combined system uses both natural and mechanical ventilation to achieve effective air distribution and prevent air stagnation. A typical combined system uses lower-level sidewall openings as the primary natural air intake and roof or upper-level sidewall openings for hot-air relief. The location and size of openings can prevent hot-air accumulation under the roof naturally. Provide mechanical ventilation where sufficient airflow cannot be established.

Inlet and Exhaust Areas

Because of the low differential pressure driving the air, natural ventilation requires numerous large inlet louver and exhaust relief areas. Mechanical ventilation requires fewer openings.

Noise

Openings required for natural ventilation allow noise generated by indoor plant equipment to pass more easily to the outdoors.

Mechanical equipment such as fans and PRVs generate noise directly, but the noise level can be managed by fan selection and acoustical treatment.

Plant Cleanliness

Natural ventilation creates negative pressure in the lower portions of the building, which may draw dust and fumes into the building through openings near ground level.

Mechanical ventilation can pressurize the building and can draw air from relatively clean sources at higher elevations.

Economics

The primary advantage to natural ventilation is that there are no operating costs for fan power. Because natural ventilation is passive, it is more reliable and has lower maintenance costs than a mechanical system. However, natural ventilation may not always be the most economical selection. The cost of louvers and inlet openings, architectural features, and gravity relief openings to achieve an acceptable ventilation rate may be higher than the first cost for mechanical ventilation.

Another consideration is the average building temperature. Because internal heat is the driving force, the naturally ventilated building is normally warmer than the power-ventilated building. This warmer average temperature may shorten the life of plant equipment such as expansion joints, seals, motors, electrical switchgear, and instrumentation. Warmer temperatures may also affect operator performance.

The large louver areas associated with natural ventilation may allow greater infiltration, thereby increasing the winter heating load. This additional heating cost may offset some of the summer energy savings of natural ventilation.

A combined system takes on the strengths of both natural and mechanical ventilation and can offer the advantages of reduced capital and operating costs.

4. STEAM GENERATOR BUILDINGS: INDUSTRIAL AND POWER FACILITIES

A steam generator uses heat energy to convert water to steam. The two basic subsystems of a steam generator are the heat energy system and the steam process system.

The heat energy system for a fueled (oil, gas, coal, etc.) steam generator includes fuel distribution piping or conveyors, preparation subsystems, and supply rate and ignition controls. Provision to supply and regulate combustion air is required at the combustion chamber; flue gas is handled downstream of the combustion area. With ash-producing fuels, bottom ash below the steam generator and fly ash entrained in the flue gas must be processed. Figure 1 shows a steam generator building with typical components.

Steam process components typically found in the steam generator building include an enclosure for the fire and heat transfer surfaces and feedwater equipment such as pumps, piping, and controls. Steam lines for primary and reheat steam are typically routed from the steam drum and reheat sections of the steam generator to the steam turbine or process systems.

The heat energy and steam process systems impose requirements on the HVAC systems for specific areas of the steam generator building.

Burner Areas

Fuel (gas, oil, coal, etc.) is transferred to the furnace, mixed with combustion air, and ignited in the burner area of the steam generator. Instrumentation must modulate the fuel in response to combustion needs. Viewports typically allow operators to monitor combustion. In many cases, these viewports are equipped with aspirating air systems to limit the amount of flue gas and heat escaping the boiler and entering the boiler room.

The burner area requires special attention for the steam generator building ventilation system. This area is often occupied by plant operators who monitor and inspect the controls and the combustion process. Heat is radiated and conducted to adjacent spaces from inspection ports, penetrations, and the steam generator. Fumes and combustion gases also can leak.

Both the burner area operator and the controls require ventilation with outdoor air. Outdoor air also provides dilution for fugitive

fumes. Outdoor air can be ducted to burner areas and discharged by supply registers or blown directly into the area with wall-mounted fans, depending on the building arrangement. The flow rate is difficult to quantify; generally, 60 air changes per hour (ach) supplied to an area 15 to 20 ft around the steam generator provide adequate ventilation. Consider providing velocity cooling of personnel workstations. In cold climates, outdoor air may need to be tempered with indoor air.

Steam Drum Instrumentation Area

A typical steam generator has a steam drum at the top of the boiler that provides the water-to-steam interface. The water level in the drum is monitored to regulate the flow of steam and feedwater. This is a critical steam generator control function, so accurate and reliable process flow measurement is important.

The steam drum instrumentation area may include sections of uninsulated furnace surface, which conducts and radiates heat to the surrounding area. The ventilation system should remove this heat to ensure that area temperatures are within instrumentation temperature limits. Instrumentation may need to be shielded from hot surfaces. Velocity cooling may be needed at operator workstations.

Wall-mounted panel fans in the outer walls are an option for providing ventilation air during warm weather. Heating is generally not a concern unless the steam generator is expected to be out of service during cold weather.

Once-through steam generators do not have drums, but have instrumentation in similar high-temperature, dusty areas.

Local Control and Instrumentation Areas

In addition to the drum and burners, the steam generator building may house local control areas for functions such as fuel supply, draft fans, or ash handling. Because areas around a steam generator may be hot and dirty, the location and selection of the control equipment should be coordinated between the electrical system engineer and the HVAC system engineer.

The alternatives are to (1) locate the control equipment remotely from the steam generator, (2) use electrical components that can withstand the environment, or (3) provide a local environmentally controlled enclosure. The first alternative requires additional cable and raceway and perhaps additional signal boosters and conditioners. The second alternative requires more robust electrical equipment that can tolerate extremely hot or dirty areas.

When the electrical and control system design dictates that the equipment be located near the steam generator, a dedicated enclosure with a supporting environmental control system may be necessary. A typical environmental control system may control an air-handling unit capable of providing adequate filtration, pressurization, and temperature control. The temperature control may be obtained with a chilled-water or direct-expansion (DX) coil with a remote condensing unit. An air-cooled condensing unit may be used if it is rated to match the surroundings.

Coal- and Ash-Handling Areas

Coal is typically stored on site, either in piles or in storage structures, including semienclosed, fully enclosed, and underground storage facilities. Material-handling equipment moves the coal to conveyors for transportation to preconditioning equipment (e.g., a crusher). Processed coal is conveyed to steam generator building storage silos. Coal feed equipment regulates the supply of coal from the silos either to the burner or to final processing equipment such as pulverizing mills.

Many new power plants are designed to burn low-cost coals from Wyoming's Powder River Basin and other similar coal seams. Many of these coals are extremely friable when dry, creating significant amounts of dust during handling. In new plants, the material handling and ventilation systems should be designed to control dusting,

Fig. 1 Steam Generator Building
(Courtesy The Babcock & Wilcox Company)

preferably by using modern chutework and coal-handling machinery design to reduce or control dust emissions during fuel handling. This can reduce the effects of mechanical dust collectors and associated makeup air on plant HVAC systems.

Some coals spontaneously begin to burn during normal outdoor ambient weather and normal powerhouse interior conditions. Under some conditions, accumulated coal dust spontaneously smolders, then suddenly flashes if the surface crust of the pile is broken, exposing the smoldering coal to oxygen. It is important that equipment in areas subject to dust accumulation be designed to reduce dust accumulation with sloped or curved surfaces, and designed to facilitate manual cleaning and washdown. Spontaneous combustion must be addressed in ventilation and dust collector design and installation to facilitate emptying dust out of the collector without exposing plant personnel to fire and explosion hazards.

Coal-handling areas in the steam generator building that require special ventilation system consideration are the conveyor, silo, feeder, mill, and their transition areas, and ash-handling areas.

Conveyor Areas. Primary concerns are dust control, outgassing from the coal, freezing of the coal and personnel access areas, and fire protection. Dust can be a concern because of the potential for environmental emission and also as a personnel and/or explosive hazard. Dust may be controlled by water-based spray systems or by air induction pickups at the point of generation. Some types of coal may outgas small quantities of methane, which could accumulate in the conveyor and storage structures. See the section on Coal Crusher and Coal Transportation System Buildings for a discussion of ventilation of methane fumes.

Natural or forced ventilation must remove heat from conveyor motors, other equipment, and building envelope loads. Ventilation air can also remove outgassed fumes. Generally, ventilation requirements can be as low as 2 to 5 ach. If air entrainment dust collection equipment is used, include provisions for makeup in the design. If natural openings are not sufficient for makeup air, supply ventilation fans may need to be electrically interlocked to operate with the dust suppression/collection equipment. Makeup air may have to be

heated if freeze protection is a design criterion. Unit heaters are generally used for spot heating. The unit heater should be specified to the hazard classification for the area it serves. Because coal dust can produce acids when wet, consider specifying noncorrosive materials and coatings.

NFPA *Standard* 120 and the U.S. Bureau of Mines (1978) provide other safety considerations for coal handling and preparation areas.

Silo and Feeder Areas. Coal is generally fully contained by feeders and silos, so no special ventilation is needed. Occasionally, coal systems include an inert gas purge system for fire prevention. Ventilation may be needed for life safety dilution ventilation of purge gases.

Coal Mill Areas. Coal mills require large power motors for the grinding process. These motors may have their own ventilation system, or the motor heat may be rejected directly to the surrounding space.

The challenge for the ventilation system is to provide enough ventilation to remove heat without creating high air velocities that disturb accumulated dust. Blowing dust can pose health risks to operators and create a dust ignition hazard. Although occurrence of dust ignition air-to-dust ratios is possible, this area is generally not classified as hazardous. The dust ignition risk is managed by house-keeping, maintenance of seals on the mill equipment, and other dust-control measures.

Forced supply ventilation is generally required for equipment cooling. Sidewall propeller fans work well if the mills are arranged near outer walls. Mills located in the interior of the building may require ducted supply air. Supply air velocities at the coal-handling equipment must be lower than the particulate entrainment velocity for the expected dust size. The maximum air velocity is established using the particle size distribution spectrum and the associated air settling velocities indicated in Figure 3 and Table 1 in Chapter 11 of the 2013 *ASHRAE Handbook—Fundamentals*.

Many utilities use carbon monoxide (CO) monitoring/trending to detect fires in coal bunkers, silos, and other areas. These systems are sometimes integrated with dust collector and other exhaust streams in these areas. Specification and design of the CO monitoring should be the responsibility of a special hazards fire protection engineer and coordinated with the industrial ventilation and HVAC design.

The National Fire Protection Association (NFPA) does not differentiate between coal types/seams in the codes and standards. The utility industry, however, has accumulated experience and established best practices in handling these fuels. This information is shared between member utilities through groups such as Edison Electric Institute and Electric Power Research Institute. Other sources of specific requirements include local fire code authorities and the plant's insurance carrier.

Ash-Handling Areas. Ash is generated when coal or heavy fuel oil is burned. Fine ash particles carried by the flue gas from the top of the steam generator are called **fly ash**. Ash that accumulates as slag in the bottom of the steam generator is called **bottom ash**.

Ash-handling equipment generally demands no special HVAC system consideration. Although fly ash is captured in the flue gas stream by a baghouse or electrostatic precipitator, uncaptured (fugitive) fly ash can create problems in equipment mechanisms because of its abrasiveness. If fugitive fly ash is expected to be in the air, HVAC equipment in the ash-handling areas should include filters to capture the ash before it enters building areas.

Stack Effect

One consideration in HVAC system design for a steam generator building is the stack effect caused by buoyancy of heated air. A 300 ft tall steam generator building with 0°F outdoor air temperature and 100°F indoor air temperature may have 0.5 in. of water negative

internal pressure at ground level. This high level of negative pressure causes abnormally large forces on doors, creating a hazard for operators.

Sources of Combustion Air

Large-draft fans supply combustion air for the steam generator. A positive-pressure steam generator is supplied by forced-draft fans, and a negative-pressure steam generator uses induced-draft fans. A balanced-draft steam generator, typical for a larger unit, uses both forced- and induced-draft fans. Because the air is heated to furnace temperatures in the combustion process, part of the fuel energy is used to heat the air. Forced-draft fans on a large steam generator can supply 100,000 cfm or more to the combustion process. A significant amount of energy is needed to preheat the combustion air.

Two prevailing methods of preheating combustion air are used. One method is to draw air in from outdoors and heat it using steam or hot-water coils using energy directly from the power cycle. Another method uses heat rejected from steam generator surfaces to the building space to heat combustion air. This approach provides energy savings over heating outdoor air. Temperatures in higher levels of the generator building can be 100°F or higher. Heat recovery is accomplished by locating the draft fan intake high in the building. Although the potential for savings is large in a cold climate, the total effect on building heating and ventilation systems should be evaluated. One effect is that drawing the air from the building makes the building pressure more negative; this increases infiltration and adds to the building heating system load, possibly offsetting the potential power cycle thermal efficiency advantage. Increased negative pressure can also contribute to stack effect problems associated with negative pressure low in the building. The draft fan can also be used to supplement ventilation during warm outdoor conditions.

5. TURBINE GENERATOR BUILDING

As shown in Figure 2, a turbine generator building usually includes a high-bay operating level, a deaerator mezzanine, and one or more suboperating levels. Typically, the turbines and electric generators are located along the centerline of the building between the operating level and the first suboperating level and are the major heat sources in the building. Deaerators are another significant heat contributor; the deaerator mezzanine is commonly open to the turbine operating level. Other room heat sources are steam, steam condensate and hot-water piping, heat exchangers, steam valve stations and traps, motors, electric transformers, and other electrical equipment.

Local Control and Instrumentation Areas

Some power plants include a local turbine-generator control panel on the operating floor. The local control panel area of the turbine generator may be either enclosed or open; for the enclosed arrangement, the environmental requirements are the same as those given in the Main Control Center section.

For an open arrangement, velocity cooling with conditioned air improves the operator's working environment. Because the area may be directly exposed to high-temperature surroundings, the recommended velocity of the conditioned air discharge is 300 to 600 fpm, depending on its service distance and workers' preference. The air distribution system should have manually adjustable air deflectors for operator comfort. In addition, the control panel may need a separate cooling source.

Deaerator Mezzanine

The deaerator and associated storage tank reject significant heat at the deaerator mezzanine level. This plant area also typically includes

Fig. 2 Generation Building Arrangement
(Courtesy Black & Veatch Corporation)

instrumentation and control equipment enclosures; accordingly, the area should have local ventilation to provide the necessary cooling.

Bridge Crane Operating Rooms

Outdoor air entering the building is heated by process heat, rises toward higher elevation, and is relieved through openings. The bridge crane operating room is as high as the roof beam and within the building exhaust airstream. If the outdoor air temperature is 95°F, the crane operating room may be surrounded by 105°F or hotter air. Hence, the bridge crane operating room is normally air conditioned.

Because the bridge crane operating room moves within the building during its operation, through-the-wall mounted air conditioners are commonly used; to simplify the electrical work, an additional power plug in the crane for the air conditioner should be provided by the crane supplier. Include provisions for the cooling-coil condensate drain in the design.

Suboperating Level

The turbine generator is located on the operating floor, a large deck surface open to the turbine building roof. The deck may be 70% or more of the turbine building area. Below the operating level are one or more suboperating levels. Ventilation supply air should be provided to the suboperating levels and at the lower elevations of the operating floor. Air rising through the operating levels brings room heat to the roof area, where it is relieved through high-elevation openings (gravity vents) or exhausted by roof-mounted exhaust fans or PRVs.

The major heat sources in the suboperating levels are high-temperature mechanical and piping systems. Other contributors are electric transformer room exhaust, switchgear room exhaust, electric reactor room exhaust, electric motor heat, etc. Electrical equipment exhaust heat in the turbine generator building is small compared to heat emitted from mechanical and piping systems. Accordingly, ventilation air from the plant distribution electric

room can generally be exhausted directly into the turbine building without ducting to the outdoors. Conditioned air may be supplied to local instrumentation panel areas.

For plants in cold climates (temperatures below 32°F), consider spot heating and/or exterior door heated-air curtains. Also consider providing freeze protection for piping close to building walls; stack effect and wind-driven infiltration can increase local heating requirements at the building perimeter. This problem can be addressed by adding capacity to installed heating systems or by providing mobile, temporary heating.

Electric Transformer Rooms

Transformer rooms are typically located at a suboperating level between the turbine building and steam generator buildings. To isolate dust, the transformer rooms should not have inlet openings to the steam generator building.

The transformer room exhaust air temperature should not exceed the design limit of the transformers. Typically, air intake is from a turbine building suboperating level or from outdoors, and exhaust air discharges at the higher level of the transformer room toward the turbine building.

Plant Electrical Distribution Equipment and Switchgear/MCC Rooms

Air for the main station switchgear and motor control center (MCC) rooms should be relatively clean. Supply air from outdoors should be filtered with MERV 6 (30% efficiency) air filters. Air can be relieved through louvers into the plant or to the outdoors.

A similar approach is used for the ventilation system for an electric reactor room. If the reactors have ducted connections for the exhausts, a removable section may be required so that the ducts can be disassembled when the reactor is lifted during maintenance.

Isophase Bus Duct Cooling

Power from the generator is conveyed by isophase bus ducts to the main transformer. This generates heat, which must be dissipated to a heat sink. A specialized forced-air system cools the isophase bus duct and consists of cooling coils, fans, dampers, and filters. For a low-velocity system, air is supplied to the cooler along two phases of the bus duct and returned in the third phase. For a higher-velocity system, air is supplied and returned midway between the transformer and generator, or is supplied at the generator end along bus ducts of all three phases and returned at the transformer end. Iso-phase bus cooling is essential for power production and delivery, so it is important to specify sufficient redundancy (in the form of dual fans, dual cooling coils and a bypass duct to provide cooling with outdoor air, or another source) in the system design.

6. COMBUSTION TURBINE AREAS

Combustion turbines are adaptable for outdoor or indoor installation. The outdoor type is usually a skid-mounted structure, with support systems typically designed and furnished by the combustion turbine vendor. The indoor type is typically enclosed in a weatherproof and acoustically treated enclosure and may have indoor support systems, designed and installed separately.

Combustion turbine installations have some or all of the following support facilities: fuel oil handling facility, natural gas pressure-reducing facility, office or administration areas, maintenance shops, battery rooms, control rooms, distributed control system (DCS) control room, communication or computer room, and a water treatment facility. Heating and ventilation design issues associated with combustion turbines include airflow, combustion air source, hot duct and equipment surfaces, fuel supply, turbine inlet cooling, noise, etc.

The turbine manufacturer typically establishes HVAC requirements and, if required by the purchaser, provides HVAC equipment for the various compartments on the turbine skid. Turbine ventilation and equipment requirements should be coordinated with the building ventilation design.

Turbine and generator casings and the surface of the exhaust duct are large contributors to the heat removal requirements. Insulate hot surfaces with appropriate materials as much as is practical and with approval of the turbine manufacturer, with appropriate airflow established to eliminate hot spots.

When heat recovery equipment is installed in the turbine exhaust, allow for the additional heat rejected into the building because of increased back pressure on the hot exhaust.

Airflow through the combustion turbine building should consider combustion air requirements, combustible gas dilution requirements based on design leakage rates, heat removal requirements, exhaust gas dilution, and electrical component cooling requirements. Combustion turbines draw combustion air through ducts from outside the building. The system design should ensure control of the building pressurization to keep the building under positive pressure, and building outdoor air should be filtered. This also offsets infiltration of dust, rain, snow, bugs, and other contaminants into the building. System design should address freeze protection for vulnerable components. For cold-climate applications during normal operation, mixing outdoor and building air to keep the outdoor supply air temperature above freezing is recommended. In electrically classified installations, the ventilation system must switch to 100% outdoor air during upset conditions.

Noise from combustion turbines is managed by a combination of site location considerations, acoustic enclosures; sound attenuation devices and engineered sound controls include those that are part of HVAC systems.

HVAC design requirements for various areas of the building or turbine skid are in Table 1. The design should use NFPA standards

such as 37, 70, and 90A; insurance carrier requirements; and applicable local codes and standards. Coordinate HVAC system design and operation with fire protection systems to ensure adequate concentration of fire suppressant and to prevent fire and smoke spread. HVAC systems also must shut down when fire or extremely high concentrations of gases are detected.

7. MAIN CONTROL CENTER

The main control center usually includes a control room, electronic and electric control panel and instrumentation rack room, computational equipment server room, automation process control system room, telecommunications equipment room, battery room, UPS room, engineer and operator training simulation room, and associated administration areas.

Because the control center usually contains temperature-sensitive electronic equipment critical to plant operation, it is generally provided with redundant air-handling units and refrigeration equipment. A back-up power supply may also be required. Passive components such as distribution ductwork and piping do not have to be duplicated. Design controls so that failure of a component common to both the primary and back-up systems does not cause failure of both systems; manual changeover is a simple solution. If the main control building is located in a fly-ash-contaminated area, room pressurization is highly recommended.

Control Rooms

The control room houses the microprocessor, printer, electronic and emergency response controls, fire protection controls, communication and security systems, regional system networks, accessories, and relevant wiring and tubing systems. An air-conditioning system typical for office occupancy, with features to meet overall design requirements for reliability and the specific environmental needs of the control equipment, is generally appropriate.

Battery Rooms

Battery rooms should be maintained between approximately 70 and 80°F for optimum battery capacity and service life. Temperature variations are acceptable as long as they are accounted for in battery sizing calculations, but the minimum room design temperature should be considered in determining battery capacity. Batteries typically used in power generation facilities produce hydrogen gas, so the HVAC system must be designed to limit the hydrogen concentration in the room. See ASHRAE *Guideline 21-2012* for methods of estimating hydrogen generation by various battery types and operating modes and optimizing the design of the ventilation system. That guideline also recommends a maximum average concentration in the room of <2% by volume; however, the designer should review applicable codes and standards required by the AHJs for potentially more conservative requirements.

8. SUBSTATION AND SWITCHYARD CONTROL STRUCTURES

Substations and switchyards increase electricity voltage from the power plant generator output voltage to transmission-level voltage, and regulate power for distribution levels. These facilities are generally located remotely, so their HVAC design should be simple, reliable, and easy to maintain.

Design Considerations

The design of the HVAC, filtration, and pressurization system should be based on the type of equipment in the room and its sensitivity to dust, smoke, temperatures, and humidity. Considerations include reliability, simplicity, and low installation and maintenance costs. ANSI/IEEE *Standard C2* addresses HVAC requirements. If the substation control building is occupied, typical human comfort

conditions for office areas (see Table 1) are adequate; otherwise, temperature limitations and humidity control protect equipment in the room. Filtration with MERV 7 or 8 efficiency filters protects equipment from dust and prolongs its life. If the substation control building is located in a heavy industrial area or near a chemical or a wastewater plant, provide gas-phase filtration to remove airborne contaminants and protect the electrical equipment from corrosion. When designing outdoor air economizers for cooling the area, use MERV 12 efficiency filters. In addition, if electrical panels or enclosures are susceptible to dust, it may be necessary to pressurize the room to control infiltration and prevent entry of dust in the building. For critical applications or remote locations, design fans and other HVAC equipment with 100% redundancy, and ensure the standby unit autostarts after a failure of the primary unit. Substations have batteries and chargers that provide back-up power for operation during blackouts or other power disruptions. Batteries and chargers should preferably be in a separate room, in accordance with Table 1 and the section on Battery Rooms.

Typical cooling systems in substations and switchyards control structures include packaged or split-type or wall-mounted DX air-conditioning units. The design should be simple, so that equipment repair or replacement can be performed as quickly as possible and the system returned to service.

HVAC systems in dispatch and load control centers should be designed like those for process computer rooms and data centers, with similar temperature, relative humidity, cleanliness, reliability, and redundancy considerations. These facilities are continuously occupied, and the HVAC system should be designed as for a control room.

9. TURBINE LUBRICATING OIL STORAGE

A typical power plant has a turbine lubricating oil storage tank and associated filtration equipment. If this storage area is inside the building, the tank should be vented to the outdoors or ventilation rates should provide for dilution of oil fumes. The ventilation systems should be coordinated with fire protection systems to ensure adequate fire suppressant concentration and to prevent spread of fire.

10. OIL STORAGE AND PUMP BUILDINGS

At a power plant, fuel oil may be the main source of energy for the steam generator, combustion turbine, or diesel generator. It may also be a back-up or supplemental fuel. Coal-fueled plants usually use oil or gas as the initial light-off fuel or for operation of an auxiliary steam generator. Auxiliary steam generators provide initial plant warm-up and building heating.

Oil for combustion is generally light oil such as No. 2 fuel oil, or heavy oil such as No. 6. Light oils can be pumped at normal temperatures, but heavy oils are highly viscous and may need to be heated for pumping. Oils are usually received by rail or truck, transported by pipeline, and stored in tanks.

Enclosures for pumps, valves, heat exchangers, and associated equipment should be heated and ventilated to remove excess heat and to dilute hydrocarbon fumes. Tank ventilation is an integral part of the tank and piping system design, which is separate from the enclosure ventilation design. Fuel oils are classified in NFPA *Standard* 30 as either combustible or flammable, depending on their vapor pressure at the indoor design temperature. Flammable liquids are hazardous; combustible liquids are not.

HVAC systems for areas containing combustible fuels must follow ventilation principles for heat removal and for good air mixing. Ventilation rates should dilute fumes expected from evaporation of spilled or leaking fuel, following ACGIH (2013) guidelines and material safety data sheets (MSDSs) provided by the material manufacturer. For fuel handling confined to piping systems, the expected leakage is nearly zero, so very low fresh air rates are

required for ventilation (generally less than 1 ach). If fuel is handled in open containers or hoses, higher rates are prudent.

If the fuel is flammable at temperatures expected in the room, follow NFPA *Standard* 30 and other safety and building codes. Electrical systems may need to be classified for operation in a hazardous location.

11. COAL CRUSHER AND COAL TRANSPORTATION SYSTEM BUILDINGS

Coal-handling facilities at a power plant receive and prepare coal and then transport it to the burners. Intermediate steps in the process may include long- or short-term storage, cleaning, and crushing. Receipt may include barge, rail car, or truck unloading. Storage may be in piles on the ground, underground, or in barns or silos. At the site, the coal is handled by mobile equipment or conveyor systems.

The following general HVAC considerations apply for the types of structures involved.

Potential for Dust Ignition Explosion

Most types of coal readily break down into dust particles when handled or conveyed. The dust can become fine enough and occur in the right particle size distribution and concentration to create a dust explosion. The design engineer should review and apply the referenced NFPA standards and guidelines to determine the dust ignition potential for each ventilation system application.

Ventilation of Conveyor and Crusher Motors in Coal Dust Environment

Heat from motors and process equipment should be removed through ventilation, either by using ducted, ventilated motors or by ventilating the building enclosures. Ventilation in enclosures containing coal should keep the velocity below the entrainment velocities of the expected particle sizes. Table 1 in Chapter 11 of the 2013 *ASHRAE Handbook—Fundamentals* has information on settling velocity. Generally, air should be mechanically exhausted to allow ventilation air to enter the building through louvers at low velocities.

Cooling or Ventilation of Electrical and Control Equipment

Electrical and control equipment may be located near coal piles or other coal-handling facilities. Air-conditioned control rooms should be pressurized with filtered outdoor air. Ventilated motor control or switchgear areas should also be pressurized with filtered air. Because of high dust concentrations in coal yards, ordinary filter media have a short life; a solution is to use inertial filters. For air-conditioned areas, inertial filters can be followed by higher-efficiency media filters.

For electrical equipment rooms adjacent to an area with the potential for a dust ignition explosion, follow NFPA *Standard* 496, which recommends the flow of clean air away from electrical equipment into the dusty area.

Ventilation of Methane Fumes

Methane and other hydrocarbons are present in coal both as free gas in cracks and voids and as adsorbents within the coal. Although most of the methane is released from the interstitial coal structure during mining and handling, some methane or other potentially flammable gases may remain in the coal. Thus, flammable concentrations of methane can accumulate when large amounts of coal are stored. The design engineer should identify the potential for methane accumulation when designing for structures associated with silos or coal storage buildings. At the mine or mine mouth, methane gas emission rates as high as 5 ft³/ton·day are possible; at other locations, the rate is usually less than 1 ft³/ton·day. Dust collection air exhaust or natural ventilation is often sufficient to prevent the

methane level from reaching the 1% explosion limit. The design engineer should apply guidelines from NFPA *Standards* 85, 120, and 850.

Underground Tunnels and Conveyors

Enclosed conveyors are generally of loose construction and require no ventilation. Smoke or gases in underground conveyor tunnels, hoppers, or conveyor transfer points could cause a personnel safety hazard. Ventilation systems should be coordinated with escape route passages to move fresh air from the direction of the egress. Ventilation rates in the range of 2 to 5 ach are generally appropriate for normal system operation.

Dust Collectors

Dust collectors are used primarily in coal- and limestone-handling operations to reduce the spread of fugitive dust. Collector effects on plant air supply, disposal of collected dust, and associated fire safety and air quality permit issues must be considered. Consult Chapter 14 in this volume and Chapters 29 and 30 in the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* and applicable ACGIH publications for detailed design and specification guidance. Provide adequate make-up air to ensure proper dust collector operation.

Successful coal dust control depends on proper conveyor transfer chute design (including transfer hoods, settling boxes, and skirt board seals) and on proper selection of air intake velocities and air-flow quantities at transfer points or chutes. Most conveyor manufacturers either have proprietary transfer chute designs meeting these objectives or follow guidance from ACGIH (2013) and other authoritative sources.

Airflow associated with these pickup points may be sufficient to meet the ventilation requirements. Air inlets must be provided. If additional ventilation is needed, the ventilation fan must coordinate with the dust collection system. For heated structures, makeup air may need to be heated.

12. HEATING/COOLING SYSTEMS

Selection of the heating and cooling systems in a power plant depends on several variables, including the geographical location and orientation of the plant and the type of fuel used. Most plants are ventilated with outdoor air, but it is customary in hot climates to air-condition many plant areas. Evaluate heating alternatives (e.g., steam, hot water, gas, electricity) to identify the most economical choice. Electricity is the primary energy source for general-purpose cooling of various areas of the plant. Areas such as the main control room, office areas, and electrical switchgear/MCC rooms are air-conditioned for continuous human occupancy or for maintaining the operability of the electrical equipment and controls. Spot cooling may also be needed at local control panel areas in the power generation (turbine-electrical generator building) and steam generator (boiler) buildings.

Cooling

The cooling source may be either a centrally located system providing chilled water to various area coolers or individual DX area coolers with either air- or water-cooled condensing units. Selection depends on the layout of the areas to be cooled and the comparative costs of the two options. The condensing system of the water chiller may be cooled with either air or available water from the plant service water system. Air-cooled chillers are used when air near the proposed chiller location is moderately clean and no fly ash or coal dust problem is anticipated. For a water-cooled system, a closed-loop cooling tower is sometimes used if service water is poor or unavailable (e.g., during start-up or plant outages). To protect chillers from fouling and corrosion by the service water,

a heat exchanger is sometimes used between the chiller condenser and the service water source. In a power plant with several operating units and individual self-supporting chilled-water systems, the chilled-water systems of each unit are sometimes interconnected to provide back-up and redundancy.

Heating

Heating in various areas of the power plant is usually provided by electric, steam, or hot-water unit heaters or heating coils in air-handling units. In a hot-water distribution system, glycol is usually added into the system for protection against freezing. Because the building's stack effect induces large quantities of infiltration air, heating requirements in the lower levels of the steam generator building may increase when the steam generator is operating. Pressurization fans directing cooler, outdoor air into the warmer upper elevations of the plant can offset this infiltration. Also, the design engineer may evaluate redistribution of hotter air from higher to lower elevations.

An alternative to heating the open areas of the plant is to use pipeline heat tracing and spot heating at personnel workstations. For this approach, the design engineer should consider all components that may require heat tracing, such as instrument lines, small and large pipes, traps, pumps, tanks, and other surfaces that may be subject to freezing temperatures. Often the large number of components and surfaces to be heat traced and insulated makes this impractical.

Hydroelectric Power Plants

Hydroelectric power plants consist of a dam structure, draft tubes with gates, and turbine generators. The facility may be arranged with the generation components within the dam structure or within structures attached to the dam. HVAC systems should be provided for reliable operation of the mechanical, electrical, and control equipment and office areas.

The system design should consider the geographical location, humidity, degree of automation needed, and potential for flooding. Dams are typically built in remote locations, so the design and arrangement of the equipment, air intakes, and exhaust ports should consider the potential for vandalism. Accordingly, intakes should include security grating or bars, should not provide a line of sight into the structure, and should be constructed of heavy-gage steel to thwart bullets. HVAC equipment should be indoors if practical, or made otherwise inaccessible.

Humidity is a major design consideration. The lake surface and outfall structure create humid outdoor conditions. Outdoor air used for ventilation may introduce humidity into indoor spaces that may cause corrosion of electrical and control equipment. In addition, dam structure and turbine components below the lake water level are usually at temperatures colder than the dew point of the outdoor air. Introducing unconditioned outdoor air can create a significant amount of condensation on structure and equipment surfaces.

Another consideration of the remote location of hydroelectric plants is that the HVAC systems need to be reliable and able to operate with minimum attention by operating and maintenance personnel. Thus, these systems may require seasonal changeover features and fully automatic functions. System controls should be integrated with the generation plant controls, such as communication of status and alarm of critical functions to an off-site monitoring facility.

HVAC design should consider the maximum and minimum lake water level. Intakes and exhausts should be above the maximum design flooding level. Suction points for cooling water sources should be below the minimum water level.

Because of the potential for introducing outdoor humidity, cooling of mechanical equipment areas (e.g., turbine generator hall, turbine and wicker gate) should use a minimum amount of ventilation air. When practical, dehumidify air mechanically or with coils using

cold lake water. Areas with heat-producing equipment such as for stop-log storage generally do not need ventilation air, which may introduce unwanted humidity. To minimize the effect of outdoor air humidity on electrical and control equipment areas, consider using water-cooled equipment and radiant cooling to cool structural surfaces. Design battery rooms and oil storage areas for the specific hazards to minimize excessive ventilation rates.

13. ENERGY RECOVERY

Energy recovery should be considered in any new system design or system upgrade. Considerations in the power plant should include the following:

- **Interfaces with existing plant process systems.** Using waste steam or steam bled from a process stream must consider process system behavior during generating unit start-up, part load, full load, shutdown, and cold standby/shutdown conditions. Any water returned to the boiler steam cycle must consider effects on the generating unit boiler water chemistry/water treatment.
- **Operating environment,** including cross contamination of clean airstreams from dirty airstreams, dusty environments, and corrosive conditions from substances such as flue gas. For details, see Chapter 26 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*.
- **Safety,** including issues resulting from the presence of coal dust, flammable gases, etc. Consult fire codes and insurance underwriters for guidance.
- **Control strategies.**
- **Constructability.**
- **Codes, standards, and local rules and regulations.**

Energy recovery systems should be evaluated by economic analysis of life-cycle costs, including

- Initial cost, including equipment and installation cost
- Fuel and station service power cost
- Operating cost savings
- Maintenance cost

Utility economic evaluations should follow the accounting guidelines and requirements as established by the Federal Energy Regulatory Commission (FERC). See Chapter 37 for further information on owning and operating costs.

14. SAFETY CONSIDERATIONS

Power plant HVAC systems should be engineered and designed to operate safely and reliably. HVAC systems often interface with other plant systems; specific requirements for these interfaces and for plant safety are defined by applicable codes and standards, regulatory authorities, owners' requirements, and insurance carriers. These requirements vary regionally, and appropriate authorities must be consulted during the design and modification of HVAC systems.

---	--

THE HVAC requirements for facilities using radioactive materials are discussed in this chapter. Such facilities include nuclear power plants, fuel fabrication and processing plants, plutonium processing plants, hospitals, corporate and academic research facilities, and other facilities housing nuclear operations or materials. The information presented here should serve as a guide; however, careful and individual analysis of each facility is required for proper application.

1. GENERAL DESIGN ISSUES

Criticality, radiation fields, and regulation are three issues that are more important in the design of nuclear-related HVAC systems than in that of other special HVAC systems.

Criticality. Criticality considerations are unique to nuclear facilities. Criticality is the condition reached when the chain reaction of fissionable material, which produces extreme radiation and heat, becomes self-sustaining. Unexpected or uncontrolled conditions of criticality must be prevented at all cost. In the United States, only a limited number of facilities, including fuel-processing facilities, weapons facilities, naval shipboard reactors, and some national laboratories, handle special nuclear material subject to criticality concerns.

Radiation Fields. All facilities using nuclear materials contain radiation fields. They pose problems of material degradation and personnel exposure. Although material degradation is usually addressed by regulation, it must be considered in all designs. The personnel exposure hazard is more difficult to measure than the amount of material degradation because a radiation field cannot be detected without special instruments. It is the responsibility of the designer and of the end user to monitor radiation fields and limit personnel exposure.

Regulation. In the United States, the Department of Energy (DOE) regulates weapons-related facilities and national laboratories, and the Nuclear Regulatory Commission (NRC) regulates commercial nuclear plants. Other local, state, and federal regulations may also be applicable. For example, meeting an NRC requirement does not relieve the designer or operator of the responsibility of

meeting Occupational Safety and Health Administration (OSHA) requirements. The design of an HVAC system to be used near radioactive materials must follow all guidelines set by these agencies and by the local, state, and federal governments.

For facilities outside the United States, a combination of national, local, and possibly some U.S. regulations apply. In Canada, the Canadian National Safety Commission (CNSC), formerly the Atomic Energy Control Board (AECB), is responsible for nuclear regulation, whereas in the United Kingdom, the Nuclear Installations Inspectorate (NII) and the Environment Agency (EA), are involved in issuing operation licenses.

1.1 AS LOW AS REASONABLY ACHIEVABLE (ALARA)

ALARA means that all aspects of a nuclear facility are designed to limit worker exposure and discharges to the environment to the minimum amount of radiation that is reasonably achievable. This refers not to meeting legal requirements, but rather to attaining the lowest cost-effective below-legal levels.

1.2 DESIGN

HVAC requirements for a facility using or associated with radioactive materials depend on the type of facility and the specific service required. The following are design considerations:

- Physical layout of the HVAC system that minimizes the accumulation of material within piping and ductwork
- Control of the system so that portions can be safely shut down for maintenance and testing or in the case of any event, accident, or natural catastrophe that causes radioactivity to be released
- Modular design for facilities that change operations regularly
- Preservation of confinement integrity to limit the spread of radioactive contamination in the physical plant and surrounding areas

The design basis in existing nuclear facilities requires that safety-class systems and their components have active control for safe shut-down of the reactor, for mitigating a design basis accident (DBA) and for controlling radiation release to the environment as the result of an accident.

Advanced nuclear steam supply systems (NSSS) are being designed that incorporate more passive control to minimize dependence on mechanical equipment to mitigate the consequences of a DBA.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

1.3 NORMAL OR POWER DESIGN BASIS

The normal or power design basis for nuclear power plants covers normal plant operation, including normal operation mode and normal shutdown mode. This design basis imposes no requirements more stringent than those specified for standard indoor conditions.

1.4 SAFETY DESIGN BASIS

The safety design basis establishes special requirements necessary for a safe work environment and public protection from exposure to radiation. Any system designated essential or safety related must mitigate the effect of a design basis accident, or natural catastrophe that may result in the release of radioactivity into the surroundings or the plant atmosphere. These safety systems must be operable at all times unless allowed by a limited condition of operation (LCO). The degree to which an HVAC system contributes to safety determines which components must function during and after a DBA or specific combinations of such events as a safe shutdown earthquake (SSE), a tornado, a loss of coolant accident (LOCA), fuel-handling accident (FHA), control rod drop accident (CRDA), main steam line break (MSLB), and loss of off-site electrical power (LOSP). Non-safety-related systems are not credited in any design basis accident and are designed not to adversely affect safety-related systems.

Previously, safety classification of structures, systems, and components (SSC) was based on a deterministic approach, but will be changed to a risk-informed classification and classified as safety-significant (SS) or low safety-significant (LSS), and categorized in four groups. NRC *Regulatory Guide* 1.201 provides information on safety classification of systems, structures and components.

System Redundancy. Systems important to safety must be redundant and single-failure-proofed. Such a failure should not cause a failure in the back-up system. For additional redundancy requirements, refer to the section on Commercial Facilities.

Seismic Qualification. All safety-class components, including equipment, pipe, duct, and conduit, must be seismically qualified by testing or calculation to withstand and perform under the shock and vibration caused by an SSE or an operating-basis earthquake (OBE) (the largest earthquake postulated for the region). This qualification also covers any amplification by the building structure. In addition, any HVAC component that could, if it failed, jeopardize the essential function of a safety-related component, must be seismically qualified or restrained to prevent such failure.

Environmental Qualification. Safety-class components must be environmentally qualified; that is, the useful life of the component in the environment in which it operates must be determined through a program of accelerated aging. Environmental factors such as temperature, humidity, pressure, and cumulative radiation dose must be considered.

Quality Assurance. All designs and components of safety-class systems must comply with the requirements of a quality assurance (QA) program for design control, inspection, documentation, and traceability of material. For U.S. plant designs, refer to Appendix B of Title 10 of the U.S. *Code of Federal Regulations*, Part 50 (10CFR50) or ASME *Standard* NQA-1 for quality assurance program requirements.

Canadian plant designs use two related series of quality assurance standards: CAN3-286.0 and its six daughter standards, plus four standards in the Z299 series. Quality programs in the United Kingdom are based on ISO 9000. For other countries, refer to the applicable national regulations.

Emergency Power. All safety-class systems must have a backup power source such as an emergency diesel generator.

1.5 OUTDOOR CONDITIONS

Chapters 14 and 15 of the 2013 *ASHRAE Handbook—Fundamentals*, the U.S. National Oceanic and Atmospheric Administration, national weather service of the site country, or site meteorology can provide information on outdoor conditions, temperature, humidity, solar load, altitude, and wind.

Nuclear facilities generally consist of heavy structures with high thermal inertia. Time and temperature lag should be considered in determining heat loads. For some applications, such as diesel generator buildings or safety-related pumphouses in nuclear power plants, the 24 h average temperature may be used as a steady-state value. For critical ventilation system design, site meteorological data should be evaluated.

1.6 INDOOR CONDITIONS

Indoor temperatures are dictated by occupancy, equipment or process requirements, and comfort requirements based on personnel activities. HVAC system temperatures are dictated by the environmental qualification of the safety-class equipment located in the space and by ambient conditions during the different operating modes of the equipment.

1.7 INDOOR PRESSURES

Where control of airflow pattern is required, a specific building or area pressure relative to the outdoor atmosphere or to adjacent areas must be maintained. The effect of prevailing wind speed and direction, based on site meteorological information, should be considered. For process facilities with pressure zones, the pressure relationships are specified in the section on Confinement Systems.

In facilities where zoning is different from that in process facilities, and in cases where any airborne radioactivity must not spread to rooms within the same zone, this airborne radioactivity must be controlled by airflow.

1.8 AIRBORNE RADIOACTIVITY

The level of airborne radioactivity within a facility and the amount released to the surroundings must be controlled to meet the requirements of 10CFR20, 10CFR50, 10CFR61, 10CFR100, 10CFR835, and U.S. DOE *Policy* P 441.1, or equivalent national regulations of the site country.

1.9 TORNADO/MISSILE PROTECTION

Protection from tornados and the objects or missiles launched by wind or other design basis events is normally required to prevent the release of radioactive material to the atmosphere. A tornado passing over a facility causes a sharp drop in ambient pressure. If exposed to this transient pressure, ducts and filter housings could collapse because the pressure inside the structure would still be that of the environment prior to the pressure drop. Protection is usually provided by tornado dampers and missile barriers in all appropriate openings to the outdoors. Tornado dampers are heavy-duty, low-leakage dampers designed for pressure differences in excess of 3 psi. They are normally considered safety-class and are environmentally and seismically qualified.

1.10 FIRE PROTECTION

Fire protection for HVAC and filtration systems must comply with applicable requirements of RG 1.189, Appendix R of 10CFR50, and NFPA, UL, and ANSI or equivalent standards of the site country. Design criteria should be developed for all building fire protection systems, including secondary sources, filter plenum protection, fire dampers, and systems for detection/suppression and

smoke management. Fire protection systems may consist of a combination of building sprays, hoses and standpipes, and gaseous or foam suppression. The type of fire postulated in the Fire Hazard Analysis (FHA) or equivalent determines which kind of system is used.

A requirement specific to U.S. nuclear commercial facilities is protection of carbon filter plenums and ventilation ductwork. Manually activated water sprays (window nozzles, fog nozzles, or standard dry pipe/wet pipe system spray heads) are usually used for fire suppression in carbon filter plenums.

Heat detectors and fire suppression systems should be considered for special equipment such as glove boxes. Application of the two systems in combination allows the shutdown of one system at a time for repairs, modifications, or maintenance.

In a DOE facility, the exhaust system duct penetrating a fire-rated boundary does not need a fire damper for maintaining the integrity of the boundary if the duct is fire rated. The exhaust duct may be rated at up to two hours by either wrapping, spraying, or enclosing the duct in an approved material and qualifying it by an engineering analysis. Additional design guidance can be obtained from the *Nuclear Air Cleaning Handbook* (DOE-HDBK-1169-2003).

Smoke control criteria can be found in NFPA *Standards* 801, 803, 804, and 901, or equivalent standards of the site country.

1.11 SMOKE MANAGEMENT

The design objective for smoke management in a nuclear facility is to protect the plant operators and equipment from internally and externally generated smoke. Smoke management involves (1) use of materials with low smoke-producing characteristics, (2) prevention of smoke movement to areas where operators may be overcome, (3) use of differential pressures to contain smoke to fire areas, (4) smoke venting to permit access to selected areas, and (5) purging to permit access to areas after a fire.

Smoke control may be static, by prevention of smoke movement (NFPA 90A), or it may be dynamic, by controlling building pressure or air velocities (NFPA 92A). Ventilation systems in the affected areas should be shut down to prevent smoke from migrating and overcoming occupants in other areas. Smoke management for an *internal* fire source should allow the plant operator to shut down the reactor in a controlled manner and maintain shutdown condition. Smoke from an *external* fire should be isolated and appropriate measures provided to prevent smoke from entering the main control room envelope. This envelope includes the main control room and other necessary areas such as restrooms, kitchens, and offices. The location of the safe shutdown panels and the pathway to the safe shutdown panel must be such that, in case of abandonment of the main control room because of fire and smoke, safe egress is ensured.

Capabilities should be provided for purging smoke from fire areas to permit reentry into the areas after the fire is isolated and extinguished. Venting may be used to remove heat and smoke at the point of the fire to permit fire fighting and to control pressures generated by fires.

NFPA 90A, 204, and 92A and NUREG 800 SRP Branch Technical Position CMEB 9.5-1 provide guidance for smoke management and discuss the discharge of smoke and corrosive gases.

Control Room Habitability Zone

The HVAC system in a control room is a safety-related system that must fulfill the following requirements during all normal and postulated accident conditions:

- Maintain conditions comfortable to personnel, and ensure that control room equipment functions continuously and complies with its qualification limit
- Protect personnel from exposure to radiation or toxic chemicals, in the event of a design basis accident

- Protect personnel from combustion products (smoke) emitted from on-site and off-site fires

Additional information may be obtained from the NRC Standard Review Plans, Sections 6.4 and 9.4.1.

Air Filtration

HVAC filtration systems can be designed to remove either radioactive particles or radioactive gaseous iodine from the airstream. They filter potentially contaminated exhaust air prior to discharge to the environment and may also filter potentially contaminated make-up air for power plant control rooms and technical support centers.

The composition of the filter train is dictated by the type and concentration of the contaminant, the process air conditions, and the filtration levels required by the applicable regulations [e.g., NRC *Regulatory Guides* RG 1.52, RG 1.140; ASME AG-1, N509, and 510 (for equipment designed to N509), and N511 (for equipment designed to AG-1); 10CFR20, 10CFR100]. Filter trains may consist of one or more of the following components: prefilters, high-efficiency particulate air (HEPA) filters, carbon filters (adsorbers), heaters, demisters and associated ductwork, housings, fans, dampers, and instrumentation. For nuclear-safety-related versions of this equipment, the latest edition of ASME AG-1 codifies rules for materials; design; inspection and testing; fabrication; packaging, shipping, receiving, storage, and handling; and quality assurance. Information common to all equipment is compiled in AG-1, Section AA: General Requirements. The AG-1 Code discusses specific rules for each of the major components in separate sections.

For DOE facilities, the *Nuclear Air Cleaning Handbook* (DOE-HDBK-1169-2003) recommends the design of systems and use of major components for nuclear process facilities and laboratories.

Demisters (Mist Eliminators). Demisters are required to protect HEPA and carbon filters if entrained moisture droplets are expected in the airstream. They should be fire resistant. For details, see AG-1, Section FA.

Heaters. Electric heating coils may be used to meet the relative humidity conditions requisite for carbon filters. For safety-class systems, electric heating coils should be connected to the emergency power supply. Interlocks should be provided to prevent heater operation when the exhaust fan is deenergized. For details, see AG-1, Section CA.

Prefilters/Postfilters. Extended-surface filters are selected for the efficiency required by the particular application. AG-1, Table FB-4200-1, lists the average atmospheric dust spot efficiency ranges. ARI 850 provides efficiency tolerances for the various classes. These types of filters are often used as prefilters for HEPA filters to prevent them from being loaded with atmospheric dust and to minimize replacement costs. High-efficiency (90 to 95%) filters are also often used as postfilters downstream of the carbon filter in lieu of downstream HEPAs. For details, see AG-1, Section FB.

European filter standards use efficiency tolerances from EN 779 in place of ARI 850.

HEPA Filters. HEPA filters are used where there is a risk of particulate airborne radioactivity. For details, see AG-1, Sections FC and FK. For DOE sites, the construction and quality assurance testing of HEPA filters are per DOE *Standards* 3020 and 3025.

Carbon Filters. Activated carbon adsorbers are used mainly to remove radioactive iodine in gaseous state. Bed depths are typically 2 or 4 in. Carbon filters have an efficiency of 99.9% for elemental iodine and 95 to 99% for organic iodine, although they lose efficiency as relative humidity increases. For this reason, they are often preceded by a heating element to keep the relative humidity of the entering air below 70%. Nuclear carbon filters can be either tray type (Type II), rechargeable (Type III), or modular (Type IV). For details on each type, see AG-1, Sections FD, FE, and FH. Carbon

efficiency is tested in accordance with ASTM D3803-91 (2004) or its latest edition.

Both carbon and HEPA filters may be affected by exposure to paint solvent, chemicals, and fire, and thus should be tested upon exposure.

Design information for ventilation and air-conditioning system design, ductwork, housings, fans, dampers, and instrumentation are contained in AG-1, Sections CA, RA, SA, HA, BA, DA, and IA, respectively.

Sand Filters. Sand filtration is a passive air filtration system that consists of multiple layers of sand and gravel through which air is drawn and filtered. The air enters an inlet tunnel that runs the entire length of the filter. Smaller cross-sectional laterals running perpendicular to the inlet tunnel distribute air across the base of the sand. Air rises through several layers of various sizes of sand and gravel, typically at a facial velocity of 5 fpm. It is then collected in the outlet tunnel for discharge to the atmosphere. Sand filters require no maintenance, and the sand is not changed or replaced during its active service life. A detailed discussion of sand filters is given in Chapter 9 of the DOE's (2003) *Nuclear Air Cleaning Handbook*. At present, there are no national consensus codes and standards relating to sand filters, although ASME's Code of Nuclear and Air Gas Treatment (CONAGT) Committee is developing a sand filter section for ASME Code AG-1.

2. DEPARTMENT OF ENERGY FACILITIES

The following discussion applies to U.S. National Laboratory facilities. Nonreactor nuclear HVAC systems must be designed in accordance with DOE Order O 420.1B. Critical items and systems in plutonium processing facilities are designed to confine radioactive materials under both normal and DBA conditions.

2.1 CONFINEMENT SYSTEMS

Zoning

Typical process facility confinement systems are shown in Figure 1. Process facilities comprise several zones.

Primary Confinement Zone. This zone includes the interior of the hot cell, canyon, glove box, or other means of containing radioactive material. Containment must prevent the spread of radioactivity within or from the building under both normal conditions and

Fig. 1 Typical Process Facility Confinement Categories

upset conditions up to and including a facility DBA. Complete isolation from neighboring facilities is necessary. Multistage HEPA filtration of the exhaust is required.

Secondary Confinement Zone. This zone is bounded by the walls, floors, roofs, and associated ventilation exhaust systems of the operating and maintenance areas or rooms surrounding the primary confinement zone.

Tertiary Confinement Zone. This zone is bounded by the walls, floors, roofs, and associated ventilation exhaust systems of the facility. They provide a final barrier against the release of hazardous material to the environment. Radiation monitoring may be required at exit points.

Uncontaminated Zone. This zone includes offices and cold shop areas.

Air Locks

Air locks in nuclear facilities are used as safety devices to maintain a negative differential pressure when a confinement zone is accessed. They are used for placing items in primary confinement areas and for personnel entry into secondary and tertiary confinement areas. Administrative controls ensure proper operation of the air lock doors.

There are three methods of ventilating personnel air locks (ventilated vestibules):

- The **clean conditioned supply air** method, where the air lock is at positive pressure with respect to the adjacent zones. For this method to be effective, the air lock must remain uncontaminated at all times.
- The **flow-through ventilation air** method, where no conditioned air is supplied to the air lock and the air lock stays at negative pressure with respect to the less contaminated zone.
- The **combined ventilation air** method, which is a combination of the other two methods. This may be the most effective method, when properly designed.

Zone Pressure Control

Negative static pressure increases (becomes more negative) from the uncontaminated zone to the primary confinement zone, causing any air leakage to be inward, toward areas of higher potential contamination. All zones should be maintained negative with respect to atmospheric pressure. Zone pressure control cannot be achieved through the ventilation system alone; confinement barrier construction must meet all applicable specifications.

Cascade Ventilation

Confinement barriers are enhanced by the use of a cascaded ventilation system, in which pressure gradients cause air to flow from areas of lower contamination to areas of higher contamination through engineered routes. In a cascade ventilation system, air is routed through areas or zones from lower contamination to higher contamination and then to highest contamination, thus reducing the number of separate ventilation systems and the amount of air required for contamination control.

Properly designed air locks should be provided for access between noncontaminated and contaminated areas. If there is a potential for development of differential pressure reversal, HEPA filters should be used at the inlet air openings between areas of higher and lower contamination levels to control the spread of contamination into less contaminated or cleaner areas. Appropriate sealing mechanisms should be used for doors or hatches leading into highly contaminated areas.

Differential Pressures

Differential pressures help ensure that air flows in the proper direction in case of a breach in a confinement zone barrier. The

design engineer must incorporate the desired magnitudes of the differential pressures into the design early to avoid later operational problems. These magnitudes are normally specified in the design basis document of the safety analysis report (SAR). The following are approximate values for differential pressures between the three confinement zones.

Primary Confinement. With respect to the secondary confinement area, air-ventilated glove boxes are typically maintained at pressures of -0.3 to -1.25 in. of water, inert gas glove boxes at -0.3 to -1.5 in., and canyons and cells at a minimum of -1.0 in.

Secondary Confinement. Differential pressures of -0.03 to -0.15 in. of water with respect to the tertiary confinement area are typical.

Tertiary Confinement. Differential pressures of -0.01 to -0.15 in. of water with respect to the atmosphere are typical.

2.2 VENTILATION

Ventilation systems are designed to confine radioactive materials under normal and DBA conditions and to limit radioactive discharges to allowable levels. They ensure that airflows are, under all normal conditions, toward areas (zones) of progressively higher potential radioactive contamination. Air-handling equipment should be sized conservatively so that upsets in the airflow balance do not cause the airflow to reverse direction. Examples of upsets include improper use of an air lock, a credible breach in the confinement barrier, or excessive loading of HEPA filters.

HEPA filters at the ventilation inlets in all primary confinement zone barriers prevent movement of contamination toward zones of lower potential contamination in case of an airflow reversal. Ventilation system balancing helps ensure that the building air pressure is always negative with respect to the outdoor atmosphere.

Recirculating refers to the reuse of air in a particular zone or area. Room air recirculated from a space or zone may be returned to the primary air-handling unit for reconditioning and then, with the approval of health personnel, be returned to the same space (zone) or to a zone of greater potential contamination. All air recirculated from secondary and tertiary zones must be HEPA-filtered before reintroduction to the same space. Recirculating air is not permitted in primary confinement areas, except those with inert atmospheres.

A safety analysis is necessary to establish minimum acceptable response requirements for the ventilation system and its components, instruments, and controls under normal, abnormal, and accident conditions.

Analysis determines the number of exhaust filtration stages required in different areas of the facility to limit (in conformance with the applicable standards, policies, and guidelines) the amount of radioactive or toxic material released to the environment during normal and accident conditions. Consult DOE *Order O 420.1B, Standard 1189*, and Handbook 1169 (DOE 2003) for air-cleaning system criteria.

Ventilation Requirements

A partial recirculating ventilation system may be considered for economic reasons. However, it must be designed to prevent contaminated exhaust from entering the room air-recirculating systems.

The exhaust system is designed to (1) clean radioactive contamination from the discharge air, (2) safely handle combustion products, and (3) maintain the building under negative pressure relative to the outdoors.

Provisions may be made for independent shutdown of ventilation systems or isolation of portions of the systems to facilitate operations, filter change, maintenance, or emergency procedures such as fire fighting. All possible effects of partial shutdown on the airflows in interfacing ventilation systems should be considered. Positive means must be provided to control the backflow of air that might

transport contamination. A HEPA filter installed at the interface between the enclosure and the ventilation system minimizes contamination in the ductwork; a prefilter reduces HEPA filter loading. These HEPA filters should not be considered the first stage of an airborne contamination cleaning system.

Ventilation Systems

The following is a partial list of elements that may be included in the overall air filtration and air-conditioning system:

- Air-sampling devices
- Pre- and/or postfilters (e.g., carbon adsorbers, multiple-bed sand, HEPA)
- Scrubbers
- Demisters
- Process vessel vent systems
- Condensers
- Distribution baffles
- Fire suppression systems
- Fire and smoke dampers
- Exhaust stacks
- Fans
- Coils
- Heat removal systems
- Pressure- and flow-measuring devices
- Duct test ports
- Radiation-measuring devices
- Criticality-safe drain systems
- Tornado dampers
- Smoke dampers

The ventilation system and associated fire suppression system are designed for fail-safe operation. The ventilation system is equipped with alarms and instruments that report and record its behavior through readouts in control areas and utility service areas.

Control Systems

Control systems for HVAC systems in nuclear facilities have some unique safety-related features. Because the exhaust system is to remain in operation during both normal and accident-related conditions, redundancy in the form of standby fans is often provided. These standby fans and their associated isolation dampers energize automatically upon a set reduction in either airflow rate or specific location pressure, as applicable. For DOE facilities, maintaining exhaust airflow is important, so fire dampers are excluded from all potentially contaminated exhaust ducts.

Pressure control in the facility interior maintains zones of increasing negative pressure in areas of increasing contamination potential. Care must be taken to prevent wind from unduly affecting the atmospheric control reference. Pulsations can cause the pressure control system to oscillate strongly, resulting in potential reversal of relative pressures. One alternative is to use a variety of balancing and barometric dampers to establish an air balance at the desired differential pressures, lock the dampers in place, and then control the exhaust air to a constant flow rate.

Air and Gaseous Effluents Containing Radioactivity

Air and all other gaseous effluents are exhausted through a ventilation system designed to remove radioactive particulates. Exhaust ducts or stacks located downstream of final filtration that may contain radioactive contaminants should have two monitors, one a continuous air monitor (CAM) and the other a fixed sampler. These monitors may be a combination unit. Exhaust stacks from nuclear facilities are usually equipped with an isokinetic sampling system that relies on a relatively constant airflow rate. The isokinetic sensing probe is a symmetrically arranged series of pickup tubes connected through sweeping bends to a stainless steel header that

connects with capillary tubing to a sampling station (CAM). The air velocity through an isokinetic sampling system should be the same as the airstream being sampled. This ensures that particles captured by the isokinetic sampling probe and conveyed to the sampling station are the same size particles that are conveyed in the airstream being sampled. Typically, an exhaust system flow controller modulates the exhaust fan inlet dampers or motor speed to hold the exhaust airflow rate steady while the HEPA filters load.

CAMs can also be located in specific ducts where a potential for radiological contamination has been detected. These CAMs are generally placed beyond the final stage of HEPA filtration, as specified in ANSI *Standard* N13.1. Each monitoring system is connected to an emergency power supply.

The following are design considerations for CAM systems:

- Maintain fully developed turbulent flow at the nonisokinetic sampling point.
- Maintain fully developed laminar flow at the isokinetic sampling point.
- Ensure fully developed turbulent flow is developed between the final filtration and the isokinetic sampling point.
- For accurate CAM operation, heat tracing on the sampling air tubing may be required.
- Maintain the ratio of the sample airflow rate to total discharge airflow rate constant.

3. COMMERCIAL FACILITIES

3.1 OPERATING NUCLEAR POWER PLANTS

The two kinds of commercial light-water power reactors currently in operation in the United States, and in many other countries, are the pressurized water reactor (PWR) and the boiling water reactor (BWR). Heavy water (deuterium oxide) reactors are used in Canada and some other countries. Gas-cooled reactors constitute most of the installed base in Great Britain, but are in the process of being phased out. For all these types, the main objective of the HVAC systems, in addition to ensuring personnel comfort and reliable equipment operation, is protecting operating personnel and the general public from airborne radioactive contamination during normal and accident conditions. Radiation exposure limits are controlled by 10 CFR 20. The “as low as reasonably achievable” (ALARA) concept is the design objective of the HVAC system. The radiological dose is not allowed to exceed the limits as defined in 10CFR50 and 10CFR100. For other countries operating commercial nuclear plants, the specific national rules and regulations should be consulted.

NRC Regulatory Guides (RGs) delineate techniques of evaluating specific problems and provide guidance to applicants concerning the information the NRC needs for its review of the facility. The regulatory guides that relate directly to HVAC system design are RG 1.52, RG 1.78, RG 1.140, RG 1.194, RG 1.196, and RG 1.197. Deviations from RG criteria must be justified by the owner and approved by the NRC. Some countries also invoke NRC regulatory guides as part of the design requirements. Deviations from RG criteria must be requested through the applicable government agency in the country of construction.

The design of the HVAC systems for a U.S. nuclear power generating station must ultimately be approved by the NRC in accordance with Appendix A of 10CFR50. The NRC developed standard review plans (SRPs) as part of Regulatory Report NUREG-0800 to provide an orderly and thorough review. The SRP provides a good basis or checklist for the preparation of a safety analysis report (SAR). The SRP is the basis for information provided by an applicant in an SAR as required by Section 50.34 of 10CFR50. Technical specifications for nuclear power plant systems are developed by the

owner and approved by the NRC as outlined in Section 50.36 of 10CFR50. Technical specifications define the safety limits, limiting conditions for operation (LCO), and surveillance requirements (SR) for all systems important to plant safety.

Minimum requirements for the performance, design, construction, acceptance testing, and quality assurance of equipment used in safety-related air and gas treatment systems in nuclear facilities are found in ASME N509, N510, N511, and AG-1.

Temperature and humidity conditions are dictated by the nuclear steam supply system (NSSS). For U.S. plants, the common modes of operation are normal, hot shutdown, cold shutdown, and refueling.

Normal Operation. NSSS temperature and humidity requirements are specified by the NSSS supplier. Some plants require recirculation filtration trains in the containment building to control the level of airborne contamination. In existing plants, containment cooling is necessary for maintaining the components in the containment and to ensure that design limits are not exceeded during accidents. Cooling is provided by a containment cooling system. Some next-generation plants are mostly of passive design and thus do not need active containment cooling systems.

Refueling Condition. The temperature in the refueling or fuel-handling area is determined by the need to perform refueling activities safely. Also, because personnel work in protective clothing, they can be vulnerable to heat stress. To prevent this, area cooling can be provided by a normal non-safety-related cooling system. Outdoor air should be provided for ventilation.

Accident Scenarios

Plants are analyzed for four types of accidents: (1) loss of coolant accident (LOCA), (2) fuel handling accident (FHA), (3) control rod drop accident (CRDA), and (4) a main steam line break (MSLB). For all plant types, it necessary to evaluate the limiting accident event and to conduct safety assessments, so measures can be taken to mitigate any accident’s consequences.

Major NSSS Types

Pressurized-Water Reactors (PWRs). These reactors, widely used in the United States, use enriched uranium for fuel. The reactor, steam generators, and other components of the NSSS are housed in the containment structure. Other support systems are housed in the auxiliary building, control building, turbine building, and diesel building. In PWR design, the steam turbine is powered by nonradioactive steam for the generation of electricity. General design requirements of the PWR plant are contained in ANSI/ANS *Standard* 56.6-1986. Figure 2 shows a typical PWR.

Boiling-Water Reactor (BWRs). Also widely used in the United States, this type of design reactor uses enriched uranium for fuel. The reactor pressure vessel and related piping are housed within the primary containment, which is also referred to as the drywell (Figure 3). The drywell is a low-leakage, pressure-retaining structure designed to withstand the high temperature and pressure from a major break in the reactor coolant line. The drywell is housed within a concrete structure called the secondary containment or the reactor building. Other support systems are housed in the control building, turbine building, and diesel building. In BWR design, the steam turbine is powered by radioactive steam for the generation of electricity. General design requirements of the BWR plant are contained in ANSI/ANS *Standard* 56.7-1987.

Heavy Water Reactors. Canadian power reactors use natural uranium fuel and heavy water (deuterium oxide), which acts as a moderator and a coolant source. The reactor core is mounted in a large, horizontal steel vessel called a calandria, which is enclosed in a concrete containment structure. This design enables the reactors to be refueled while the unit is operating at full power.

(From NRC web site: www.nrc.gov)

Commercial Plant License Renewal and Power Uprate

Nuclear power plants were originally licensed for a 40 year term and a defined power output capacity. Most nuclear plants currently operating in the United States have applied for or will be applying for license renewal to extend the plant operating license from 40 to 60 years. As part of the license renewal process, passive plant components, such as HVAC ductwork and piping, are reviewed, and renewal licenses are granted based on the commitment to perform aging management review (AMR) of long-lived components. Credit is taken for the maintenance rule to address upkeep and replacement of active components. Maintenance rule requirements are outlined in 10CFR50.65, Nuclear Energy Institute documents, Nuclear Management Resources Council (NUMARC) 93-0, and NRC Regulatory Guide RG 1.160.

In addition to license renewal, most plants are increasing their power output capacity by as much as 5 to 15% by conducting power uprate evaluations. Power uprates are often done in steps, and are often categorized as (1) measurement uncertainty recapture power uprates, (2) stretch power uprates, and (3) extended-power uprates. As part of the power uprate, the effects of power output on plant and HVAC systems are evaluated, and these systems are upgraded as needed.

3.2 NEW NUCLEAR POWER PLANTS

Many new nuclear power generation plants are being considered for construction in the United States, as well as in other parts of the world. The U.S. NRC has streamlined the application and licensing process for the new reactors, and the *Code of Federal Regulations* 10CFR52 governs the issuance of combined construction and operating license. The new plants are being designed and licensed to satisfy the demand for additional generation capacity in a competitive environment, while contributing to sustainable growth. Advantages of the newer plants include standardized designs with shortened construction times; up to 60-year service life; and the possibility of using flexible fuel [including mixed oxide (MOX) fuel]. The status of design certification and combined construction and operating license (COL) applications for various new U.S. plants can be found at the NRC Web site (www.nrc.gov).

New reactors being considered in the United States are the advanced passive 1000 (AP1000), economic simplified boiling-water reactor (ESBWR), U.S. evolutionary power reactor (USEPR), advanced boiling-water reactor (ABWR) and U.S. advanced pressurized water reactor (USAPWR). The AP1000 and the ESBWR use passive cooling systems, and the need for safety-related HVAC systems is limited. The ABWR and the USAPWR are enhanced designs of the boiling water reactor and pressurized water reactor, respectively, and HVAC systems for these reactors are not expected to be very much different than those at currently operating BWR and PWR plants. The USEPR is a pressurized water reactor of European design. Brief overviews of HVAC for AP1000, ESBWR, and USEPR plants are as follows.

Advanced Passive AP1000

HVAC systems at AP1000 plants have several differences from those at pressurized-water reactor plants. The main control room (MCR) has both a normal and an emergency HVAC system. The normal system maintains temperature and relative humidity during normal plant operation, and the emergency system uses passive cooling heat sinks to maintain habitability in the main control room during accident conditions. The normal HVAC system has supplemental air filtration that can be used to filter outdoor air with HEPA and charcoal filters, and maintains the main control room at a slight positive pressure to prevent infiltration of unfiltered air into the main control room envelope. On detection of high radiation in the supply air or an extended loss of ac power, the normal system is isolated and the safety-related emergency habitability system is activated. During emergency-mode operation, air is supplied to the MCR from pressurized storage tanks that are sized to meet the ventilation and pressurization requirements for a 72 h accident event. Passive heat sinks are used in the MCR, instrumentation and control (I&C), and dc equipment rooms to limit temperature rise in those rooms after loss of normal HVAC systems. The heat sinks primarily consist of the thermal mass of concrete in the ceilings and walls. Safety-related HVAC equipment is limited to containment isolation valves, control room isolation valves, and the emergency habitability system. Limiting active safety equipment and using passive safety features is part of the AP1000 design philosophy.

The AP1000 has a containment air filtration system, but it serves no safety-related function and is isolated during accident conditions.

It is designed to provide intermittent venting of the containment to the atmosphere during normal plant operation. HVAC systems serving the AP1000 diesel generator, radioactive waste (radwaste), annex, and turbine buildings are similar to those in existing PWRs, with a few exceptions: (1) the containment HVAC recirculation system is non-safety-related; (2) the containment HVAC recirculation system uses chilled water to cool containment; and (3) the diesel generators (and thus the diesel generator building) are not safety related.

Economic Simplified Boiling-Water Reactor (ESBWR)

ESBWR HVAC systems have several differences from those at operating boiling-water reactor plants. The control building ventilation system has two subsystems: the control building general-area ventilation system (CBGAVS), which serves general areas in the control building, and the control room habitability-area (CRHA) ventilation system (CRHAVS), which serves the main control room. The CRHAVS provides cooling to MCR, which is served by two redundant recirculation air-handling units (AHUs). Recirculation air-handling units in the main control room draw air from the ceiling space plenum, condition it, and discharge it to an underfloor air distribution system. There is an outdoor air AHU for providing makeup to the MCR for normal habitability. During emergency mode, the CRHA is isolated at the boundary by isolation dampers. The recirculation AHU continues to cool while a battery-powered emergency filter unit (EFU) with HEPA and carbon filters provides filtered outdoor air. If power is lost, the EFU continues to operate for pressurization and to maintain the MCR at 0.125 in. of water positive relative to the surroundings for the 72 h accident coping period. During this time, the walls and boundary areas act as passive heat sinks to limit the temperature rise in the main control room.

The reactor building (RB) ventilation system (RBVS) has three non-safety-related subsystems: the contaminated-area ventilation subsystem (CONAVS), refueling and pool-area ventilation subsystem (REPAVS), and the reactor building clean-area ventilation subsystem (CLAVS). These systems are separated from the each other with isolation dampers. The CLAVS and CONAVS subsystems are split into separate trains for serving the two halves of the RB. The RBVS has two non-safety-related filter trains (with HEPA and carbon filters), which are backed up with power supply from the diesel generators. Those systems operate on loss of power, but are not credited in the accident analysis. The fuel building ventilation system (FBVS) has two non-safety-related subsystems: the fuel building general-area ventilation subsystem (FBGAVS) and the fuel building fuel-pool-area ventilation subsystem (FBFPVS). The FBGAVS and the FBFPVS subsystems are once-through systems, and room coolers provide supplementary cooling for selected rooms in the fuel building.

The ESBWR uses a centralized non-safety-related chilled-water plant and provides chilled water to various buildings, including the drywell, based on the primary/secondary loop design concept.

U.S. Evolutionary Power Reactor (USEPR)

Unlike the AP1000 and the ESBWR, the USEPR is not of passive design and is similar to PWR plants, except that the emergency (safety) systems have a four-loop or four-train design: there are four electrical trains of safety systems, four emergency diesels and four loops of safety chilled water. The main control room HVAC system has an active and diverse cooling system consisting of two trains of safety-related water-cooled chillers and two trains of safety-related air-cooled chillers. The main control room air-conditioning system (CRACS) is designed to maintain habitability in the main control room and adjoining rooms during normal operation and during accident conditions involving radiation and toxic gas releases. The CRACS maintains the control room envelope at a 0.125 in. of water positive pressure relative to surrounding areas during accident conditions. The CRACS filtration and air-conditioning equipment and

associated ductwork are located inside the control room pressure boundary, thus eliminating the potential for in leakage of unfiltered air. Smoke detectors and toxic gas sensors in the outdoor air supply duct actuate an alarm in the main control room and automatically place the cooling system in recirculation mode.

The containment building ventilation system (CBVS) is composed of three separate subsystems: the (1) non-safety-related full- and low-flow containment purge system, (2) non-safety-related containment filtration system, and (3) safety-related containment cooling system. The containment low-flow purge subsystem operates during normal plant operation to facilitate containment entry and to support outages activities, whereas the full-flow purge system operates only during outages to control the containment environment. The containment filtration subsystem consists of a filter unit with HEPA and carbon filters and a heater, and is used for cleanup of the containment environment. The containment cooling subsystem contains fans, cooling coils, and associated ductwork for cooling various areas of the containment.

4. PLANT HVAC&R SYSTEMS

4.1 PRESSURIZED-WATER REACTORS

Containment Building

Containment Cooling. The following systems are typical for containment cooling:

Reactor containment coolers. These units remove most of the heat load. Distribution of the air supply depends on the containment layout and the location of the major heat sources.

Reactor cavity air-handling units or fans. These units are usually transfer fans without coils that provide cool air to the reactor cavity.

Control rod or control element drive mechanism (CRDM or CEDM) air-handling units. The CRDM and CEDM are usually cooled by an induced-draft system using exhaust fans. Because the flow rates, pressure drops, and heat loads are generally high, the air should be cooled before it is returned to the containment atmosphere.

Essential containment cooling units. The containment air-cooling system, or a part of it, is normally designed to provide cooling during normal plant operation and after a postulated accident. The system must be able to perform at high temperature, pressure, humidity, and levels of radioactivity. Cooling coils are provided with essential plant service water.

System design must accommodate both normal and accident conditions. The ductwork must be able to endure the rapid pressure build-up associated with accident conditions, and fan motors must be sized to handle the high-density air.

In addition, the system must be analyzed to identify measures to mitigate the effect of water hammer as addressed in NRC's Generic Letter 96-06.

Radioactivity Control. Airborne radioactivity is controlled by the following means:

Essential air filtration units. Redundant filter units powered by two Class 1E buses are used to reduce the amount of airborne radioactivity. The typical system consists of a demister, a heater, a HEPA filter bank, and a carbon adsorber, possibly followed by a second HEPA filter bank or by a high-efficiency (90 to 95%) filter bank. The electric heater is designed to reduce the relative humidity of the incoming air from 100% to less than 70%. All the components of the air filtration unit are environmentally qualified (EQ), and designed to meet the requirements of a LOCA.

In the case of an accident and the subsequent operation of the filter train, the carbon can become loaded with radioactive iodine such that the decay heat could cause the carbon to self-ignite if the airflow

stops. Heat build-up in the carbon adsorber bed should be evaluated, and an appropriate redundant decay heat removal mechanism should be provided.

Containment power access purge or minipurge. Ventilation is sometimes necessary during normal operation, when the reactor is under pressure, to control containment pressure or the level of airborne radioactivity within the containment. The maximum opening size allowed in the containment boundary during normal operation is 8 in.

The system consists of a supply fan, double containment isolation valves in each of the containment wall penetrations (supply and exhaust), and an exhaust filtration unit with a fan. The typical filtration unit contains a HEPA filter and a carbon adsorber, possibly followed by a second HEPA filter or by a medium-efficiency (90 to 95%) filter bank. The system is non-safety-related, and operates during personnel access into the containment with the reactor under pressure. During normal plant operation, the containment tends toward positive pressure because of air leaks and the exhaust fan is often operated as needed to control pressure inside the containment.

This **minipurge** system should not be connected to any duct system inside the containment. It should include a debris screen within the containment over the inlet and outlet ducts, so that the containment isolation valves can close even if blocked by debris or collapsed ducts.

Containment refueling purge. Ventilation is required to control the level of airborne radioactivity during refueling. Because the reactor is not under pressure during refueling, there are no restrictions on the size of the penetrations through the containment boundary. Large openings of 42 to 48 in., each protected by double containment isolation valves, may be provided. The required ventilation rate is typically based on 1 air change per hour.

The system consists of a supply air-handling unit, double containment isolation valves at each supply and exhaust containment penetration, and an exhaust fan. Filters are recommended.

Containment combustible gas control. In the case of a LOCA, when a strong solution of sodium hydroxide or boric acid is sprayed into the containment, various metals react and produce hydrogen. Also, if some of the fuel rods are not covered with water, the fuel rod cladding can react with steam at elevated temperatures to release hydrogen into the containment. Therefore, redundant hydrogen recombiners are needed to remove hydrogen from the containment atmosphere, recombine the hydrogen with oxygen, and return the air to the containment. The recombiners may be backed up by special exhaust filtration trains.

4.2 BOILING-WATER REACTORS

Primary Containment

The primary containment HVAC system consists of recirculating cooling units. It normally recirculates and cools the primary containment air to maintain the environmental conditions specified by the NSSS supplier. During an accident, the system may perform a safety-related function of recirculating the air to prevent stratification of any hydrogen that may be generated if the system is credited in the accident analysis. Depending on the specific plant design, the cooling function may or may not be safety related. Primary containment cooling is necessary for maintaining the life of the components inside the containment and for ensuring that the safety temperature limit of the primary containment is maintained during an accident.

Resistance temperature detectors (RTDs) measure containment temperatures at various locations, and provide input into the volumetric average temperature, which is used as the measure of the containment temperature. The plant's technical specification operating limit is established based on the volumetric average temperature. Temperature problems have been experienced in many BWR primary containments because of temperature stratification

and underestimation of heat loads. The cooling system should be designed to adequately mix the air to prevent stratification. Heat load calculations should include a safety factor sufficient to allow for deficiencies and degradation in insulation.

Reactor Building

The reactor building completely encloses the primary containment, auxiliary equipment, and refueling area. Under normal conditions, the reactor building HVAC system maintains the design space conditions and minimizes the release of radioactivity to the environment. The HVAC system consists of a 100% outdoor air cooling system. Outdoor air is filtered, heated, or cooled as required before being distributed throughout the various building areas. The exhaust air flows from areas with the least potential contamination to areas of most potential contamination. Before exhausting to the environment, potentially contaminated air is filtered with HEPA filters and carbon adsorbers; all exhaust air is monitored for radioactivity. To ensure that no unmonitored exfiltration occurs during normal operations, the ventilation systems maintain the reactor building at a negative pressure relative to the atmosphere.

During an event involving a LOCA, MSLB, FHA, or high radiation in the ventilation exhaust, the HVAC system's safety-related function is to isolate the secondary containment consisting of the reactor building and the refueling area. Once isolated by fast-closing valves, the secondary containment boundary functions to contain any leakage from the primary containment or refueling area.

Once the secondary containment is isolated, a safety-related standby gas treatment system (SGTS) is started to reduce the ground level releases by drawing down the secondary containment pressure to about -0.25 in. of water within 120 s. The SGTS exhausts air from the secondary containment to the environment at an elevated release location referred to as the main stack. The SGTS consists of redundant filtration trains, which consist primarily of HEPA filters and carbon adsorbers. The capacity of the SGTS is based on the amount of exhaust air needed to reduce the pressure in the secondary containment and maintain it at the design level, given the containment leakage rates and required drawdown times.

In addition to the SGTS, some designs include safety-related recirculating air systems within the secondary containment to mix, cool, and/or treat the air during accidents. These recirculation systems sometimes use portions of the normal ventilation system ductwork; therefore, if the ductwork is used for that purpose, then it must be classified as safety related.

Other than the emergency core cooling system (ECCS) pump rooms, the isolated secondary containment area is not cooled during accident events. All safety-related components in the secondary containment must be environmentally qualified to operate at the maximum temperature and the temperature profile for the accident event. Safety-related room coolers served by the plant service water provide cooling to the emergency core cooling system (ECCS) pumps during accident conditions.

Turbine Building

Only a BWR supplies radioactive steam directly to the turbine, which could cause a release of airborne radioactivity to the surroundings. Therefore, areas of the BWR turbine building in which release of airborne radioactivity is possible should be enclosed. These areas must be ventilated and the exhaust filtered to ensure that no radioactivity is released to the atmosphere. Filtration trains typically consist of a prefilter, a HEPA filter, and a carbon adsorber, possibly followed by a second HEPA filter bank or by a medium-efficiency (90 to 95%) filter bank. Filtration requirements are based on the plant and site configuration and commitments for 10CFR50, Appendix I requirements. Depending on outdoor air conditions at the location, the turbine building is cooled either with outdoor air or by area coolers served by a dedicated chilled-water system.

4.3 HEAVY WATER REACTORS

Containment Inlet Air-Conditioning/Exhaust Ventilation System

The production of heavy water in sufficient quantities for the needs of a heavy water reactor is complex and expensive. Once produced, however, deuterium oxide (D_2O) may be reused indefinitely as long as it does not become contaminated. Because heavy water reactor containments are vented and require makeup air, ordinary water (H_2O) is one contaminant that must be contained. This is normally accomplished by means of a non-nuclear safety desiccant air-conditioning unit mounted on the roof of the service building. This unit typically contains a rotary desiccant dryer, hot-water heating coils and chilled-water cooling coils both upstream and downstream of the desiccant wheel, a desiccant regeneration duct containing an electric heater, and a flow control system. The resulting inlet makeup air contains very little moisture. To prevent any radioactive contaminants from escaping up the stack, the containment exhaust ventilation unit typically contains a prefilter bank, a HEPA filter bank, a Type III carbon filter, a second HEPA filter bank, and an exhaust fan.

4.4 AREAS OUTSIDE PRIMARY CONTAINMENT

All areas located outside the primary containment are designed to the general requirements contained in ANSI/ANS *Standard* 59.2. These areas are common to any type of plant.

Auxiliary Building

The auxiliary building contains a large amount of support equipment, much of which handles potentially radioactive material. The building may be air conditioned for equipment protection, and the exhaust is filtered to prevent the release of potential airborne radioactivity. The filtration trains typically consist of a prefilter, a HEPA filter, and a carbon adsorber, possibly followed by a second HEPA filter bank or by a high-efficiency (90 to 95%) filter bank.

The HVAC system is a once-through system, as needed for general cooling. Ventilation is augmented by area or room coolers in the individual equipment rooms requiring additional cooling. The building is maintained at negative pressure relative to the outdoors.

If the equipment in these rooms is not safety related, the area is cooled by normal air-conditioning units. If they are safety related, the area is cooled by safety-related or essential area or room coolers units powered from the same Class 1E (according to IEEE *Standard* 323) power supply as the equipment in the room.

The normal and essential functions may be performed by one cooling unit having both a normal and an essential cooling coil and a safety-related fan served from a Class 1E bus. The normal coil can be a direct-expansion or chilled-water cooling coil served by a normal chilled-water system. The essential coil operates with chilled water from a safety-related chilled-water system or the plant service water, or a safety-related cooling water source.

Control Room

The control room HVAC system serves the control room habitability zone (those spaces that must be habitable following a postulated accident to allow orderly shutdown of the reactor) and performs the following functions:

- Controls indoor environmental conditions
- Provides pressurization to prevent infiltration
- Minimizes unfiltered inleakage to that credit in dose assessments
- Protects the zone from hazardous chemical fume intrusion
- Protects the zone from fire
- Removes noxious fumes, such as smoke

In defining the control room envelope or pressure boundary, it is necessary to ensure that, in the event of abandonment as a result of fire or smoke in the control room, access to the remote shutdown panel is safeguarded.

Design requirements for the control room HVAC system are outlined in 10CFR50, GDC 19 Appendix A, Standard Review Plan Sections 6.4 and 9.4.1, NCR *Regulatory Guides* RG 1.52, 1.78, 1.194, 1.196, and 1.197, and NUREG 0737. In 2003, NRC issued Generic Letter 2003-01 to address control room habitability findings at U.S. nuclear power plants, which suggested that licensees may not have been meeting the control room licensing and design basis, and applicable regulatory requirements, and that existing technical specification surveillance requirements may not have been adequate. As a result, all nuclear plants are required to conduct control room inleakage testing using the tracer gas (SF_6) to validate the integrity of the control room boundary and to ensure compliance with dose assessments per GDC 19, Appendix A. It is also necessary to develop and maintain a control room integrity program in accordance with the plant technical specification requirements to control and maintain boundary breaches. Plants are also required to conduct self-assessments of their control room habitability program every three years and inleakage testing every six years. Control room HVAC filter units are designed to filter radioactive contaminants and are fabricated, designed, and tested per ASME *Standards* N509, N510, N511, and AG-1.

Control Cable Spreading Rooms

These rooms are located directly above and below the control room. They are usually served by an independent ventilating or cooling system or by the air-handling units that serve the electric switchgear room or the control room.

Diesel Generator Building

Nuclear power plants have an auxiliary or back-up power source for all essential and safety-related equipment in case of loss of off-site electrical power. The auxiliary power source consists of at least redundant diesel generators, each sized to meet the emergency power load. Heat released by the diesel generator and associated auxiliary systems is normally removed by a safety-related ventilation.

Emergency Electrical Switchgear Rooms

These rooms house the electrical switchgear that controls essential or safety-related equipment. The switchgear located in these rooms must be protected from excessive temperatures (1) to ensure that its qualified life, as determined by environmental qualification, is maintained and (2) to preserve power circuits required for proper operation of the plant, especially its safety-related equipment.

Battery Rooms

Battery rooms should be maintained at approximately 70 to 80°F for optimum battery capacity and service life. Temperature variations are acceptable as long as they are accounted for in battery sizing calculations. The minimum room design temperature should be taken into account in determining battery capacity. Because batteries produce hydrogen gas during charging periods, the HVAC system must be designed to limit the hydrogen concentration to the lowest of the levels specified by IEEE *Standard* 484, ASHRAE guidelines, OSHA, and the lower explosive limit (LEL) (see Chapter 11 of the 2013 *ASHRAE Handbook—Fundamentals* for more information). The recommended hydrogen concentration (by volume) in the battery room is 2% or less. If battery design information is not available, it is recommended that the exhaust system be designed to provide a minimum of five air changes per hour.

Fuel-Handling Building

New and spent fuel is stored in the fuel-handling building. The building is air conditioned for equipment protection and ventilated with a once-through air system to control potential airborne radioactivity. Normally, the level of airborne radioactivity is so low that the exhaust need not be filtered, although it should be monitored. If significant airborne radioactivity is detected, as can happen during an FHA, the normal building ventilation is isolated and the safety-related system started automatically. The safety-related ventilation system should exhaust through filtration trains powered by Class 1E buses.

Personnel Facilities

For nuclear power plants, these areas usually include decontamination facilities, laboratories, and medical treatment rooms.

Pumphouses

Cooling water pumps are protected by houses that are often ventilated by fans to remove the heat from the pump motors. If the pumps are essential or safety related, the ventilation equipment must also be considered safety related.

Radioactive Waste Building

The building is normally air conditioned for equipment protection and ventilated to control potential airborne radioactivity. The air may require filtration through HEPA filters and/or carbon adsorbers prior to release to the atmosphere.

Technical Support Center

The technical support center (TSC) is an outside facility located close to the control room. Although normally unoccupied, it is used by plant management and technical support personnel during training exercises and accident events.

The TSC HVAC system is designed to provide the same level of comfort (temperature and humidity) and radiological habitability conditions as provided for the control room. The TSC HVAC system is a non-safety-related system, but is augmented to the same level of importance as the main control room HVAC system. An air filtration system (HEPA carbon postfilter) provides the facility protection from radiological releases during an accident. Additional components, such as moisture separators, heaters, and prefilters, are sometimes also used. Because the operation and availability of the TSC is credited in the plant's emergency operating procedures, the TSC HVAC system should be designed with some redundancy such that maintenance on the HVAC system does not require declaration of the TSC as unavailable.

4.5 NONPOWER MEDICAL AND RESEARCH REACTORS

The requirements for HVAC and filtration systems for nuclear nonpower medical and research reactors are set by the NRC. The criteria depend on the type of reactor (ranging from a nonpressurized swimming pool type to a 10 MW or more pressurized reactor), the type of fuel, the degree of fuel enrichment, and the type of facility and environment. Many of the requirements discussed in the sections on various nuclear power plants apply to a certain degree to these reactors. It is therefore imperative for the designer to be familiar with the NRC requirements for the reactor under design.

4.6 LABORATORIES

Requirements for HVAC and filtration systems for laboratories using radioactive materials are set by the DOE and/or the NRC. Laboratories located at DOE facilities are governed by DOE regulations. All other laboratories using radioactive materials are regulated by the

NRC. Other agencies may be responsible for regulating other toxic and carcinogenic material present in the facility.

Laboratory containment equipment for nuclear processing facilities is treated as a primary, secondary, or tertiary containment zone, depending on the level of radioactivity anticipated for the area and on the materials to be handled. For additional information see Chapter 16.

Glove Boxes

Glove boxes are windowed enclosures equipped with one or more flexible gloves for handling material inside the enclosure from the outside. The gloves, attached to a porthole in the enclosure, seal the enclosure from the surrounding environment. Glove boxes permit hazardous materials to be manipulated without being released to the environment.

Because the glove box is usually used to handle hazardous materials, the exhaust is filtered with a HEPA filter before leaving the box and prior to entering the main exhaust duct. In nuclear processing facilities, a glove box is considered primary confinement (see Figure 1), and is therefore subject to the regulations governing those areas. For nonnuclear processing facilities, the designer should know the designated application of the glove box and design the system according to the regulations governing that particular application.

Laboratory Fume Hoods

Nuclear laboratory fume hoods are similar to those used in non-nuclear applications. Air velocity across the hood opening must be sufficient to capture and contain all contaminants in the hood. Excessive hood face velocities should be avoided because they cause contaminants to escape when an obstruction (e.g., an operator) is positioned at the hood face. For information on fume hood testing, refer to ASHRAE *Standard* 110.

Radiobenches

A radiobench has the same shape as a glove box except that in lieu of the panel for the gloves, there is an open area. Air velocity across the opening is generally the same as for laboratory hoods. The level of radioactive contamination handled in a radiobench is much lower than that handled in a glove box.

4.7 DECOMMISSIONING NUCLEAR FACILITIES

The exhaust air filtration system for decontamination and decommissioning (D&D) activities in nuclear facilities depends on the type and level of radioactive material expected to be found during the D&D operations. The exhaust system should be engineered to accommodate the increase in dust loading, with more radioactive contamination than is generally anticipated, because the D&D activities dislodge previously fixed materials, making them airborne. Good housekeeping measures include chemical fixing and vacuuming the D&D area as frequently as necessary.

The following are some design considerations for ventilation systems required to protect the health and safety of the public and the D&D personnel:

- Maintain a higher negative pressure in the areas where D&D activities are being performed than in any of the adjacent areas.
- Provide an adequate capture velocity and transport velocity in the exhaust system from each D&D operation to capture and transport fine dust particles and gases to the exhaust filtration system.
- Exhaust system inlets should be as close to the D&D activity as possible to enhance the capture of contaminated materials and to minimize the amount of ductwork that is contaminated. A movable inlet capability is desirable.

- With portable enclosures, filtration of the enclosure inlet and exhaust air must sustain the correct negative internal pressure.

Low-Level Radioactive Waste

Requirements for the HVAC and filtration systems of low-level radioactive waste facilities are governed by 10CFR61. Each facility must have a ventilation system to control airborne radioactivity. The exhaust air is drawn through a filtration system that typically includes a demister, heater, prefilter, HEPA filter, and carbon adsorber, maybe followed by a second filter. Ventilation systems and their CAMs should be designed for the specific characteristics of the facility.

4.8 WASTE-HANDLING FACILITIES

The handling of radioactive waste requires inventory control of the different radioactive wastes. See the section on Codes and Standards for pertinent publications.

4.9 REPROCESSING PLANTS

A reprocessing plant is a specific-purpose facility. Spent nuclear fuel is opened and the contents dissolved in nitric acid to enable the constituents to be chemically separated and recovered. The offgas contains hazardous chemical and radioactive contaminants. Special cleanup equipment, such as condensers, scrubbers, cyclones, mist eliminators, and special filtration, is required to capture the vapors.

4.10 MIXED-OXIDE FUEL FABRICATION FACILITIES

The mixed-oxide (MOX) fuel fabrication facility (MFFF) is designed to produce MOX fuel for use in commercial nuclear power plants. In the United States, this facility is DOE operated and NRC licensed. MOX fuel fabrication consists of blending polished plutonium dioxide with uranium dioxide to form mixed-oxide pellets and loading them into fuel rods that form fuel assemblies for use as nuclear fuel. The MFFF HVAC design includes several important design features, and it complies with the performance criteria of 10CFR70, ASME AG-1, IEEE 323, and other applicable codes and standards.

In addition to maintaining the design environmental conditions, the HVAC systems are designed to maintain a pressure differential between the building confinement zones and between the building and the outdoors to ensure that cascaded airflow is from zones of lesser contamination potential to zones of greater contamination. The supply air system provides air to all confinement zones. Each confinement zone has its own exhaust system, and the pressure boundaries are maintained by cascaded airflow from tertiary confinement (negative) to secondary confinement (more negative), and then to primary confinement (most negative) zones. Primary and secondary confinement ventilation exhaust systems include both the intermediate and the final filter units in series. Tertiary confinement exhaust systems include only the final filter units. Intermediate filter units contain roughing filter(s) (i.e., stainless steel mesh filter) and HEPA filter(s) in series. Final filter units contain roughing filter(s), prefilter(s) (i.e., stainless steel/glass fiber mesh filter), and two banks of HEPA filter(s) in series. Air locks between confinement zones are designed to minimize personnel contamination exposure by maintaining pressures between various zones. Primary and secondary confinement exhaust systems are provided with on-site emergency diesel power, and battery back-up is provided for the primary confinement exhaust system.

Glove boxes (GB) are provided with room ventilation air, dry air, or inert gas, as determined by the process requirements. GB exhaust piping is connected to common headers for intermediate and final filtration. The ventilation system is designed to maintain a

normal operating pressure of -1.2 to -2.0 in. of water. Pressure-relief valves and vacuum breakers are provided to keep GB pressures within their structural design limits under conditions such as loss of supply flow or failed open valves. Additionally, dump valves (high-volume relief valves connected to exhaust header) are provided to ensure that, in the event of a glove port or bag port breach, the capture velocity at the breach is at least 125 fpm.

Detailed analysis, using compressible-flow pipe network analysis software, is performed for the MFFF ventilation systems and GB ventilation system, and the results are used for airflow balancing and to confirm that confinement is maintained during normal and design-basis accident conditions.

Sprinkler systems for HEPA filtration units are eliminated by integrating ventilation exhaust system design with fire-safety design. To confirm this design approach, a prototype final filter unit is tested in a testing laboratory for higher soot loading and differential pressures than calculated design values. The test results should show no breach in any filter in the prototype unit.

Sheet metal thickness and reinforcement for galvanized steel and stainless steel duct systems, with pressures from $+30$ to -30 in. of water, round duct diameter up to 60 in., rectangular duct width up to 144 in., and temperature exposure up to 400°F, are designed using SMACNA standards. Seismic supports for the duct systems and redundant tornado dampers at outer wall openings are designed to protect the duct systems during abnormal events.

---	--

IN underground mines, lower worker productivity, illness, and potentially death can result from poor working environment conditions. It is therefore extremely important to design, install, and manage underground ventilation systems with the necessary care and attention. Excess humidity, high temperatures, inadequate oxygen, and excessive concentrations of potentially dangerous gases can significantly affect the quality of the working environment if not properly controlled. Ventilation and air cooling are needed in underground mines to minimize heat stress and remove contaminants. As mines become deeper, heat removal and ventilation problems become more difficult and costly to solve.

Caution: This chapter presents only a very brief overview of the principles of mine ventilation planning. The person responsible for such planning should either be an experienced engineer, or work under the direct supervision of such an engineer. Several English-language texts have been written on mine ventilation since 1980 (Bossard 1982; Hall 1981; Hartman et al. 1997; Hemp 1982; Kennedy 1996; McPherson 1993; Mine Ventilation Society of South Africa 1982; Tien 1999). The ventilation engineer is strongly encouraged to study these references.

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic aerosol concentrations under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

1. DEFINITIONS

Definitions specific to mine ventilation and air conditioning are as follows.

Heat stress is a qualitative assessment of the work environment based on temperature, humidity, air velocity, and radiant energy. Many heat stress indices have been proposed (see Chapter 9 of the 2013 *ASHRAE Handbook—Fundamentals* for a thorough discussion); the most common in the mining industry are effective temperature (Hartman et al. 1997), air cooling power (Howes and Nixon 1997), and wet-bulb temperature. The following wet-bulb temperature ranges were derived from experience at several deep western U.S. metal mines:

- $t_{wb} \leq 80^\circ\text{F}$ Worker efficiency 100%
- $80 < t_{wb} \leq 85^\circ\text{F}$ Economic range for acclimatized workers
- $85 < t_{wb} \leq 91^\circ\text{F}$ Safety factor range; corrective action required
- $91^\circ\text{F} < t_{wb}$ Only short-duration work with adequate breaks

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Heat strain is the physiological response to heat stress. Effects include sweating, increased heart rate, fatigue, cramps, and progressively worsening illness up to heat stroke. Individuals have different tolerance levels for heat.

Reject temperature, based on the heat stress/strain relationship is the wet-bulb temperature at which air should be rejected to exhaust or recooled. Reject temperature ranges between 78 and 85°F wb, depending on governmental regulation, air velocity, and expected metabolic heat generation rate of workers. Specifying the reject temperature is one of the first steps in planning air-conditioning systems. The ventilation engineer must be able to justify the reject temperature to management because of the economics involved. If too high, work productivity, health, safety, and morale suffer; if too low, capital and operating costs become excessive.

Critical ventilation depth is the depth at which the air temperature in the intake shaft rises to the reject temperature through auto-compression and shaft heat loads. Work areas below the critical ventilation depth rely totally on air conditioning to remove heat. The critical ventilation depth is reached at about 8000 to 10,000 ft, depending on surface climate in the summer, geothermal gradient, and shaft heat loads such as pump systems.

Base heat load is calculated at an infinite airflow at the reject temperature passing through the work area. The temperature of an infinite airflow will not increase as air picks up heat. **Actual heat load** is measured or calculated at the average stope temperature. It is always greater than the base heat load because the average stope temperature is lower than the reject temperature. More heat is drawn from the wall rock. **Marginal heat load** is the difference between base and actual heat loads. It is the penalty paid for using less than an infinite airflow (i.e., the lower the airflow, the lower the inlet temperature required to maintain the reject temperature and the higher the heat load).

Temperature-dependent heat sources (TDHs) depend on the temperature difference between the source and air. Examples include wall rock, broken rock, and fissure water (in a ditch or pipe).

Temperature-independent heat sources (TIHs) depend only on the energy input to a machine or device after the energy required to raise the potential energy of a substance, if any, is deducted. Examples include electric motors, lights, substation losses, and the calorific value of diesel fuel.

Passive thermal environmental control separates heat sources from ventilating airflows. Examples include insulating pipes and wall rock, and blocking off inactive areas. **Active thermal environmental control** removes heat via airflow and air conditioning quickly enough so that air temperature does not rise above the reject.

Positional efficiency, an important design parameter for mine cooling systems, is the cooling effect reaching the work area divided by the machine evaporator duty. The greater the distance between the machine and work area, the more heat that the cooling medium (air or water) picks up en route.

Percent utilization is the ratio of the evaporator duty of the refrigeration plant over a year in energy units to the duty if the plant had worked the entire year at 100% load. This consideration becomes important when evaluating surface versus underground plants.

Coefficient of performance (COP) usually is defined as the evaporator duty divided by the work of compression in similar units. In mines, the overall COP is used: the evaporator duty divided by all power-consuming devices needed to deliver cooling to the work sites. This includes pumps and fans as well as refrigeration machine compressors.

A **shaft** is a vertical opening or steep incline equipped with skips to hoist the ore, and cages (elevators) to move personnel and supplies. Electric cables and pipes for fresh water, compressed air, cooling water, pump water, and other utilities are installed in shafts. **Drifts and tunnels** are both horizontal openings; a tunnel opens to daylight on both ends, whereas a drift does not. In metal mining, a **stope** is a production site where ore is actually mined. In coal mining, coal is usually produced by either **longwall** (one continuous production face hundreds of feet long) or **room-and-pillar** (multiple production faces in a grid of rooms with supporting pillars in between) methods.

2. SOURCES OF HEAT ENTERING MINE AIR

Adiabatic Compression

Air descending a shaft increases in pressure (because of the mass of air above it) and thus also increases in temperature as if compressed in a compressor. This is because of conversion of potential energy to internal energy, even if there is no heat interchange with the shaft and no evaporation of moisture.

For dry air at standard conditions (59°F at 14.696 psia), the specific heat at constant pressure c_p is 0.24 Btu/lb·°F. For most work, c_p can be assumed constant, but extreme conditions might warrant a more precise calculation: 1 Btu is added (for descending airflow) or subtracted (for ascending airflow) to each pound of air for every 778 ft. The dry-bulb temperature change is $1/(0.24 \times 778 \times 1) = 0.00535^\circ\text{F}$ per foot, or 1°F per 187 ft of elevation. The specific heat for water vapor is 0.45 Btu/lb·°F. So, for constant air/vapor mixtures, the change in dry-bulb temperature is $(1 + W)/(0.24 + 0.45W)$ per 778 ft of elevation, where W is the humidity ratio in pounds of water per pound of dry air.

The theoretical heat load imposed on intake air by adiabatic compression is given in Equation (1), which is a simplified form of the general energy equation:

$$q = 60Q\rho E \Delta d \quad (1)$$

where

- q = theoretical heat of autocompression, Btu/h
- 60 = 60 min/h
- Q = airflow in shaft, cfm
- ρ = air density, lb/ft³
- E = energy added per unit distance of elevation change, 1 Btu/778 ft·lb
- Δd = elevation change, ft

Example 1. What is the equivalent heat load from adiabatic compression of 300,000 cfm at 0.070 lb/ft³ density flowing down a 5000 ft shaft?

Solution:

$$q = (60)(300,000)(0.070)(1/778)(5000) = 8,097,686 \text{ Btu/h}$$

The adiabatic compression process is seldom truly adiabatic: *autocompression* is a more appropriate term. Other heating or cooling sources, such as shaft wall rock, introduction of groundwater or water sprayed in the shaft to wet the guides, compressed-air and water pipes, or electrical facilities, often mask the effects of adiabatic compression. The actual temperature increase for air descending a shaft usually does not match the theoretical adiabatic temperature increase, for the following reasons:

- The effect of seasonal and daily surface temperature fluctuations, such as cool night air on the rock or shaft lining (rock exhibits

thermal inertia, which absorbs and releases heat at different times of the day)

- The temperature gradient of rock related to depth
- Evaporation of moisture in the shaft, which suppresses the dry-bulb temperature rise while increasing the moisture content of the air

The wet-bulb temperature lapse rate varies, depending on the entering temperature and humidity ratio, and the pressure drop in the shaft. It averages about 2.5°F wet bulb per 1000 ft, and is much less sensitive to evaporation or condensation than the dry bulb.

Electromechanical Equipment

Electric motors and diesel engines transfer heat to the air. Loss components of substations, electric input to devices such as lights, and all energy used on a horizontal plane appear as heat added to the mine air. Energy expended in pumps, conveyors, and hoists to increase the potential energy of a material does not appear as heat, after losses are deducted.

Vehicles with electric drives, such as scoop-trams, trucks, and electric-hydraulic drill jumbos, release heat into the mine at a rate equivalent to the nameplate and a utilization factor. For example, a 150 hp electric loader operated at 80% of nameplate for 12 h a day liberates $(150 \text{ hp})(42.4 \text{ Btu/min}\cdot\text{hp})(0.80)(12 \text{ h/day})(60 \text{ min/h}) = 3,663,360 \text{ Btu/day}$. Dividing by 24 h/day gives an average heat load over the day of 152,640 Btu/h. During the 12 h the loader is operating, the heat load is doubled to 305,280 Btu/h. The dilemma for the ventilation engineer is that, if heat loads are projected at the 152,640 rate, the stope temperature will exceed the reject temperature for half the day, and the stope will be overventilated for the other half; if projected at 305,380 Btu/h, the stope will be greatly overventilated when the loader is not present. Current practice is to accept the additional heat load while the loader is present. Operators get some relief when they leave the heading to dump rock, at which time the ventilation system can partially purge the heading.

Diesel equipment dissipates about 90% of the heat value of the fuel consumed, or 125,000 Btu/gal, to the air as heat (Bossard 1982). The heat flow rate is about three times higher for a diesel engine than for an equivalent electric motor. If the same 150 hp loader discussed previously were diesel powered, the heat would average about 458,000 Btu/h over the day, and 916,000 Btu/h during actual loader operation. Both sensible and latent heat components of the air are increased because combustion produces water vapor. If a wet scrubber is used, exhaust gases are cooled by adiabatic saturation and the latent heat component increases even further.

Fans raise the air temperature about 0.45°F per in. of water static pressure. Pressures up to 10 in. of water are common in mine ventilation. This is detrimental only when fans are located on the intake side of work areas or circuits.

Groundwater

Transport of heat by groundwater has the largest variance in mine heat loads, ranging from essentially zero to overwhelming values. Groundwater usually has the same temperature as the virgin rock. Ventilating airflows can pick up more heat from hot drain water in an uncovered ditch than from wall rock. Thus, hot drain water should be stopped at its source or contained in pipelines or in covered ditches. Pipelines can be insulated, but the main goal is isolating the hot water so that evaporation cannot occur.

Heat release from open ditches increases in significance as airways age and heat flow from surrounding rock decreases. In one Montana mine, water in an open ditch was 40°F cooler than when it flowed out of the wall rock; the heat was transferred to the air. Evaporation of water from wall rock surfaces lowers the surface temperature of the rock, which increases the temperature gradient

of the rock, depresses the dry-bulb temperature of the air, and allows more heat to flow from the rock. Most of this extra heat is expended in evaporation.

Example 2. Water leaks from a rock fissure at 20 gpm and 125°F. If the water enters the shaft sump at 85°F, what is the rate of heat transfer to the air?

Solution:

$$\text{Heat rate} = (20 \text{ gpm})(60 \text{ min/h})(8.33 \text{ lb/gal})(1 \text{ Btu/lb}\cdot\text{°F}) \times (125 - 85\text{°F}) = 399,840 \text{ Btu/h}$$

Wall Rock Heat Flow

Wall rock is the main heat source in most deep mines. Temperature at the earth's core has been estimated to be about 10,300°F. Heat flows from the core to the surface at an average of 0.022 Btu/h·ft². The implication for mine engineers is that a geothermal gradient exists: rock gets warmer as the mine deepens. The actual gradient varies from approximately 0.5 to over 4°F per 100 ft of depth, depending on the thermal conductivity of local rock. Table 1 gives depths and maximum **virgin rock temperatures (VRTs)** for various mining districts. Table 2 gives thermal conductivities and diffusivities for rock types commonly found in mining. These two variables are required for wall rock heat flow analysis.

Wall rock heat flow is unsteady-state: it decays with time because of the insulating effect of cooled rock near the rock/air boundary.

Equations exist for both cylindrical and planar openings, but this section discusses cylindrical equations (Goch and Patterson 1940). The method can solve for either instantaneous or average heat flux rate. The instantaneous rate is recommended because it is better used for older tunnels or drifts. For newer drifts, a series of instantaneous rates over short time periods is equivalent to the average rate. The Goch and Patterson calculations are easily performed on a computer using the following variables and equations:

$$Fo = \frac{\alpha\theta}{r^2} \tag{2}$$

$$\epsilon = \{1.017 + 0.7288 \log_{10}(Fo) + 0.1459[\log_{10}(Fo)]^2 - 0.01572[\log_{10}(Fo)]^3 - 0.004525[\log_{10}(Fo)]^4 + 0.001073[\log_{10}(Fo)]^5\}^{-1} \tag{3}$$

$$\text{Heat flux, Btu/h}\cdot\text{ft}^2 = \frac{k(t_{vr} - t_a)(\epsilon)}{r} \tag{4}$$

$$\text{Total heat flow, Btu/h} = (\text{Heat flux})(L)(P) \tag{5}$$

where

- Fo = Fourier number, dimensionless
- k = thermal conductivity of rock, Btu/h·ft·°F
- L = length of section, ft
- P = perimeter of section, ft
- r = radius of circular section, ft, or equivalent radius of rectangular section; $r = (A/\pi)^{1/2}$, where
- A = cross-sectional area of section, ft²
- t_a = air dry-bulb temperature, °F
- t_{vr} = virgin rock temperature, °F
- α = thermal diffusivity of rock (equals k/ρc), ft²/h, where
- ρ = rock density, lb/ft³
- c = heat capacity, Btu/lb·°F
- ε = function of Fourier number for instantaneous rate, dimensionless (Whillier and Thorpe 1982)
- θ = average age of section, h

Example 3. A 500 ft long section of drift, 12 ft high by 15 ft wide, was driven in quartzite with a VRT of 110°F. The drift was started 20 days before the face was reached, and the face is 1 day old. One design criterion is keeping the average dry-bulb temperature of the air in the drift at 80°F. How much heat will flow into the section?

Solution: From Table 2, the thermal conductivity of quartzite is 3.18 Btu/h·ft·°F and the diffusivity is 0.090 ft²/h. The average age of the section is (20 + 1 days)/2 = 10.5 days, or 252 h. The cross-sectional area of the drift is 12 × 15 = 180 ft² and the perimeter is (12 + 15) × 2 = 54 ft. The equivalent radius of the drift is (180/π)^{1/2} = 7.57 ft. The following equations are then applied:

$$\text{Using Equation (2), } Fo = \frac{\alpha\theta}{r^2} = \frac{(0.090)(252)}{7.57^2} = 0.396$$

$$\text{Using Equation (3), } \epsilon = 1.336$$

Using Equation (4),

$$\text{Heat flux} = \frac{k(t_{vr} - t_a)(\epsilon)}{r} = \frac{(3.18)(110 - 80)(1.336)}{7.57} = 16.84 \text{ Btu/h}\cdot\text{ft}^2$$

Using Equation (5),

$$\text{Total heat flow} = (\text{Heat flux})(L)(P) = (16.84)(500)(54) = 454,700 \text{ Btu/h}$$

Thus, to keep the average temperature of the drift section at 80°F db, 37.9 tons of refrigeration are needed in that section.

The Goch and Patterson method lacks a convective heat transfer coefficient at the rock/air boundary, and overestimates heat transfer in a dry drift by 8 to 15%. It also does not have a wetness factor.

Because a drift with water on the perimeter draws more heat from wall rock, the method underestimates heat flow. Almost all drifts have some wetness on the floor, back, and side walls, though it may not be visible. Comparisons of the Goch and Patterson method with field measurements and results from commercial software under typical conditions (a drift with 20 to 60% of the perimeter wetted) indicate that the overestimate is nearly equal to the underestimate. When using Goch and Patterson for drift heat loads, keep drift section lengths under 200 ft and do not apply any contingency factor to the calculated heat load.

Heat load calculations for stoping require a large number of variables. Irregular shapes, sporadic advance rates, intermittent TIH sources, fissure water, and nonhomogeneous or anisotropic (with directionally differing heat conducting properties) rock are difficult to model (Duckworth and Mousset-Jones 1993; Marks and Shaffner 1993). For cut-and-fill stoping with a sand floor, measured heat loads are about 70% of the heat loads predicted by Goch and Patterson. Other stoping methods such as room-and-pillar or tabular reef mining are more amenable to planar heat load equations. Patterson (1992) gives empirical graphs relating heat load to productivity and depth.

Ventilation engineers needing to project heat loads for new mines or extensive tunnel projects can write their own computer program using the Goch and Patterson equations, or use a commercial software package. These programs account for convective heat transfer, wetness, elevation changes, and TIH sources that can make hand calculations tedious. However, program input must be carefully derived or the output will be misleading.

Heat from Broken Rock

Freshly blasted broken rock can liberate significant amounts of heat in a confined area. The broken rock's initial and final temperatures, and cooling of the rock en route from the face to the hoisting facility, must be estimated.

$$\text{Heat, Btu} = (\text{mass})(\text{specific heat})(\text{VRT} - \text{final temperature}) \quad (6)$$

$$\text{Heat load, Btu/h} = \frac{\text{Heat}}{(\text{time, h})} \quad (7)$$

Example 4. A 12 ft high by 15 ft wide by 10 ft long drift round is blasted in quartzite where the VRT is 120°F. Quartzite has a 168 lb/ft³ density and a 0.2 Btu/lb·°F specific heat. By the time the rock is hoisted to the surface 4 h later, it has cooled to 90°F. What is the heat load imposed on the drift and shaft?

Solution:

$$\text{Heat} = (12 \text{ ft} \times 15 \text{ ft} \times 10 \text{ ft} \times 168 \text{ lb/ft}^3)(0.2 \text{ Btu/lb} \cdot \text{°F}) \\ \times (120 - 90 \text{ °F}) = 1.8144 \times 10^6 \text{ Btu}$$

$$\text{Heat load} = \frac{1.8144 \times 10^6 \text{ Btu}}{4 \text{ h}} = 453,600 \text{ Btu/h}$$

Heat from Other Sources

Heat produced by oxidation of timber and sulfide minerals can be locally significant and even cause mine fires. Fortunately, timber is seldom used for ground support in modern mines. Heat from blasting can also be appreciable. The typical heat potential in various explosives is similar to that of 60% dynamite, about 1800 Btu/lb. This heat is usually swept out of the mine between shifts and thus is not tallied in heat load projections. Body metabolism is only a concern in refuge chambers and is rarely if ever included in heat load projections. Although these heat sources are usually neglected, the ventilation engineer must remain vigilant for cases where local effects might be significant.

Summation of Mine Heat Loads

Mine cooling requirements should be estimated after mining methods, work sites, production rates, and equipment are specified,

and heat sources identified. The time frame, during which the ventilation and cooling systems must provide an acceptable work environment, is normally 10 years, but can vary.

Total heat for a mine or mine section is the summation of all TIH and TDH sources. It helps to plot heat sources on a schematic. The heat load from the surface to the entrance of the stope is assessed first, starting with TIH sources because they influence TDH sources. Shaft heat loads, autocompression, and drift heat loads are added to the air en route to stopes. The process should take only one iteration to find a stope entering temperature. Stope heat load is calculated by assuming that the wet bulb leaving the stope equals the design reject temperature. The air temperature entering the stope is estimated, and heat load equations are used to calculate the exit temperature. If this exit temperature exceeds the reject temperature, a lower stope entering temperature is assumed and a new exit temperature is calculated. The process is repeated with new stope entering temperatures until the calculated stope exit temperature equals the design reject temperature.

If the entering stope temperature calculated from the surface is greater than the entering stope temperature calculated from the reject temperature, higher airflow or air conditioning will be needed. Psychrometrics can determine the size of the airflow increase or cooling required.

3. HEAT EXCHANGERS

Underground heat exchangers can be water-to-refrigerant, air-to-refrigerant, water-to-water, air-to-water, or air-to-air. Brine can be used instead of water where freezing might occur. Heat exchangers can be direct (e.g., spray chambers) or indirect (e.g., conductive heat transfer through tubes or plates).

See Chapters 19 to 24, 26 to 30, 37 to 40, and 42 to 48 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for general guidelines when designing large cooling plants for mine duty.

Shell-and-Tube and Plate Heat Exchangers

Shell-and-tube heat exchangers are the mainstay of refrigeration machines used in mines. Machines in the 200 to 400 ton range may use either direct expansion (DX) or flooded evaporators. In both cases, the working fluid (refrigerant or water) is circulated through the tubes.

South African mines often use plate-and-frame evaporators in large surface chilled-water plants (van der Walt and van Rensburg 1988). These machines can cool water to within a degree of freezing without danger of rupture. In contrast, shell-and-tube evaporators should not be expected to chill water below 38°F. Manufacturers must be consulted.

Shell-and-tube water-to-water heat exchangers have been used in mine cooling systems to avoid pumping return water against high heads (the U-tube effect). Chilled water from the surface is sent down to the high-pressure (tube) side of the exchanger. Water on the low-pressure side operates district chiller systems or spot coolers. The shell-and-tube water-to-water heat method is not very popular, perhaps because it requires high-pressure supply and return piping. The second law of thermodynamics limits the approach temperature of the outlet high-pressure water to the inlet low-pressure water temperature. This tends to limit heat removal in deep mines that would require at least three heat exchanger stations, in series, in the shaft.

Cooling Coils

Cooling coils can be DX or chilled-water coils. DX coils are used with spot coolers and typically range from 15 to 60 tons. Some modern spot coolers use dual coils in parallel for compactness. Chilled-water coils, used in district chiller systems, are also used in a wide range of sizes.

Air-side fouling is the main operational problem with cooling coils in mines. Coils with fin spacing tighter than 6 fins per inch are not recommended. Water-side fouling is minimal if the water is of fair quality, the circuit is closed, and a corrosion inhibitor is added to the circuit.

Small Spray Chambers

Small spray chambers can be used as an alternative to cooling coils. Heat transfer is direct, air-to-water. Spray chamber maintenance is minimal, and the amount of water sprayed is typically one-half to one-third that required for a cooling coil at the same duty. Some washing effect also occurs in the chamber.

Spray chambers are open systems that dump water into a ditch or collection pond after spraying. This water drains to the dewatering system or is pumped back to the chiller plant. Small spray chambers are still popular for small duties in mines that chill service water, but the pumping system must be able to handle the increased service water requirement.

Cooling Towers

When heat loads are large, the full capacity of a mine’s heat removal system will probably be needed. A key component of the heat removal system is exhaust air. The ventilation engineer for a deep, hot mine must be proficient at designing underground cooling towers for condenser heat rejection, and spray chambers for cooling airflows.

Rather than using the standard HVAC&R method of assessing cooling tower performance, as described in Chapter 40 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*, mining engineers use the South African factor-of-merit method, developed in the 1970s for designing direct-contact heat exchangers (Bluhm 1981; Burrows 1982; Whillier 1977). This method requires a psychrometric program and the following equations:

$$\Sigma = h - (c_{pw})(W)(t) \tag{8}$$

Note that *t* is either the wet-bulb temperature for air, or the water temperature, depending on whether Σ_{ai} or Σ_{wi} is calculated.

$$q = (M_w)(c_{pw})(t_{wi} - t_{wo}) \tag{9}$$

$$q = (M_a)(\Sigma_{ao} - \Sigma_{ai}) \tag{10}$$

$$n_w = \frac{t_{wi} - t_{wo}}{t_{wi} - t_{ai}} \tag{11}$$

$$R = \frac{(M_w)(c_{pw})(t_{wi} - t_{ai})}{(M_a)(\Sigma_{wi} - \Sigma_{ai})} \tag{12}$$

$$N = \frac{F}{(1 - F)(R^{0.4})} \tag{13}$$

$$n_w = \frac{(1 - e^{-N(1-R)})}{(1 - Re^{-N(1-R)})} \text{ (for counterflow towers)} \tag{14}$$

where

- a* = air
- c_{pw}* = specific heat of water at constant pressure, 1 Btu/lb·°F
- F* = factor of merit, roughly equivalent to *UA* factor in conductive heat transfer, dimensionless; ranges from 0 (no heat transfer) to 1 (as much as heat transfer as allowed by second law takes place)
- h* = enthalpy of moist air, Btu/lb
- i* = inlet
- M* = mass flow rate, water or air, lb/min

- N* = number of transfer units, an intermediate factor for calculating water efficiency
- n_w* = water efficiency, dimensionless
- o* = outlet
- q* = heat rate to be transferred in chamber, Btu/lb
- R* = tower capacity factor, dimensionless; ratio of heat capacity of water to heat capacity of air under limits of second law
- t* = temperature, °F
- W* = humidity ratio of moist air, lb water per lb air
- w* = water
- Σ = energy of air, Btu/lb; total enthalpy minus enthalpy of liquid water evaporated into air [approximated by $(c_{pw})(W)(t)$, where *t* is wet bulb]; dependent only on wet bulb and barometric pressure

Designing an underground cooling tower requires the exhaust air mass flowrate *M_a*, the wet- and dry-bulb temperatures available at the tower, and the ambient barometric pressure. A psychrometric program is needed to calculate enthalpy, density, humidity ratio, and specific volume from the wet bulb, dry bulb, and barometric pressure. Tower airflow is taken from measurements or from the mine plan. The temperature, if not measurable (e.g., in a new mine), can be assumed to approach the reject temperature. Experience shows that air usually enters exhaust at about 82 to 83°F wb. Designing a cooling tower involves the following steps:

1. Calculate heat rejection rate in the tower (evaporator duty × condenser heat rejection factor, typically between 1.2 and 1.4). Discuss with the manufacturer.
2. Select condenser water flow and use Equation (9) to calculate Δt_w in the tower and machine condensers.
3. Specify cooling tower diameter and tower air velocity.
4. Calculate *M_w*/*M_a*.
5. Calculate heat rejection rate per cfm in tower.
6. Calculate air enthalpy *h* and use Equation (8) to calculate Σ_{ai} .
7. Select a factor of merit for tower using Table 3.
8. Estimate tower capacity factor *R* (e.g., *R* = 0.5). Using *R* = 1 in Equation (14) will result in division by zero. Skip to Step 10 if *R* = 1, and use the value of *F* for *n_w*.
9. Use Equation (13) to calculate *N*.
10. Use Equation (14) to calculate water efficiency *n_w*.
11. Use Equation (11) to calculate inlet water temperature *t_{wi}*.
12. Use Equation (8) to calculate Σ_{wi} , the energy of air at inlet water temperature *t_{wi}*.
13. Use Equation (12) to calculate a new tower capacity factor *R*.
14. Compare the *R* calculated in Step 13 with the *R* estimated in Step 8. If different by more than 1%, return to Step 8 and re-estimate *R*. Repeat Steps 9 to 14 until the calculated *R* is within 1% of the estimated *R*.
15. Calculate air and water temperatures leaving the tower and the evaporation rate.

Keep the following empirical design criteria in mind during Steps 1 to 5:

Table 3 Factors of Merit

	Factor of Merit Range	Source
Vertical counterflow, open, unpacked	0.50 to 0.70	Hemp 1982
Horizontal cross-flow		
Single-stage	0.40 to 0.55	Hemp 1982
Two-stage	0.57 to 0.72	Marks 1988
Three-stage	0.69 to 0.81	Marks 1988
Four-stage	0.76 to 0.87	Marks 1988
Commercial packed cooling		
Counterflow tower	0.68 to 0.78	Patterson 1992
Cross-flow tower	0.55 to 0.65	Patterson 1992

- Realistic Δt_w in tower is 12 to 16°F
- Realistic water loading in tower is 6 to 18 gpm per square foot
- Optimum water velocity in machine condenser tubes (3 to 13 fpm, per manufacturer's recommendations) is based on tubing material and water quality
- Realistic maximum air velocity in tower is 1600 fpm
- Realistic ratios of the mass flows of water to air M_w/M_a range from 0.5 to 2.5
- A realistic heat rejection rate in tower is 32 to 65 Btu/h per cfm

Values outside these design parameters are sometimes used (especially when plant duty is increased at a future date), but the penalty paid is a higher condensing temperature and lower COP. Once q , F , M_a , t_{ai} , and M_w are specified, only one t_{wi} , t_{wo} , and t_{ao} will balance all equations.

Example 5. Design a cooling tower for a 1000 ton refrigeration plant planned for a deep, hot mine. Exhaust airflow for heat rejection is 250,000 cfm at 83°F saturated. Barometric pressure is 15.226 psia (31 in. of mercury, or 1000 ft below sea level). What size cooling tower is needed, how much condenser cooling water is required, what are the inlet and outlet air and water temperatures, and how much makeup water is needed?

Solution:

Step 1. For a refrigeration plant to produce 1000 tons of cooling, it must reject about 1000 tons \times 12,000 Btu/h \cdot ton \times 1.25 condenser heat rejection factor = 15,000,000 Btu/h.

Step 2. Select a condenser water flow. For this example, start with 1 gpm per 12,000 Btu/h rejected. The condenser flow is thus 1250 gpm, or 10,413 lb/min at 8.33 lb/gal. The change in water temperature is calculated from Equation (9):

$$\Delta t_w = \frac{15,000,000 \text{ Btu/h}}{(10,413 \text{ lb/min})(60 \text{ min/h})(1 \text{ Btu/lb} \cdot \text{°F})} = 24^\circ\text{F}$$

That exceeds the realistic 12 to 16°F Δt_w , so arbitrarily increase the water flow to 2000 gpm and recalculate Δt_w . In practice, selecting the condenser water flow is anything but arbitrary. Generally, the higher the flow, the better, but higher flows require larger condensers to keep tube velocity within design limits, larger cooling towers with more nozzles, and significantly larger pumps. Actual condenser water flow is a compromise between machine and tower performance, capital cost, and overall plant COP (operating cost). At 2000 gpm for this example, $\Delta t_w = 15^\circ\text{F}$, which is acceptable.

Step 3. Specify cooling tower diameter by using a midrange value to 12 gpm/ft².

$$(\pi/4)d^2 = \frac{2000 \text{ gpm}}{12 \text{ gpm/ft}^2} \quad \therefore d = 14.57 \text{ ft} \approx 15 \text{ ft}$$

$$\text{Air velocity} = \frac{250,000 \text{ cfm}}{(\pi/4)(15^2)} = 1415 \text{ fpm} (< 1600 \text{ fpm; acceptable})$$

Step 4. Calculate M_w/M_a .

$$M_w = (2000 \text{ gpm})(8.33 \text{ lb/gal}) = 16,660 \text{ lb}_w/\text{min}$$

The specific volume for 83°F saturated inlet air at 15.226 psia is 13.71 ft³/lb_a. M_a is therefore

$$M_a = \frac{250,000 \text{ cfm}}{13.71 \text{ ft}^3/\text{lb}_a} = 18,235 \text{ lb}_a/\text{min}$$

$$M_w/M_a = \frac{16,660}{18,235} = 0.914 \quad (0.5 < M_w/M_a < 2.5; \text{acceptable})$$

Step 5. The heat rejection rate in the tower is

$$\frac{15,000,000 \text{ Btu/h}}{250,000 \text{ cfm}} = 60 \text{ Btu/h per cfm}$$

This rate is approaching the upper acceptable limit. Consideration should be given to routing more air through the tower if possible. All design criteria have now been met.

Step 6. The enthalpy of air h_{ai} at 83°F saturated and 15.226 psia is 45.95 Btu/lb. $\Sigma_{ai} = 45.95 - (1)(0.0237)(83) = 43.98 \text{ Btu/lb}$.

Step 7. Select a factor of merit for the tower. From Table 3, an open, unpacked, vertical counterflow cooling tower can conservatively be expected to have a 0.55 factor of merit. If the tower is well designed and actually has a higher factor, the tower will return cooler water to the plant and COP will increase.

Step 8. Estimate $R = 0.5$ (first pass).

Step 9. Calculate N from Equation (13):

$$N = \frac{0.55}{(1 - 0.55)(0.5^{0.4})} = 1.613$$

Step 10. Calculate n_w from Equation (14):

$$n_w = \frac{1 - e^{-1.613(1 - 0.5)}}{1 - 0.5e^{-1.613(1 - 0.5)}} = 0.713$$

Step 11. Calculate t_{wi} from Equation (11) (after manipulation, and assuming that $t_{wi} - t_{wo} = \Delta t_w$):

$$t_{wi} = \frac{\Delta t_w}{n_w} + t_{ai} = \frac{15}{0.713} + 83 = 104.04^\circ\text{F}$$

Step 12. Σ_{wi} at 104.04°F and 15.226 psia = 77.11 - (1)(0.047)(104.04) = 72.22 Btu/lb.

Step 13. Calculate the new R using Equation (12):

$$R = \frac{(16,660)(1)(104.04 - 83)}{(18,235)(72.22 - 43.98)} = 0.681$$

Step 14. The new R is higher than the 0.5 R estimated in Step 8. Return to Step 8 and iterate until the R calculated in Step 13 equals the R projected in Step 8. This occurs at $R = 0.662$.

Step 15. All other values can now be calculated.

Per Step 11, $t_{wi} = 106.09^\circ\text{F}$

$$t_{wo} = 106.09 - 15 = 91.09^\circ\text{F}$$

$$\begin{aligned} \Sigma_{ao} &= \Sigma_{ai} + \frac{15,000,000 \text{ Btu/h}}{(18,235 \text{ lb/min})(60 \text{ min/h})} \\ &= 43.98 + 13.71 = 57.69 \text{ Btu/lb} \end{aligned}$$

$$t_{ao} = 94.5^\circ\text{F} \text{ (via psychrometric iteration)}$$

The water evaporated in the tower is the difference in humidity ratios $\Delta W \times$ the mass flow of dry air. From psychrometric equations, $W_{83^\circ\text{F}} = 0.0237 \text{ lb}_w/\text{lb}_a$ and $W_{94.5^\circ\text{F}} = 0.0347 \text{ lb}_w/\text{lb}_a$.

$$\begin{aligned} \text{Evaporation rate} &= (18,235 \text{ lb/min}) \frac{0.0347 - 0.0237 \text{ lb}_w/\text{lb}_a}{8.33 \text{ lb}_w/\text{gal}} \\ &= 24.1 \text{ gpm} \end{aligned}$$

Total makeup water depends on evaporation rate, water carryover (if any), and blowdown used to control dissolved solids in the condenser circuit. Leakages and carryover can be deducted from the blowdown. Makeup water is usually planned at 1 to 3% of the condenser water flow, depending on the quality of the makeup water, allowable cycles of concentration of dissolved solids, and water treatment plan.

Vertical unpacked cooling towers in mines often use clog-resistant full-cone nozzles circling the top of the tower, at least 40 ft above the pond. South African mines tend to use ham-type sprayers. Nozzle pressure of 30 psig is typically specified: lower water pressures do not generate the fine water droplets preferred for heat transfer, and higher pressures increase pumping costs. Higher pressures

can also impinge water drops into side walls, where the water runs in sheets down the sides. This drastically reduces the surface area of the water flow, which reduces heat transfer. Rings circling the tower are recommended to kick water running down the sides back into the airstream. Unpacked towers do not have as high a factor of merit as towers with film packing or splash bars, but they are virtually maintenance free and have low resistance to airflow. Figure 1 shows a typical underground vertical counterflow cooling tower.

After a cooling tower begins operation, the actual factor of merit should be determined. This is accomplished by measuring air and water flow rates and temperatures at the tower inlet and outlet, and then working the cooling tower equations in reverse. The actual factor of merit can be used to determine performance at other inlet conditions. This applies to mine, industrial, and commercial cooling towers.

Large Spray Chambers (Bulk Air Coolers)

The procedure for designing spray coolers is the same as for cooling towers, with the following minor changes:

$$q = M_w c_{pw} (t_{wo} - t_{wi}) \tag{15}$$

$$q = M_a (\Sigma a_i - \Sigma a_o) \tag{16}$$

$$n_w = \frac{1 - e^{-R(1-X)}}{R} \tag{17}$$

where $X = e^N$ for horizontal cross-flow chambers.

A perfect counterflow tower has a factor of merit of 1.0, but the factor of merit for a single cross-flow chamber (see Chapter 40 in the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*) cannot exceed 0.63 (Bluhm 1981). Two-stage cross-flow chambers are most often specified. Counterflow performance is approximated, and the counterflow equation for water efficiency can be used. Three-stage chambers can be designed when water flow must be limited to control pumping costs. Four-stage chambers are rarely cost effective in mining applications.

Spray chambers often use vee-jet nozzles at 30 psig, placed uniformly along the chamber length and designed to cover the cross section evenly. Sprays should just reach the back of the chamber.

Fig. 1 Underground Open Counterflow Cooling Tower

Mist eliminators are usually installed at the chamber exit. Whereas cooling towers need makeup water to replace evaporated water, bulk air coolers gain water through condensation. This water can be sent to the condenser side as makeup. Figure 2 shows a typical two-stage horizontal cross-flow spray chamber.

4. MINE-COOLING TECHNIQUES

A mine-cooling system typically sends air, water, or ice into the mine at a low enthalpy state and removes it at a higher one. In hot mines, heat is typically rejected to water being pumped to the surface, and to exhaust air being drawn from the mine. There are many combinations and variations on how this is accomplished. Economics and site-specific conditions determine the optimum methods.

Increasing Airflows

This alternative should be considered first: it is usually less expensive to moderately increase airflows than to install refrigeration if the mine is above the critical ventilation depth. Increasing airflows also helps remove diesel fumes, which is increasingly important for modern mining. However, in deep, usually older mines with small cross-sectional airways, airflow increases may not be practical because of the cube relationship between fan power and airflow increase through a given resistance. Circuit resistance reduction via new airways or stripping existing airways is very expensive.

Chilling Service Water

When a mine requires additional heat removal, and airflow increases are not practical, consider chilling the service water. Most mining methods require that water be sprayed on rock immediately after blasting to control dust; chilled water can intercept rock heat before the heat escapes into the air. This is a very flexible method of heat removal because it is applied when and where it is needed the most. After blasted rock is removed, the water is turned off and routed elsewhere. Main water lines should be insulated when service water is chilled.

Water is usually chilled in surface plants. A single-pass system is used if regional water supplies are plentiful. If scarce, water is pumped to the surface, recooled, and returned underground. Recycling can ease discharge permit requirements and thus save on treatment costs. Some mines have zero discharge permits. Regions with low winter temperatures and low relative humidities during summer

Fig. 2 Two-Stage Horizontal Spray Chamber

have a natural cooling capacity that is adaptable to water chilling on the surface. Warm mine water is precooled in an evaporative cooling tower before being sent to the refrigeration plant.

Reducing Water Pressure and Energy Recovery Systems

All mines send water underground for drilling, cleaning, suppressing dust, and wetting broken rock. Hot mines using extensive cooling systems often send large volumes of water underground solely for air conditioning. The pressure of descending water must be broken periodically. The most common methods are the open cascade system and pressure-reducing valves. Turbines can also break the pressure and recover a significant portion of the potential energy that would otherwise be lost. Two types of turbines are suitable for mine use: the Pelton wheel, which is most often used, and a centrifugal pump specially designed to run in reverse. The Pelton wheel rotor is shaped like the spokes of a wheel, with cups attached to the ends of the spokes. One or two nozzles shoot high-pressure water onto the cups, spinning the wheel. It is at least 80% efficient over a range of flows, simply constructed, and readily controlled. A wide operating range is important because water demand fluctuates. A turbine can turn either a generator or pump. Turning a generator is preferred because it separates service and cooling water from the mine dewatering system so that downtime in one system is less likely to disrupt the other.

Besides providing power to help return service water to the surface, turbines have another advantage: unrecovered potential energy is converted to heat at a rate of 1 Btu/lb per 778 ft of depth. If, for example, a 6000 ft deep mine uses 1000 gpm for air conditioning without energy recovery, the water will heat by 7.71°F. If 80% efficient turbines are used, the water temperature rise is about $0.2 \times 7.71 = 1.54^\circ\text{F}$. The refrigerating effect lost is only 64 instead of 321 tons.

Other energy recovery devices include hydrotransformers (large pistons transfer force from the high-pressure side to the lower-pressure side), and three-pipe feeder systems that deliver chilled water on one side while pumping out crushed ore on the other. These concepts have been tested in Europe and South Africa.

Bulk Cooling Versus Spot Cooling

Engineers must balance bulk cooling and spot cooling. **Bulk cooling** using a centrally located plant cools the entire mine, or a large section of it. Benefits are lower cost per ton installed, generally better maintenance, and lower temperatures in non-stopping areas such as haul drifts. Bulk cooling intake air is often done at warm-climate mines to provide winter-like or better conditions year round. Air is cooled in large direct-contact spray chambers adjacent to the shaft and then injected into the shaft below the main landing.

Cooling the entire mine draws more heat from surrounding wall rock, so a larger system must be designed to ensure proper stope cooling (i.e., positional efficiency suffers). When a multilevel mine is bulk cooled, cooling may be wasted on upper levels where heat load is low.

Spot cooling provides adequate temperature control in exploration and development headings, and in stopes on the fringes of mining activity. Total heat load is lower, but cost per ton is higher and temperatures in some areas might exceed design limits.

Combination (Integrated) Surface Systems

Combination (or integrated) systems can cool both air and water. Surface plants devote a higher fraction of cooling capacity to bulk cool intake air in the summer. In winter, a higher fraction is used to chill service or air-conditioning water. Water is delivered underground via open or closed systems, with or without energy recovery. Figure 3 shows components of an integrated mine cooling system.

Fig. 3 Integrated Cooling System

Underground Refrigeration

Larger refrigeration machines also can be located underground. They usually produce chilled water for cooling air in spray chambers, and heat is rejected to exhaust air via cooling towers. Another method is to operate district cooling systems, using a chiller to produce water for a closed network of cooling coils installed in parallel. These coils can be used in auxiliary systems at individual work areas, or installed in a bank. As with spot coolers, coils should be installed upwind of blasting to limit air-side fouling. Condenser heat from district chiller systems is rejected either to service water or to the mine-dewatering system.

Ice Plants

For ultradeep mines (>12,000 ft), or those at the performance limits of existing water and airflow heat rejection systems, ice cooling should be considered. In going from 32 to 90°F before being pumped out of the mine, cooling water starting as ice can remove about 4.5 times the heat as the same mass flow of chilled water in going from 45 to 90°F:

$$\text{Heat removal (Btu/lb)} = \text{Sensible} + \text{Latent}$$

$$\text{Heat removal of chilled water} = (1 \text{ Btu/lb} \cdot ^\circ\text{F})(90 - 45) = 45 \text{ Btu/lb}$$

$$\text{Heat removal of ice} = (1 \text{ Btu/lb} \cdot ^\circ\text{F})(90 - 32) + 144 \text{ Btu/lb} = 202 \text{ Btu/lb}$$

$$\text{Heat removal factor increase of ice over water} = 202/45 = 4.5$$

South African mines have been at the forefront in this application (Sheer et al. 2001). Both chunk and slurry delivery methods send ice to underground chambers, where it mixes with warm water returning from the mining area. The cold mixed water is then sent back to the mining area.

Several successful systems have been installed. Cost has dropped as technology improves; the overall COP of ice systems for ultradeep mines is now competitive with traditional cooling methods.

Thermal Storage

This Canadian innovation uses near-surface ice stopes or rock rubble to effectively and inexpensively heat intake air in the winter and cool it in the summer (Stachulak 1989).

Controlled Recirculation

This technique, used in conjunction with bulk air cooling, can reduce ventilation and air-conditioning requirements in older, deep mines, especially heavily mechanized ones (Tien 1999). Besides increasing air velocities in work areas without drawing more surface air through a high-resistance circuit, controlled recirculation reduces the heat load caused by autocompression. Using Equation (1), for every 100,000 cfm at standard density brought from the surface, the lost cooling capacity per 1000 ft of descent is

$$\begin{aligned} \text{Heat Load} &= (100,000 \text{ ft}^3/\text{min})(60 \text{ min/h})(0.075 \text{ lb/ft}^3) \\ &\times \left(\frac{1 \text{ Btu}}{778 \text{ ft/lb}} \right) (1000 \text{ ft}) \\ &= 578,406 \text{ Btu/h, or } 48.2 \text{ tons of cooling lost} \\ &\text{per } 100,000 \text{ cfm, per } 1000 \text{ ft} \end{aligned}$$

Controlled recirculation systems must be designed very carefully, with stringent monitoring and control safeguards.

Operator Cabs and Cooling Vests

Mechanization can add significant heat, especially in confined auxiliary-ventilated spaces. Most noncoal mines have converted to diesel equipment, although some use electric loaders and trucks. Coal mines are also mechanizing, but more slowly. The biggest problem with diesel engine heat is related to the greatest advantage of these vehicles: mobility. Heat and emissions from a diesel vehicle in a confined area can tax almost any ventilation system. Increasingly, cabs are being specified for large diesel vehicles. Cabs come equipped with window-type air conditioners and HEPA filters to capture diesel particulate and dust. After the diesel vehicle has left the heading, the mine ventilation and cooling system can provide an acceptable environment for other personnel. Cabs are expensive; however, because a loader often visits multiple headings in a week, the cost of a cab is much less than maintaining the design reject wet-bulb temperature in all headings at all times.

Cooling vests are not popular in mining. They are bulky, reduce mobility, and are time-consuming to prepare and use. Vests have limited application for mechanics, electricians, pipe-fitters, and others who must enter hot areas to set up ventilation and cooling. Vests using blue-ice packs or dry ice last two to three hours; those using compressed-air venturi-type coolers require an umbilical cord.

Other Methods

Other methods being developed include the air cycle (air, compressed on the surface and sent underground to a turbine, turns a generator and exits at -40°F), and the ammonia cycle (sending down liquid ammonia, evaporating it, and sending the vapor back to surface condensers). These methods may be best suited to ultradeep mines where other cooling methods are already fully developed.

Transferring heat from current stopes to wall rock or rock rubble in previously worked-out stopes (the only method that does not remove heat from the mine) has also been considered. Refrigeration equipment would have to operate at a high condensing temperature to produce water hot enough to transfer heat to worked-out stopes.

5. SELECTING A MINE-COOLING METHOD

After mine-cooling and ventilation requirements have been projected, the designer must analyze and select the best method(s) for meeting those requirements. Cost-benefit analysis is the most widely used, but hardware reliability, dependency on outside factors, flexibility, safety, and technological level are just as important. Some factors to consider include the following:

- **Seasonal ambient conditions.** Warm-climate mines tend to bulk-cool air on the surface in industrial direct-contact spray chambers located close to the intake shaft.
- **Orebody and mining methods.** The more massive the orebody, the more ideal bulk cooling becomes. When stopes are scattered and continuously advanced into new areas, district or spot cooling might be better.
- **Mining rate.** This is critical: heat removal is energy related, not necessarily power related. A fast mining rate prompts a high instantaneous heat load (Btu/h), but less heat energy (Btu) per ton of production. This is because wall rock is covered by fill or isolated before its total heat energy has escaped into the airstream. The Btu per ton of production incurs the air-conditioning costs. Leave as much heat in the wall rock as possible.
- **Size and condition of major airways.** In older mines, small airways often limit airflow increases. This may prompt the need for air conditioning sooner than it normally would have been necessary.
- **Heat sources.** The contribution of TIH and TDH sources to the total can help determine the balance of passive to active thermal environmental controls, the ratio of airflow to air conditioning, and whether cabs should be specified.
- **Cost of power, water, labor, and supplies.** Knowing these costs is critical for assessing optimum capital expenditure to control operating costs. For example, if power cost is high, spending extra for a higher-COP system may be warranted.
- **Governmental regulations.** Heat stress standards can influence the size of the system. Other safety issues may constrain design, such as not using combustible pipe insulation or ammonia machines underground.

Basic cooling alternatives for specific cases are summarized in Table 4. Airflows are described as limited, medium, or large. One way to express airflow for a given mine is the ratio of tons of airflow per ton of ore. Limited airflow is defined as less than 8 tons of air per ton of ore, medium airflow is 8 to 16 tons per ton, and large airflow is over 16 tons per ton.

Table 4 Basic Cooling Alternatives

	Warm Climate	Cool/Cold Climate
Massive orebody (deep)	Large or medium airflow	Medium airflow
	Chill service water	Chill service water
	Bulk-cool air on surface	Bulk-cool air underground
	Bulk-cool air underground	Thermal storage
Massive orebody (shallow)	Large airflow	Large or medium airflow
	Bulk-cool air on surface	Chill service water on surface
	Chill service water	Shell and tube
Scattered orebody (multilevel)	Shell and tube	Shell and tube
	Large airflow if not too deep	Large or medium airflow
	Chill service water	Chill service water
	Bulk-cool air on surface	District chiller systems
	District chiller systems	Thermal storage
Ultradeep orebody (massive and/or multilevel)	Spot coolers/spray chambers	
	Limited airflow	Limited airflow
	Chill service water	Chill service water
	District chiller systems	District chiller systems
	Ice cooling	Ice cooling
Small orebody	Controlled recirculation	Controlled recirculation
	Bulk-cool air on surface	District chiller systems
	Chill service water	Chill service water
	District chiller systems	Spot coolers
Porous rock	Spot coolers	
	District chiller systems	District chiller systems
	Spot coolers	Spot coolers

These ranges are based on an unpublished study of approximately 100 mines of all types, worldwide. The ranges discussed are for heat removal only. Additional airflow for methane or radon removal must be addressed separately.

6. MECHANICAL REFRIGERATION PLANTS

Surface Plants

Centrifugal or helical rotary screw machines are typically used in surface plants to chill water or bulk-cool air. Banks of machines are usually installed in parallel: plant design must accommodate one machine being down at any given time for maintenance while others operate. Shell-and-tube heat exchangers are standard, although plate-and-frame are used if water close to the freezing point is specified. The most common refrigerant for positive-displacement compression is HCFC-22. Ammonia is also commonly used in surface plants. Absorption machines can be considered if external waste heat is available.

Underground Plants

Large underground plants do the same work as surface plants, but are closer to work areas. Better positional efficiency and percent utilization are the advantages. Whereas surface plants use atmospheric air for heat rejection, underground plants use mine exhaust air, which raises natural ventilation pressure and aids circuit fans. Components for underground machines must be disassembled for transport down the shaft.

The main disadvantage of underground refrigeration is that heat rejection is limited by the amount of available exhaust air. Excavating underground refrigeration rooms and spray chambers is more costly than erecting prefabricated surface buildings. Maintenance is also more difficult because of shaft logistics. Power is more difficult to supply to an underground facility, and subject to more disruptions.

Spot Coolers

Spot coolers with 15 to 100 ton capacity allow driving long development headings, or cooling exploration sites before installing primary ventilation and cooling equipment. Development headings can be advanced more rapidly and under more comfortable conditions. Condenser heat is most often removed by service water, although some air-to-air condensers are used.

Spot coolers use reciprocating, scroll, or small screw compressors. Hermetic scroll compressors are becoming more popular because they handle liquid slugging better than reciprocating compressors and are less expensive. Spot coolers use direct exchange (DX) air-cooling coils. The packaged unit includes a fan, which draws air through the coil (or coils, in a dual-coil unit) and then blows it through duct to the heading. Spot coolers must be compact and portable because they are moved often. The service water required is typically 1.1 gpm per ton, but can be less if the water temperature is under 55°F, or more if it is over 70°F. A return drain pipe is recommended to prevent contact between hot discharge water (often over 100°F) and ambient air. Coils sometimes receive dusty air immediately after blasting; if so, coils must be washed at least every other day.

Spot coolers are expensive, but often are the only choice for cooling exploration, development, and small-scale stoping on the fringes of mining activity.

Maintenance

Mines with extensive systems (e.g., a large chiller plant, or over 10 spot coolers) should employ a mechanic specializing in refrigeration. Mines with over 2000 tons probably need a second mechanic.

These persons should be factory trained and must be certified to handle refrigerants. Refrigeration specialists can be assisted periodically or full time by apprentice mechanics. Another viable approach is a maintenance contract with the equipment manufacturer or supplier, or an independent HVAC&R shop. Some mines have a full-time person cleaning coils.

A fouling factor ($\text{ft}^2 \cdot \text{h} \cdot ^\circ\text{F}/\text{Btu}$) should be calculated from lab analysis of the condenser water, especially for district chillers using sump water. Planning a tube-cleaning regimen, either manual, acid circulation, or automatic with brushes and a flow reversal valve, is critical. Underground condensers can become plugged within a couple of weeks without cleaning, depending on the fouling factor. Water treatment is needed to control scale, corrosion, and organisms in surface or underground plants with cooling towers.

7. MINE AIR HEATING

Cold-climate mines typically heat intake air in the winter. In Canada, heating intake air can cost more than all other ventilation costs combined (Hall et al. 1989). However, without heat, water in the shaft will freeze, disrupting hoisting operations and damaging shaft support members, cables, and pipes. Very cold air and icy floors are safety and health hazards; heavy gloves and other protective clothing required can make routine tasks difficult. Intake air is typically heated to just above the freezing point. Autocompression and shaft heat loads further temper the air as it downcasts into the mine.

Steam coils operated by boilers burning wood, coal, fuel oil, or natural gas often served as shaft heaters in the past. Electric resistance heaters have also been used, but they are expensive to operate. Waste heat from compressor stations has also been used.

When exhaust and intake shafts are located close together, a circulating glycol or heat pump system can be used to transfer heat from exhaust air to intake. For every degree of total heat (sensible plus latent) given up by warm saturated exhaust air, the same mass flow of cold intake air can be heated sensibly by 4 degrees. Either coils or a cooling tower extracts heat from exhaust air, and then coils transfer this heat to the intake air.

Controlled recirculation (up to 25% of total airflow) can also be applied to heat intake air (Hall et al. 1989). The system is temporarily shut down during blasting.

Some cold-climate mines isolate the primary production shaft from the ventilation circuit. A slight upcast flow of uncontaminated air maintains good conditions in the shaft for hoisting ore and moving personnel and supplies. The disadvantage of this method is that ventilation duties of the production shaft must be transferred to one or more expensive stand-alone intake airways.

Natural gas and/or propane heaters are typically used at modern mines. Natural gas is preferred because it is less expensive and it burns more cleanly. Where natural gas is not available, propane must be trucked to the mine site. The same heater can burn either natural gas or propane; thus, propane can be used for back-up in case natural gas is cut off (mechanical conversion is required from gas to propane). Direct-fired heaters are usually preferred because the entire heat value of the fuel enters the intake airstream. If indirect heaters are used, roughly 15 to 25% of the heat is lost up the flue pipe.

Two types of natural gas or propane heaters have been used to heat intake air: (1) a grid of burner bars installed in a housing at the intake shaft, sometimes with louvers to adjust the flow of intake air and to mix air from the heaters with outdoor air; and (2) a crop dryer type of burner. Temperature sensors installed downstream can modulate both heater types to ensure that no more heat is applied than necessary to bring the temperature of the mixed intake air to 34°F.

Carbon monoxide sensors should also be installed downstream of the heaters. Experience at two mines in the western United States

Table 5 Heating Values for Fuels

Fuel	Value	Source
Natural gas	1000 Btu/ft ³	Kennedy 1996
Propane	90,000 Btu/gal	Kennedy 1996
Bituminous coal	12,300 to 14,400 Btu/lb	Abbeon Cal 2001
Fuel oil	143,000 Btu/gal	Abbeon Cal 2001
Wood	15,000,000 to 31,000,000 Btu/cord	Abbeon Cal 2001

shows that the CO content of intake air heated by direct-fired burners can reach 10 to 20 parts per million.

Equation (18) is used to calculate the total heat required, assuming that the air has a low humidity ratio (which is the case for very cold air), and that no water is evaporated in the heater. Heating values for different fuels are given in Table 5.

$$\text{Heat, Btu/h} = (\text{Airflow, cfm})(60 \text{ min/h})(\text{density, lb/ft}^3) \times (0.24 \text{ Btu/lb}\cdot^\circ\text{F})(\Delta t, ^\circ\text{F}) \quad (18)$$

where $\Delta t = 34^\circ\text{F}$ minus the intake air temperature.

Example 6. A mine is located where the atmospheric air temperature can drop to -20°F for two or more weeks per year. Occasionally the temperature drops to -30°F . An intake shaft handles 400,000 cfm, and the density of air entering the shaft in winter is 0.070 lb/ft³. What heating should be installed at the shaft intake to keep the shaft free of ice?

Solution: Sizing heaters is usually based on average cold periods, not extreme cold snaps. Here, a direct-fired heater is sized to raise -20°F air to 34°F . When the temperature drops to -30°F for short periods, intake airflow should be temporarily reduced. Using Equation (18),

$$\text{Heat} = (400,000)(60)(0.070)(0.24)[34 - (-20)] = 21,800,000 \text{ Btu/h}$$

If natural gas is used, the volume required is

$$\frac{21,800,000 \text{ Btu/h}}{1000 \text{ Btu/ft}^3} = 21,800 \text{ ft}^3/\text{h}$$

If propane is used, the gallons required are

$$\frac{21,800,000 \text{ Btu/h}}{90,000 \text{ Btu/gal}} = 242 \text{ gal per hour}$$

8. MINE VENTILATION

Mine ventilation supplies air (oxygen) to underground facilities, and removes dangerous or harmful contaminants such as methane, radon, strata gases, dust, blasting fumes, and diesel emissions. Ventilation also removes heat and helps control humidity in hot mines. Planning a ventilation system consists of five basic steps: (1) determining airflows; (2) planning the primary circuit; (3) specifying circuit fans, ventilation controls, and their installation; (4) determining auxiliary system requirements; and (5) assessing health and safety aspects.

Determining Airflows

Mining operations generate differing types and amounts of contaminants, and airflows dilute and remove these contaminants. The ventilation engineer must work closely with mine planning staff to understand where and how much production will take place, and what contaminants will be generated. The federal Mine Safety and Health Administration (MSHA 2013) regulates contaminant concentrations to limits specified in the Federal Register, CFR 30. Controlling the most problematic contaminant normally keeps all others within their legal limits. For coal mines, contaminants of concern are typically methane and coal dust; for uranium mines, radioactive dust and radon progeny; for non-dieselized hard rock mines, usually silica dust and blasting fumes; for dieselized mines, typically diesel emissions. Design airflows for dieselized

nonuranium metal mines range from 75 to 150 cfm per diesel horsepower, depending on the reference cited. With the current emphasis on controlling diesel emissions, start planning at 100 cfm per horsepower.

Total airflow is a summation of airflows for individual work areas, plus a leakage factor. Leakage is defined as airflow that does not ventilate any active work area or permanent site such as a pump room. A “tight” system minimizes leakage through well-constructed doors and seals, by minimizing the number of possible leakage paths, and by careful fan placement. Leakage can range from 10% of total airflow at a tight metal mine to 80% at some coal mines.

The ratio of tons of air per ton of ore production is about 2 to 4 for block cave mines, 6 to 8 for nondieselized cut-and-fill metal mines, and 9 to 16 for dieselized metal mines. Gassy coal and uranium mines can have significantly higher ratios, depending on the methane or radon generation rate.

Example 7. A new mechanized cut-and-fill gold mine is planned. Ore production is expected to be 1,200,000 tons per year. Intake air density is 0.070 lb/ft³. What is the rough airflow required for ventilation?

Solution: The airflow range is 9 to 16 tons of air per ton of ore for dieselized metal mines. For a first-pass guess, assume an average 12.5 tons per ton. The total weight of the air through the mine in a year is

$$(1,200,000 \text{ tons ore per year}) \times (12.5 \text{ tons air per ton ore}) = 15,000,000 \text{ tons air per year}$$

$$\text{Airflow cfm} = \frac{(15,000,000 \text{ tons/yr})(2000 \text{ lb/ton})}{(0.070 \text{ lb/ft}^3)(525,600 \text{ min/yr})} = 815,400 \text{ cfm}$$

Ratios provide a good first guess. However, the ventilation engineer should derive the total airflow by listing all operations, estimating leakages, and adding the specific airflows required to ventilate each operation (zero-based planning). As with reject temperature, the total airflow selected should be economically justifiable to management.

Airflow specification may change with time because of production, equipment, or mining method changes.

Planning the Circuit

With airflow specified and work sites plotted, the ventilation engineer must lay out the primary circuit. The three basic types of airways are intake, work area, and exhaust. Sizing airways is normally based on keeping velocity within acceptable limits: if velocity is too low, the airway is oversized and thus costs more than necessary; if it is too high, pressure drop is too large and raises operating costs. Air velocity should not exceed 1200 fpm in production shafts and haul drifts. Higher velocities can create dust problems and lead to employee discomfort. However, velocities in bare circular concrete exhaust shafts can approach 5000 fpm if necessary. Air velocity in vertical upcast exhaust shafts should avoid the 1400 to 2300 fpm range because water droplets become entrained into the airstream and may form sheets, causing surging at the main fan.

Resistance to airflow is calculated using Atkinson’s (1854) and McPherson’s (1993) equations:

$$\Delta H = RQ^2 \frac{d}{0.075} \quad (19)$$

where

- ΔH = pressure drop, in. of water
- R = resistance, in. of water $\cdot \text{min}^2/\text{ft}^6$
- Q = airflow, cfm
- d = actual air density, lb_m/ft^3
- 0.075 = standard air density, lb_m/ft^3

$$R = \frac{kLP}{5.2A^3} \quad (20)$$

where

- k = friction factor, $\text{lb}_f \cdot \text{min}^2 / \text{ft}^4$ (includes effects of pipes, ground support, and rock surface roughness)
- L = length, ft
- P = perimeter of opening, ft
- 5.2 = conversion factor, $\text{lb}_f / \text{ft}^2 \cdot \text{in. of water}$
- A = area of opening, ft^2

For rectangular drifts, the k factor can range from 22×10^{-10} for a smooth, concrete-lined straight drift to 90×10^{-10} for an unlined, irregular curved drift. For shafts, the k factor can range from 12×10^{-10} for a smooth-sided borehole to over 500×10^{-10} for a heavily timbered rectangular shaft. See Hartman et al. (1997), McPherson (1993), and Tien (1999) for more precise airway resistance specification.

Example 8. Mine plans call for 65,000 cfm to be sent through 2000 ft of 10 ft wide by 10 ft high drift. The k factor from measurements of similar drifts is $50 \times 10^{-10} \text{ lb}_f \cdot \text{min}^2 / \text{ft}^4$. The average temperature is 75°F wb and 80°F db. The barometric pressure is 13.8 psia. What is the resistance of this drift, and what is the air pressure drop?

Solution: Using psychrometric equations in Chapter 1 of the 2013 *ASHRAE Handbook—Fundamentals*, the density is $0.0683 \text{ lb}/\text{ft}^3$.

$$\begin{aligned} R &= \frac{kLP}{5.2A^3} = \frac{(50 \times 10^{-10})(2000)(40)}{(5.2)(100)^3} \\ &= 7.69 \times 10^{-11} \text{ in. of water} \cdot \text{min}^2 / \text{ft}^6 \\ \Delta H &= RQ^2 \frac{d}{0.075} = (7.69 \times 10^{-11})(65,000)^2 \frac{0.0683}{0.075} \\ &= 0.30 \text{ in. of water} \end{aligned}$$

A mine ventilation circuit contains airways in series and in parallel. The overall resistance (Hartman et al. 1997) is

$$\text{For series: } R_T = R_1 + R_2 + R_3 + \dots + R_n \quad (21)$$

$$\text{For parallel: } \frac{1}{\sqrt{R_T}} = \frac{1}{\sqrt{R_1}} + \frac{1}{\sqrt{R_2}} + \frac{1}{\sqrt{R_3}} + \dots + \frac{1}{\sqrt{R_n}} \quad (22)$$

Example 9. If Airway #1 has a resistance of 1×10^{-10} , Airway #2 has a resistance of 2×10^{-10} , and Airway #3 has a resistance of 3×10^{-10} , what is the resistance of these three branches in series and in parallel?

Solution:

Series:

$$\begin{aligned} R_T &= 1 \times 10^{-10} + 2 \times 10^{-10} + 3 \times 10^{-10} \\ &= 6.0 \times 10^{-10} \text{ in. of water} \cdot \text{min}^2 / \text{ft}^6 \end{aligned}$$

Parallel:

$$\begin{aligned} \frac{1}{\sqrt{R_T}} &= \frac{1}{\sqrt{1 \times 10^{-10}}} + \frac{1}{\sqrt{2 \times 10^{-10}}} + \frac{1}{\sqrt{3 \times 10^{-10}}} \\ R_T &= 1.92 \times 10^{-11} \text{ in. of water} \cdot \text{min}^2 / \text{ft}^6 \end{aligned}$$

Modern ventilation network computer analysis uses Kirchhoff's laws to balance airflows: (1) the summation of airflows into a junction equals the summation out, and (2) the summation of pressure drops around any enclosed mesh equals zero.

Computer simulation allows quick analysis of a wide range of scenarios. Most programs use a balancing algorithm based on the work of Hardy Cross in the 1960s and 1970s. The program iterates as it converges on final balanced airflows. Fan curves or regulators can be inserted in almost any branch.

Regulators or section booster fans control airflow in branches. Without regulation, too little or too much airflow may occur; nevertheless, circuits should be designed with as many free-split branches

(branches without a fan or regulator) as possible to minimize overall resistance. Free-split branches are often located in circuit extremities.

A mine should have more intakes than exhausts. This enhances safety, because miners have more escape paths, and because more paths bring in fresh air if a fire occurs in one of the intakes. Also, exhaust shafts can generally handle greater air velocities and hence larger quantities, so fewer exhaust shafts are needed.

Metal mines often contain circuit booster fans. Underground boosters can create neutral points in the system where air short circuits from intake to exhaust above the point, and recirculates from exhaust to intake below the point. Uncontrolled recirculation should be minimized.

Exhausting primary circuits are commonly used in both metal and coal mines (intakes do not have airlocks). Under normal operation, this produces a negative mine pressure gradient. If fans fail or are deactivated, barometric pressure in the mine rises, which temporarily helps keep methane in coal mines from flowing away from gob (mining waste) areas (Kennedy 1996).

Specifying Circuit Fans

Primary fans are either centrifugal or axial. South African mines typically use large centrifugals, whereas most U.S. and Canadian mines use axials. Both types have advantages. Efficiency (up to 90%) is about the same with either type. Centrifugals are heavier duty, quieter, do not have a pronounced stall region, and can generate higher static pressures (over 30 in. of water). Axials are more compact, and airflows can be easily adjusted by blade angle changes. Primary fans range from 100 to over 3500 hp each. Surface installations with multiple fans are common for large airflows and for back-up operation when one fan is turned off for maintenance. Circuit fans can also be installed underground, especially in metal mines.

Primary fans are specified while the circuit is designed. Engineers must often balance airway considerations (sizes and numbers) and fan specifications. Select a fan that will operate on an efficient part of its curve. Fan speed, quantity, pressure, and power are related in the fan laws equations, described in Chapter 21 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*. Take care also to anticipate future circuit changes as mining operations advance.

The fan installation must be designed after primary fans are selected. Consequences of fan downtime must be carefully considered, especially for coal mines, because methane concentrations can increase when circuit airflows decrease. Fans exhausting a mine are typically mounted horizontally near a vertical shaft or borehole. A 90° transition turns the air into the fan inlet. An isolation door is installed between the transition and fan. Coal mines require a blast door to dampen a shock wave caused by a possible methane or coal dust explosion. An evasé, or diffuser, is attached to the fan outlet to recover part of the velocity pressure exiting the mine. A silencer can be added if surface noise reduction is desired. Increasingly, variable-speed drives are used with electric motors to turn the fans. These drives provide soft start, and speeds from 50 to 100% of synchronous speed, and even to 110% for temporary emergency duty. The installation must be designed for accessibility and ease of maintenance.

Determining Auxiliary System Requirements

Auxiliary fan and duct systems deliver air into dead-end headings. These systems are generally not permitted in coal mines but are common in metal mines. A blowing system is most often used. A fan is set in a fresh air base at the start of a drift, and duct is installed as the drift advances. For drifts under 1000 ft, flexible brattice-cloth duct can be used. Longer drifts that require booster fans need rigid duct because duct gage pressure can drop below atmospheric. Rigid duct also offers less resistance than brattice-cloth duct, but it is about eight times as expensive.

The air quantity needed at the face is determined by the equipment used and the rate at which blasting and diesel fumes must be removed. Ducts are sized for the air quantity needed and for space limitations in the drift. Fans are selected to provide the specified airflow. In general, a single-stage axial fan can generate up to 10 in. of water static pressure, which should deliver required airflow up to 2500 ft through properly sized duct. A larger duct or a two-stage axial fan is needed if distance is much longer. For very long drifts, booster fans are needed about every 2500 ft.

An exhausting system is often used for drifts requiring quick ingress after blasting. Air flows to the face through the drift, captures fumes, and is blown back to the circuit through duct. This keeps the drift clear of fumes. Disadvantages include the following: (1) the air picks up heat and humidity en route to the face, (2) rigid duct is required, and (3) the face is not swept by air as with a blowing system. A face overlap fan and duct can be installed.

Chapter 21 of the 2013 *ASHRAE Handbook—Fundamentals* provides a friction chart for round duct. However, it is better to acquire the friction chart of the specific duct being considered from the supplier. Shock losses through couplings and bends must be tallied. One important consideration is leakage through couplings. This can be minimized by careful installation, keeping duct pressure under 10 in. of water static pressure, and installing longer pieces of duct (up to 100 ft for brattice cloth, or 20 ft for rigid).

Cassettes loaded with brattice-cloth duct are now used for drifts driven by rapidly advancing tunnel boring machines.

Duct damage is common in mines. Mobile equipment and fly rock from blasting can punch holes in the duct. These factors can drastically reduce airflow. Take care to minimize damage, and to quickly repair or replace damaged pieces.

Assessing Health and Safety

Few aspects of underground mining have as direct an impact on health, safety, and morale as ventilation. No component of ventilation design should be undertaken without a rigorous review of health and safety aspects, including the risk of

- Fire and explosion
- Dangerous and toxic substances
- Heat
- Ventilation equipment usage

For metal mines, fire is the most significant potential ventilation hazard. Fuel, heat, and oxygen are required for combustion; removing any of these components will prevent combustion. Fuel sources such as oil, diesel fuel, and blasting agents are kept in special areas designed to keep out ignition sources. Sprinkler or chemical suppression systems can be installed in these areas as well as in repair shops. Mobile equipment fires are a special concern for modern mining: vehicles should be fitted with a dry chemical fire suppression system, triggered either automatically or by the operator. Electric substation and conveyor fires can be very dangerous.

Engineers should anticipate various scenarios in ventilation circuits. What are the fire risks in any given area? If a fire broke out in any location, how would circuits respond? Would fire-induced natural drafts change airflow quantities and directions? How would fire be detected, how would miners be notified, how would they escape, and how would the fire be fought? MSHA requires that refuge chambers be constructed if miners cannot be hoisted to the surface within 1 h of notification. The ventilation staff must work closely with the safety department and mine management in preplanning how to respond to different emergencies.

Spontaneous combustion is a problem for both metal and coal mines. Fortunately, timber is now seldom used for ground support, although many older mines have worked-out areas that contain timber. Coal, being combustible, can be particularly troublesome.

Circuits must be designed so that spontaneous combustion fires will not contaminate active workings.

For coal mines, methane and coal dust explosions pose the greatest risk. Equipment must be rated “permissible,” or non-sparking. Airways should be coated with rock dust to prevent a methane ignition from propagating. Methane is explosive in air from 5 to 15% concentration. Whenever methane reaches 0.25%, MSHA requires that changes be made to improve ventilation. At 0.5%, further steps must be taken, and no other work is permitted until the concentration drops. At 1%, all personnel except those working on ventilation must be evacuated from the affected area.

Ventilation is the first line of defense against toxic or asphyxiating gases. These can be generated by blasting (CO, CO₂, NH₃, and NO_x) and by diesel engines (CO, NO_x, SO₂, various hydrocarbon compounds, and soot). The rock itself can release CO₂ and H₂S.

The relationship between heat stress and accident frequency has been clearly established in South African mines (Stewart 1982). Work area temperatures should be kept under 85°F wb, especially where heavy physical work is performed.

Ventilation and air-conditioning equipment may also pose health and safety risks. All fan inlets require screens. Fans should be equipped with vibration sensors that can deactivate the fan if necessary. Silencers may be needed if personnel work nearby. Refrigeration rooms must be well ventilated in case of a sudden refrigerant release. Duct, pipe insulation, and other substances such as foam for seals should be approved by MSHA in accordance with 30 CFR Part 7. Electrical systems must meet rigorous MSHA codes.

CHAPTER 30

INDUSTRIAL DRYING

<i>Mechanism of Drying</i>	30.1
<i>Applying Hygrometry to Drying</i>	30.1
<i>Determining Drying Time</i>	30.2
<i>Drying System Selection</i>	30.3
<i>Types of Drying Systems</i>	30.3

DRYING removes water and other liquids from gases, liquids, and solids. The term is most commonly used, however, to describe removing water or solvent from solids by thermal means. **Dehumidification** refers to the drying of a gas, usually by condensation or by absorption with a drying agent (see Chapter 32 of the 2013 *ASHRAE Handbook—Fundamentals*). **Distillation**, particularly **fractional distillation**, is used to dry liquids.

It is cost-effective to separate as much water as possible from a solid using mechanical methods *before* drying using thermal methods. Mechanical methods such as filtration, screening, pressing, centrifuging, or settling require less power and less capital outlay per unit mass of water removed.

This chapter describes industrial drying systems and their advantages, disadvantages, relative energy consumption, and applications.

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

1. MECHANISM OF DRYING

When a solid dries, two processes occur simultaneously: (1) the transfer of heat to evaporate the liquid and (2) the transfer of mass as vapor and internal liquid. Factors governing the rate of each process determine the drying rate.

The principal objective in commercial drying is to supply the required heat efficiently. Heat transfer can occur by convection, conduction, radiation, or a combination of these. Industrial dryers differ in their methods of transferring heat to the solid. In general, heat must flow first to the outer surface of the solid and then into the interior. An exception is drying with high-frequency electrical currents, where heat is generated within the solid, producing a higher temperature at the interior than at the surface and causing heat to flow from inside the solid to the outer surfaces.

2. APPLYING HYGROMETRY TO DRYING

In many applications, recirculating the drying medium improves thermal efficiency. The optimum proportion of recycled air balances the lower heat loss associated with more recirculation against the higher drying rate associated with less recirculation.

Because the humidity of drying air is affected by the recycle ratio, the air humidity throughout the dryer must be analyzed to determine whether the predicted moisture pickup of the air is physically

attainable. The maximum ability of air to absorb moisture corresponds to the difference between saturation moisture content at wet-bulb (or adiabatic cooling) temperature and moisture content at supply air dew point. The actual moisture pickup of air is determined by heat and mass transfer rates and is always less than the maximum attainable.

ASHRAE psychrometric charts for normal and high temperatures (No. 1 and No. 3) can be used for most drying calculations. The process does not exactly follow the adiabatic cooling lines because some heat is transferred to the material by direct radiation or by conduction from the metal tray or conveyor.

Example 1. A dryer has a capacity of 90.5 lb of bone-dry gelatin per hour. Initial moisture content is 228% bone-dry basis, and final moisture content is 32% bone-dry basis. For optimum drying, supply air is at 120°F db and 85°F wb in sufficient quantity that the exhaust air is 100°F db and 84.5°F wb. Makeup air is available at 80°F db and 65°F wb.

Find (1) the required amount of makeup and exhaust air and (2) the percentage of recirculated air.

Solution: In this example, the humidity in each of the three airstreams is fixed; hence, the recycle ratio is also determined. Refer to ASHRAE Psychrometric Chart No. 1 to obtain the humidity ratio of makeup air and exhaust air. To maintain a steady-state condition in the dryer, water evaporated from the material must be carried away by exhaust air. Therefore, the pickup (the difference in humidity ratio between exhaust air and makeup air) is equal to the rate at which water is evaporated from the material divided by the weight of dry air exhausted per hour.

Step 1. From ASHRAE Psychrometric Chart No. 1, the humidity ratios are as follows:

	Dry bulb, °F	Wet bulb, °F	Humidity ratio, lb/lb dry air
Supply air	120	85	0.018
Exhaust air	100	84.3	0.022
Makeup air	80	65.2	0.010

Moisture pickup is $0.022 - 0.010 = 0.012$ lb/lb dry air. The rate of evaporation in the dryer is

$$90.5 (228 - 32)/100 = 177 \text{ lb/h}$$

The dry air required to remove the evaporated water is $177/0.012 = 14,750$ lb/h.

Step 2. Assume x = percentage of recirculated air and $(100 - x)$ = percentage of makeup air. Then

$$\begin{aligned} \text{Humidity ratio of supply air} = & \\ & (\text{Humidity ratio of exhaust and recirculated air})(x/100) \\ & + (\text{Humidity ratio of makeup air})(100 - x)/100 \end{aligned}$$

Hence,

$$0.018 = 0.022(x/100) + 0.010(100 - x)/100$$

$$x = 66.7\% \text{ recirculated air}$$

$$100 - x = 33.3\% \text{ makeup air}$$

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

3. DETERMINING DRYING TIME

The following three methods of finding drying time are listed in order of preference:

- Conduct tests in a laboratory dryer simulating conditions for the commercial machine, or obtain performance data using the commercial machine.
- If the specific material is not available, obtain drying data on similar material by either of the above methods. This is subject to the investigator's experience and judgment.
- Estimate drying time from theoretical equations (see the Bibliography). Care should be taken in using the approximate values obtained by this method.

When designing commercial equipment, tests are conducted in a laboratory dryer that simulates commercial operating conditions. Samples used in the laboratory tests should be identical to the material found in the commercial operation. Results from several tested samples should be compared for consistency. Otherwise, test results may not reflect the drying characteristics of the commercial material accurately.

When laboratory testing is impractical, commercial drying data can be based on the equipment manufacturer's experience.

Commercial Drying Time

When selecting a commercial dryer, the estimated drying time determines what size machine is needed for a given capacity. If the drying time has been derived from laboratory tests, the following should be considered:

- In a laboratory dryer, considerable drying may result from radiation and heat conduction. In a commercial dryer, these factors are usually negligible.
- In a commercial dryer, humidity may be higher than in a laboratory dryer. In drying operations with controlled humidity, this factor can be eliminated by duplicating the commercial humidity condition in the laboratory dryer.
- Operating conditions are not as uniform in a commercial dryer as in a laboratory dryer.
- Because of the small sample used, the test material may not be representative of the commercial material.

Thus, the designer must use experience and judgment to modify the test drying time to suit the commercial conditions.

Dryer Calculations

To estimate preliminary cost for a commercial dryer, the circulating airflow rate, makeup and exhaust airflow rate, and heat balance must be determined.

Circulating Air. The required circulating or supply airflow rate is established by the optimum air velocity relative to the material. This can be obtained from laboratory tests or previous experience, keeping in mind that the air also has an optimum moisture pickup. (See the section on Applying Hygrometry to Drying.)

Makeup and Exhaust Air. The makeup and exhaust airflow rate required for steady-state conditions within the dryer is also discussed in the section on Applying Hygrometry to Drying. In a **continuously operating dryer**, the relationship between moisture content of the material and quantity of makeup air is given by

$$G_T(W_2 - W_1) = M(w_1 - w_2) \quad (1)$$

where

- G_T = dry air supplied as makeup air to the dryer, lb/h
- M = stock dried in a continuous dryer, lb/h
- W_1 = humidity ratio of entering air, lb water vapor per lb dry air
- W_2 = humidity ratio of leaving air, lb water vapor per lb dry air (in a continuously operating dryer, W_2 is constant; in a batch dryer, W_2 varies during part of the cycle)

- w_1 = dry basis moisture content of entering material, lb of water per lb
- w_2 = dry basis moisture content of leaving material, lb of water per lb

In **batch dryers**, the drying operation is given as

$$G_T(W_2 - W_1) = (M_1) \frac{dw}{d\theta} \quad (2)$$

where

- M_1 = mass of material charged in a discontinuous dryer, lb per batch
- $dw/d\theta$ = instantaneous time rate of evaporation corresponding to w

The makeup air quantity is constant and is based on the average evaporation rate. Equation (2) then becomes identical to Equation (1), where $M = M_1/\theta$. Under this condition, humidity in the batch dryer decreases during the drying cycle, whereas in the continuous dryer, humidity is constant with constant load.

Heat Balance. To estimate the fuel requirements of a dryer, a heat balance consisting of the following is needed:

- Radiation and convection losses from the dryer
- Heating of the commercial dry material to the leaving temperature (usually estimated)
- Vaporization of the water being removed from the material (usually considered to take place at the wet-bulb temperature)
- Heating of the vapor from the wet-bulb temperature in the dryer to the exhaust temperature
- Heating of the total water in the material from the entering temperature to the wet-bulb temperature in the dryer
- Heating of the makeup air from its initial temperature to the exhaust temperature

The energy absorbed must be supplied by the fuel. The selection and design of the heating equipment is an essential part of the overall design of the dryer.

Example 2. Magnesium hydroxide is dried from 82% to 4% moisture content (wet basis) in a continuous conveyor dryer with a fin-drum feed (see Figure 7). The desired production rate is 3000 lb/h. The optimum circulating air temperature for drying is 160°F, which is not limited by the existing steam pressure of the dryer.

Step 1. Laboratory tests indicate the following:

Specific heats	
air (c_a)	= 0.24 Btu/lb·°F
material (c_m)	= 0.3 Btu/lb·°F
water (c_w)	= 1.0 Btu/lb·°F
water vapor (c_v)	= 0.45 Btu/lb·°F
Temperature of material entering dryer	= 60°F
Temperature of makeup air	
dry bulb	= 70°F
wet bulb	= 60°F
Temperature of circulating air	
dry bulb	= 160°F
wet bulb	= 100°F
Air velocity through drying bed	= 250 fpm
Dryer bed loading	= 6.82 lb/ft ²
Test drying time	= 25 min

Step 2. Previous experience indicates that the commercial drying time is 70% greater than the time obtained in the laboratory test. Thus, the commercial drying time is estimated to be $1.7 \times 25 = 42.5$ min.

Step 3. The holding capacity of the dryer bed is

$$3000(42.5/60) = 2125 \text{ lb at 4\% (wet basis)}$$

The required conveyor area is $2125/6.82 = 312$ ft². Assuming the conveyor is 8 ft wide, the length of the drying zone is $312/8 = 39$ ft.

Step 4. The amount of water in the material entering the dryer is

$$3000[82/(100 + 4)] = 2370 \text{ lb/h}$$

The amount of water in the material leaving is

$$3000[4/(100 + 4)] = 115 \text{ lb/h}$$

Thus, the moisture removal rate is $2370 - 115 = 2255 \text{ lb/h}$.

Step 5. The air circulates perpendicular to the perforated plate conveyor, so the air volume is the face velocity times the conveyor area:

$$\text{Air volume} = 250 \times 312 = 78,000 \text{ cfm}$$

ASHRAE Psychrometric Charts 1 and 3 show these air properties:

Supply air (160°F db, 100°F wb)

$$\begin{aligned} \text{Humidity ratio} &= 0.0285 \text{ lb per lb of dry air} \\ \text{Specific volume} &= 16.33 \text{ ft}^3 \text{ per lb of dry air} \end{aligned}$$

Makeup air (70°F db, 60°F wb)

$$\text{Humidity ratio } W_1 = 0.0086 \text{ lb per lb of dry air}$$

The mass flow rate of dry air is

$$(78,000 \times 60)/16.33 = 286,500 \text{ lb/h}$$

Step 6. The amount of moisture pickup is

$$2255/286,500 = 0.0079 \text{ lb per lb of dry air}$$

The humidity ratio of the exhaust air is

$$W_2 = 0.0285 + 0.0079 = 0.0364 \text{ lb per lb of dry air}$$

Substitute in Equation (1) and calculate G_T as follows:

$$G_T(0.0364 - 0.0086) = (3000/1.04)(82 - 4)/100$$

$$G_T = 81,000 \text{ lb dry air per hour}$$

Therefore,

$$\begin{aligned} \text{Makeup air} &= 100 \times 81,000/286,500 = 28.3\% \\ \text{Recirculated air} &= 71.7\% \end{aligned}$$

Step 7. Heat Balance

$$\begin{aligned} \text{Sensible heat of material} &= M(t_{m2} - t_{m1})c_m \\ &= (3000/1.04)(100 - 60)0.3 \\ &= 34,600 \text{ Btu/h} \end{aligned}$$

$$\begin{aligned} \text{Sensible heat of water} &= M_w(t_w - t_{m1})c_w \\ &= 2370(100 - 60)1.0 \\ &= 94,800 \text{ Btu/h} \end{aligned}$$

$$\begin{aligned} \text{Latent heat of evaporation} &= M(w_1 - w_2)H \\ &= 2255 \text{ lb/h} \times 1037 \text{ Btu/lb} \\ &= 2,338,400 \text{ Btu/h} \end{aligned}$$

$$\begin{aligned} \text{Sensible heat of vapor} &= M(t_2 - t_w)c_v \\ &= 2255(160 - 100)0.45 \\ &= 60,900 \text{ Btu/h} \end{aligned}$$

$$\text{Required heat for material} = 2,528,700 \text{ Btu/h}$$

The temperature drop ($t_2 - t_3$) through the bed is

$$\frac{\text{Required heat}}{\text{Supplied air, (lb/h)} \times c_a} = \frac{2,528,700}{286,500 \times 0.24} = 37^\circ\text{F}$$

Therefore, the exhaust air temperature is $160 - 37 = 123^\circ\text{F}$.

$$\begin{aligned} \text{Required heat for makeup air} &= G_T(t_3 - t_1)c_a \\ &= 81,000(123 - 70)0.24 \\ &= 1,030,000 \text{ Btu/h} \end{aligned}$$

The total heat required for material and makeup air is

$$2,528,700 + 1,030,000 = 3,559,000 \text{ Btu/h}$$

Additional heat that must be provided to compensate for radiation and convection losses can be calculated from the known construction of the dryer surfaces.

4. DRYING SYSTEM SELECTION

A general procedure for selecting a drying system is as follows:

1. Survey of suitable dryers.
2. Preliminary cost estimates of various types.
 - (a) Initial investment
 - (b) Operating cost
3. Drying tests conducted in prototype or laboratory units, preferably using the most promising equipment available. Sometimes a pilot plant is justified.

4. Summary of tests evaluating quality of samples of the dried products.

Factors that can overshadow the operating or investment cost include the following:

- Product quality, which should not be sacrificed
- Dusting, solvent, or other product losses
- Space limitation
- Bulk density of the product, which can affect packaging cost

Friedman (1951) and Parker (1963) discuss additional aids to dryer selection.

5. TYPES OF DRYING SYSTEMS

Radiant Infrared Drying

Thermal radiation may be applied by infrared lamps, gas-heated incandescent refractories, steam-heated sources, and, most often, electrically heated surfaces. Infrared heats only near the surface of a material, so it is best used to dry thin sheets.

Using infrared heating to dry webs such as uncoated materials has been relatively unsuccessful because of process control problems. Thermal efficiency can be low; heat transfer depends on the emitter's characteristics and configuration, and on the properties of the material to be dried.

Radiant heating is used for drying ink and other coatings on paper, textile fabrics, paint films, and lacquers. Inks have been specifically formulated for curing with tuned or narrow wavelength infrared radiation.

Ultraviolet Radiation Drying

Ultraviolet (UV) drying uses electromagnetic radiation. Inks and other coatings based on monomers are cure-dried when exposed to UV radiation. This method has superior properties (Chatterjee and Ramaswamy 1975): the print resists scuff, scratch, acid, alkali, and some solvents. Printing can also be done at higher speeds without damage to the web.

Major barriers to wider acceptance of UV drying include the high capital installation cost and the increased cost of inks. The cost and frequency of replacing UV lamps are greater than for infrared ovens.

Overexposure to radiation and ozone, which is formed by UV radiation's effect on atmospheric oxygen, can cause severe sunburn and possibly blood and eye damage. Safety measures include fitting the lamp housings with screens, shutters, and exhausts.

Conduction Drying

Drying rolls or drums (Figure 1), flat surfaces, open kettles, and immersion heaters are examples of direct-contact drying. The heating surface must have close contact with the material, and agitation may increase uniform heating or prevent overheating.

Conduction drying is used to manufacture and dry paper products. It (1) does not provide a high drying rate, (2) does not furnish uniform heat and mass transfer conditions, (3) usually results in a poor moisture profile across the web, (4) lacks proper control, (5) is costly to operate and install, and (6) usually creates undesirable working conditions in areas surrounding the machine. Despite these disadvantages, replacing existing systems with other forms of drying is expensive. For example, Joas and Chance (1975) report that RF (dielectric) drying of paper requires approximately four times the capital cost, six times the operating (heat) cost, and five times the maintenance cost of steam cylinder conduction drying. However, augmenting conduction drying with dielectric drying sections offsets the high cost of RF drying and may produce savings and increased profits from greater production and higher final moisture content.

Fig. 1 Drum Dryer

Fig. 2 Platen-Type Dielectric Dryer

Further use of large conduction drying systems depends on reducing heat losses from the dryer, improving heat recovery, and incorporating other drying techniques to maintain quality.

Dielectric Drying

When wet material is placed in a strong, high-frequency (2 to 100 MHz) electrostatic field, heat is generated within the material. More heat is developed in the wetter areas than in the drier areas, resulting in automatic moisture profile correction. Water is evaporated without unduly heating the substrate. Therefore, in addition to its leveling properties, dielectric drying provides uniform heating throughout the web thickness.

Dielectric drying is controlled by varying field or frequency strength; varying field strength is easier and more effective. Response to this variation is quick, with neither time lag nor thermal lag in heating. The dielectric heater is a sensitive moisture meter.

Several electrode configurations are used. The platen type (Figure 2) is used for drying and baking foundry cores, heating plastic preforms, and drying glue lines in furniture. The rod or stray field types (Figure 3) are used for thin web materials such as paper and textile products. The double-rod types (over and under material) are used for thicker webs or flat stock, such as plywood.

Dielectric drying is popular in the textile industry. Because air is entrained between fibers, convection drying is slow and uneven. Because the yarn is usually transferred to large packages immediately after drying, however, even and correct moisture content can be obtained by dielectric drying. Knitting wool seems to benefit from internal steaming in hanks.

Warping caused by nonuniform drying is a serious problem for plywood and linerboard. Dielectric drying yields warp-free products.

Dielectric drying is not cost-effective for overall paper drying but has advantages when used at the dry end of a conventional steam drum dryer. It corrects moisture profile problems in the web without overdrying. This combination of conventional and dielectric drying is synergistic: the drying effect of the combination is greater than

Fig. 3 Rod-Type Dielectric Dryers

Fig. 4 Cross Section and Longitudinal Section of Rotary Dryer

the sum of the two types of drying. This is more pronounced in thicker web materials, accounting for as much as a 16% line speed increase and a corresponding 2% energy input increase.

Microwave Drying

Microwave drying or heating uses ultrahigh-frequency (900 to 5000 MHz) radiation. It is a form of dielectric heating and is used for heating nonconductors. Because of its high frequency, microwave equipment is capable of generating extreme power densities.

Microwave drying is applied to thin materials in strip form by passing the strip through the gap of a split waveguide. Entry and exit shielding make continuous process applications difficult. Its many safety concerns make microwave drying more expensive than dielectric drying. Control is also difficult because microwave drying lacks the self-compensating properties of dielectrics.

Convection Drying (Direct Dryers)

Some convection drying occurs in almost all dryers. True convection dryers, however, use circulated hot air or other gases as the principal heat source. Each means of mechanically circulating air or gases has its advantages.

Rotary Dryers. These cylindrical drums cascade the material being dried through the airstream (Figure 4). The dryers are heated directly or indirectly, and air circulation is parallel or counterflow. A

Fig. 5 Compartment Dryer Showing Trucks with Air Circulation

variation is the rotating-louver dryer, which introduces air beneath the flights to provide close contact.

Cabinet and Compartment Dryers. These batch dryers range from the heated loft (with only natural convection and usually poor and nonuniform drying) to self-contained units with forced draft and properly designed baffles. Several systems may be evacuated to dry delicate or hygroscopic materials at low temperatures. Material is usually spread in trays to increase the exposed surface. Figure 5 shows a dryer that can dry water-saturated products.

When designing dryers to process products saturated with solvents, special features must be included to prevent explosive gases from forming. Safe operation requires exhausting 100% of the air circulated during the initial drying period or any part of the drying cycle when solvent is evaporating at a high rate. At the end of the purge cycle, the air is recirculated and heat is gradually applied. To prevent explosions, laboratory dryers can be used to determine the amount of air circulated, cycle lengths, and rate that heat is applied for each product. In the drying cycle, dehumidified air, which is costly, should be recirculated as soon possible. The air *must not* be recirculated when cross-contamination of products is prohibited.

Dryers must have special safety features in case any part of the drying cycle fails. The following are some of the safety design features described in *Industrial Ovens and Driers* (FMEA 1990):

- Each compartment must have separate supply and exhaust fans and an explosion-relief panel.
- The exhaust fan blade tip speed should be 5000 fpm for forward-inclined blades, 6800 fpm for radial-tip, and 7500 fpm for backward-inclined. These speeds produce high static pressures at the fan, ensuring constant exhaust volumes under conditions such as negative pressures in the building or downdrafts in the exhaust stacks.
- Airflow failure switches in both the supply and exhaust ducts must shut off fans and the heating coil and must sound an alarm.
- A high-temperature limit controller in the supply duct must shut off the heat to the heating coil and must sound an alarm.
- An electric interlock on the dryer door must interrupt the drying cycle if the door is opened beyond a set point, such as that wide enough for a person to enter for product inspection.

Tunnel Dryers. Tunnel dryers are modified compartment dryers that operate continuously or semicontinuously. Fans circulate heated air or combustion gas is circulated by fans. The material is

Fig. 6 Explosionproof Truck Dryer Showing Air Circulation and Safety Features

handled on trays or racks on trucks and moves through the dryer either intermittently or continuously. The airflow may be parallel, counterflow, or a combination obtained by center exhaust (Figure 6). Air may also flow across the tray surface, vertically through the bed, or in any combination of directions. By reheating or recirculating the air in the dryer, high saturation is reached before the air is exhausted, thus reducing the sensible heat loss.

The following problems with tunnel dryers have been experienced and should be considered in future designs:

- Operators may overload product trays to increase output, but this can overtax the system and increase drying time.
- Sometimes air from the drying tunnel is discharged into the production area, increasing the humidity. Air from the drying tunnel should be discharged to the drying system return or outdoors.
- Overloaded product trays add pressure drop, which decreases flow through the dryer. The control panel should indicate validated flow through the tunnel. High and low flow and high moisture levels should trigger alarms.
- Cycle times can be reduced by designing dryers for cross-flow rather than end-to-end flow.

A variation of the tunnel dryer is the strictly continuous dryer, which has one or more mesh belts that carry the product through it, as shown in Figure 7. Many combinations of temperature, humidity, air direction, and velocity are possible. Hot air leaks at the entrance and exit can be minimized by baffles or inclined ends, with the material entering and leaving from the bottom.

High-Velocity Dryers. High-velocity hoods or dryers have been used to supplement conventional cylinder dryers for drying paper. When used with conventional cylinder dryers, web instability and lack of process control result. Where internal diffusion is not the controlling factor in the drying rate, applications such as thin permeable webs offer more promise.

Spray Dryers. Spray dryers have been used in producing dried milk, coffee, soaps, and detergents. Because the dried product (in the form of small beads) is uniform and drying time is short (5 to

Fig. 7 Section of Blow-Through Continuous Dryer

Fig. 8 Pressure-Spray Rotary Spray Dryer

15 s), this drying method has become more important. When a liquid or slurry is dried, the spray dryer has high production rates.

Spray drying involves atomizing a liquid feed in a hot-gas drying medium. The spray can be produced by a two-fluid nozzle, a high-pressure nozzle, or a rotating disk. Inlet gas temperatures range from 200 to 1400°F, with the high temperatures requiring special construction materials. Because thermal efficiency increases with the inlet gas temperature, high inlet temperatures are desirable. Even heat-sensitive products can be dried at higher temperatures because of the short drying time. Hot gas flow may be either concurrent or countercurrent to the falling droplets. Dried particles settle out by gravity. Fine material in the exhaust air is collected in cyclone separators or bag filters. Figure 8 shows a typical spray drying system.

The physical properties of the dried product (such as particle size, bulk density, and dustiness) are affected by atomization characteristics and the temperature and direction of flow of the drying gas. The product's final moisture content is controlled by the humidity and temperature of the exhaust gas stream.

Currently, pilot-plant or full-scale production operating data are required for design purposes. The drying chamber design is determined by the nozzle's spray characteristics and heat and mass transfer rates. There are empirical expressions that approximate mean particle diameter, drying time, chamber volume, and inlet and outlet gas temperatures.

Freeze Drying

Freeze drying has been applied to pharmaceuticals, serums, bacterial and viral cultures, vaccines, fruit juices, vegetables, coffee and tea extracts, seafoods, meats, and milk.

The material is frozen, then placed in a high-vacuum chamber connected to a low-temperature condenser or chemical desiccant. Heat is slowly applied to the frozen material by conduction or infrared radiation, allowing the volatile constituent, usually water, to sublime and condense or be absorbed by the desiccant. Most freeze-drying operations occur between 14 and -40°F under minimal

pressure. Although this process is expensive and slow, it has advantages for heat-sensitive materials (see Chapter 29 of the 2014 *ASHRAE Handbook—Refrigeration*).

Vacuum Drying

Vacuum drying takes advantage of the decrease in the boiling point of water that occurs as the pressure is lowered. Vacuum drying of paper has been partially investigated. Serious complications arise if the paper breaks, and massive sections must be removed. Vacuum drying is used successfully for pulp drying, where lower speeds and higher weights make breakage relatively infrequent.

Fluidized-Bed Drying

A fluidized-bed system contains solid particles through which a gas flows with a velocity higher than the incipient fluidizing velocity but lower than the entrainment velocity. Heat transfer between the individual particles and the drying air is efficient because there is close contact between powdery or granular material and the fluidizing gas. This contact makes it possible to dry sensitive materials without danger of large temperature differences.

The dried material is free-flowing and, unlike that from convection dryers, is not encrusted on trays or other heat-exchanging surfaces. Automatic charging and discharging are possible, but the greatest advantage is reduced process time. Only simple controls are important: over (1) fluidizing air or gas temperatures and (2) the drying time of the material.

All fluidized-bed dryers should have explosion-relief flaps. Both the pressure and flames of an explosion are dangerous. When toxic materials are used, uncontrolled venting to the atmosphere is prohibited. Explosion suppression systems, such as pressure-actuated ammonium-phosphate extinguishers, have been used instead of relief venting. An inert dryer atmosphere is preferable to suppression systems because it prevents explosive mixtures from forming.

When organic and inflammable solvents are used in the fluidized-bed system, the closed system offers advantages other than explosion protection. A portion of the fluidizing gas is continuously run through a condenser, which strips the solvent vapors and greatly reduces air pollution problems, thus making solvent recovery convenient.

Materials dried in fluidized-bed installations include coal, limestone, cement rock, shales, foundry sand, phosphate rock, plastics, medicinal tablets, and foodstuffs. Leva (1959) and Othmer (1956) discuss the theory and methods of fluidization of solids. Clark (1967) and Vanecek et al. (1966) developed design equations and cost estimates.

Agitated-Bed Drying

Uniform drying is ensured by periodically or continually agitating a bed of preformed solids with a vibrating tray, a conveyor, or a vibrating mechanically operated rake, or, in some cases, by partial fluidization of the bed on a perforated tray or conveyor through which recycled drying air is directed. Drying and toasting cereals is an important application.

Drying in Superheated Vapor Atmospheres

When drying solids with air or another gas, the vaporized solvent (water or organic liquid) must diffuse through a stagnant gas film to reach the bulk gas stream. Because this film is the main resistance to mass transfer, the drying rate depends on the solvent vapor diffusion rate. If the gas is replaced by solvent vapor, resistance to mass transfer in the vapor phase is eliminated, and the drying rate depends only on the heat transfer rate. Drying rates in solvent vapor, such as superheated steam, are greater than those in air for equal temperatures and mass flow of the drying media.

This method also has higher thermal efficiency, easier solvent recovery, and a lower tendency to overdry, and it eliminates oxidation or other chemical reactions that occur when air is present. In drying cloth, superheated steam reduces the migration tendency of resins and dyes. Superheated vapor drying cannot be applied to heat-sensitive materials because of the high temperatures.

Commercial drying equipment with recycled solvent vapor as the drying medium is available. Installations have been built to dry textile sheeting and organic chemicals.

Flash Drying

Finely divided solid particles that are dispersed in a hot gas stream can be dried by flash drying, which is rapid and uniform. Commercial applications include drying pigments, synthetic resins, food products, hydrated compounds, gypsum, clays, and wood pulp.

Constant-Moisture Solvent Drying

In some cases it is desirable to dry organic solvents from a substance without changing moisture content. This is particularly true in drying pharmaceutical products, which are commonly bound with solvents such as isopropyl alcohol (IPA) or acetone. Loss of moisture content can affect the stability of some pharmaceutical compounds, which therefore must be liberated of bound solvents without changing the relative humidity. Most pharmaceutical facilities producing oral solid dosage (OSD) presentations manufacture in spaces that range from 30 to 45% rh. To maintain this level of humidity at the temperatures needed to liberate the organic solvents at the required rate, an oven must be fitted with an adequately sized humidifier. Figure 9 shows the compartment dryer from Figure 5 adapted for constant-moisture drying.

It is vital to size the preheat coil to the humidifier to allow enough "room" to provide the humidification level required. The amount of preheat is usually enough to provide makeup air to the oven at 90% rh. This allows the oven heaters to control drying temperature at the more common oven humidity levels of 30 to 45% rh. If electric heat is used, the ability to constantly vary the capacity of the heaters must be provided; silicon-controlled rectifiers (SCRs) are commonly used.

Additional insulation on the outside of the oven and the ductwork from the humidifier section onward should also be considered. Care must be taken to ensure that unwanted condensation does not form inside the oven. Dripping moisture can sometimes ruin the product, causing a substantial economic loss. If the product is pharmaceutical, then the humidifier makeup water source should be deionized or

Fig. 9 Humidified Cross-Flow Tray Dryer

produced to comply with U.S. Pharmacopoeia 34—National Formulary—29 (effective August 2010).

CHAPTER 31

VENTILATION OF THE INDUSTRIAL ENVIRONMENT

<i>Ventilation Design Principles</i>	31.2
<i>General Comfort and Dilution Ventilation</i>	31.2
<i>Heat Control</i>	31.5
<i>Energy Conservation, Recovery, and Sustainability</i>	31.6

INDUSTRIAL environments require ventilation to reduce exposure to excess heat and contaminants that are generated in the workplace; in some situations, cooling may also be required. Ventilation is primarily used to control excess heat, odors, and hazardous particulate and chemical contaminants. These could affect workers' health and safety or, in some cases, become combustible or flammable when allowed to accumulate above their minimum explosive concentration (MEC) or lower flammable limit (LFL) [also called the lower explosive limit (LEL)] (Cashdollar 2000). Excess heat and contaminants can best be controlled by using local exhaust systems whenever possible. Local exhaust systems capture heated air and contaminants at their source and may require lower airflows than general (dilution) ventilation. See Chapter 32 for more information on the selection and design of industrial local exhaust systems.

General ventilation can be provided by mechanical (fan) systems, by natural draft, or by a combination of the two. Combination systems could include mechanically driven (fan-driven) supply air with air pressure relief through louvers or other types of vents, and mechanical exhaust with air replacement inlet louvers and/or doors.

Mechanical (fan-driven) supply systems provide the best control and the most comfortable and uniform environment, especially when there are extremes in local climatic conditions. The systems typically consist of an inlet section, filtration section, heating and/or cooling equipment, fans, ductwork, and air diffusers for distributing air in the workplace. When toxic gases or vapors are not present and there are no aerosol contaminants associated with adverse health effects, air cleaned in the general exhaust system or in packaged air filtration units can be recirculated via a return duct. When applied appropriately, air recirculation can be a major contributor to a sustainable industrial ventilation design and may reduce heating and cooling costs.

In addition, regardless of the method selected, any positive ventilation into an industrial space should be from a source that is essentially free of any contaminants under both normal and abnormal conditions in the surrounding atmosphere. In many cases, this may require a sealed intake stack or ductwork, as opposed to a perimeter wall hood or other air intake device, wherein the source of intake should be from a point well above or beyond the veil of the hazardous space that may surround a ventilated space. Where this cannot be achieved, additional action should be undertaken (e.g., providing particulate or carbon filtration).

A general exhaust system, which removes air contaminated by gases, vapors, or particulates not captured by local exhausts, usually consists of one or more fans, plus inlets, ductwork, and air cleaners or filters. After air passes through the filters, it is either discharged outdoors, or partially recirculated within the building. The air filtration system's cleaning efficiency should conform to environmental regulations and depends on factors such as building location, background contaminant concentrations, type and toxicity of contaminants, and height and velocity of building exhaust discharge.

Many industrial ventilation systems must handle simultaneous exposures to temperature extremes and hazardous substances. In

these cases, the required ventilation can be provided by a combination of local exhaust, general ventilation air supply, and general exhaust systems. The ventilation engineer must carefully analyze supply and exhaust air requirements to determine the worst case. For example, air supply makeup for hood exhaust may be insufficient to control heat exposure. It is also important to consider seasonal climatic effects on ventilation system performance, especially for natural ventilation systems. Duct material and its compatibility with the exhaust airstream is also important to consider when ventilating hazardous, abrasive, or corrosive substances.

Most importantly, if the hazardous substances are ignitable gases or dusts, all electrical components of the ventilation system should be rated for the proper electrical classification in the absence of any ventilation, regardless of their locations in the ventilation system.

In specifying acceptable chemical contaminant and heat exposure levels, the industrial hygienist or industrial hygiene engineer must consult the appropriate occupational exposure limits that apply as well as any governing standards and guidelines. The legislated limits for the maximum airborne concentration of chemical substances to which a worker may be exposed are listed as (1) maximum average exposures to which a worker may be exposed over a given work day (generally assumes an 8 to 10 h work day and a traditional 40 h work week); (2) short-term exposure limits, which are the maximum average airborne concentration to which a worker may be exposed over any 15 min period; and (3) ceiling limits, which are the maximum airborne concentration to which a worker may be exposed at any time. However, occupational exposure limits for cold, heat, and contaminants are not lines of demarcation between safe and unsafe exposures. Rather, they represent conditions to which it is believed nearly all workers may be exposed day after day without adverse and/or long-term effects. Because a small percentage of workers may be affected by occupational exposure below the regulated limits, it is prudent to design for control to the most conservative occupational exposure limits (OELs) available.

In the case of exposure to hazardous chemicals, the number of contaminant sources, their generation rates, and the effectiveness of exhaust hoods may not be known. Consequently, the ventilation engineer must rely on industrial hygiene engineering practices when designing toxic and/or hazardous chemical controls. Close cooperation among the industrial hygienist, process engineer, and ventilation engineer is required.

In the case of exposure to flammable or ignitable chemicals, the specific gravity of the contaminant source(s), their concentration, and the rating of all electrical devices in the space, along with any source or point of excessive heat, must be carefully considered to prevent possible loss of life or severe injury. As with all hazardous chemicals, cooperation of knowledgeable experts, including electrical engineers, is required.

This chapter describes principles of ventilation practice and includes other information on industrial hygiene in the industrial environment. Publications from the American Industrial Hygiene Association (AIHA 2011), British Occupational Hygiene Society (BOHS 2002), U.S. Department of Health and Human Services (DHHS 1986), National Safety Council (2012), and U.S. National

The preparation of this chapter is assigned to TC 5.8, Industrial Ventilation Systems.

Institute for Occupational Safety and Health (NIOSH 1986) provide further information on industrial hygiene principles and their application.

1. VENTILATION DESIGN PRINCIPLES

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

General Ventilation

General ventilation supplies and/or exhausts air to provide heat relief, dilute contaminants to an acceptable level, and replace exhaust air. Ventilation can be provided by natural or mechanical supply and/or exhaust systems. Industrial areas must comply with ASHRAE *Standard* 62.1-2013 and other standards as required (e.g., by NFPA). Outdoor air is unacceptable for ventilation if it is known to contain any contaminant at a concentration above that given in ASHRAE *Standard* 62.1. If air is thought to contain any contaminant not listed in the standard, consult relevant federal, state, provincial, or local jurisdictions for acceptable exposure levels. In addition to their role in controlling industrial contaminants, general ventilation rates must be sufficient to dilute the carbon dioxide produced by occupants to a level acceptable under ASHRAE *Standard* 62.2.

For complex industrial ventilation problems, experimental scale models and computational fluid dynamics (CFD) models are often used in addition to field testing.

Makeup Air

When large volumes of air are exhausted to provide acceptable comfort and safety for personnel and acceptable conditions for process operations, this air must be replaced, either through intentional design strategy or through paths of least resistance. A safe and effective ventilation design should be strategic about the mechanism, locations, and physical parameters by which makeup air enters the occupied space. Makeup air, consistently provided by good air distribution, allows more effective cooling in the summer and more efficient and effective heating in the winter. When makeup air design is not incorporated into the ventilation design scheme, it may lead to inefficient operation of local exhaust systems and/or combustion equipment and cross-drafts that affect occupant comfort and environmental control settings. Relying on windows or other air inlets that cannot function in year-round weather conditions is discouraged. Some factors to consider in designs for makeup air include

- Makeup air must be sufficient to replace air being exhausted or consumed by combustion processes, local and general exhaust systems (see Chapter 32), or process equipment. (Large air compressors can consume a large amount of air and should be considered if air is drawn from within the building.)
- Makeup air systems should be designed to eliminate uncomfortable cross-drafts by properly arranging supply air outlets, and to prevent infiltration (through doors, windows, and similar openings) that may make hoods unsafe or ineffective, defeat environmental control, bring in or stir up dust, or adversely affect processes by producing temperature or airflow disturbances. The

design engineer needs to consider side drafts and other sources of air movement close to the capture area of a local exhaust hood. In industrial applications, it is common to see large fans blowing air onto workers positioned in front of the hood. This can render the local exhaust hood ineffective to the point that no protection is provided for the worker: Ahn et al. (2008), Caplan and Knutson (1977, 1978), and Tseng et al. (2010) found that air movement in front of laboratory hoods can cause contaminants to escape from the hood and into the operator's breathing zone. Hoods should be located safe distances from doors and openable windows, supply air diffusers, and areas of high personnel traffic (AIHA *Standard* Z9.5; NFPA *Standard* 45).

- Makeup air should be obtained from a clean source with no more than trace amounts of any airborne contaminants or hazardous, ignitable substances. Supply air can be filtered, but infiltration air cannot. For transfer air use, see ASHRAE *Standard* 62.1.
- Makeup air for spaces contaminated by toxic, ignitable, or combustible chemicals may have to be acquired through carefully sealed ductwork from an area known to be free of contamination and be supplied at sufficient rates, pressures, and mixing efficiencies to (1) remove all contamination, and (2) prevent infiltration of similar contaminants from surrounding areas or adjacent spaces.
- Makeup air should be used to control building pressure and airflow from space to space to (1) avoid positive or negative pressures that make it difficult or unsafe to open doors, (2) minimize drafts, and (3) prevent infiltration.
- Makeup air should be used to reduce contaminant concentration, to control temperature and humidity, and minimize undesirable air movement.
- Makeup air systems should be designed to recover heat and conserve energy (see the section on Energy Conservation, Recovery, and Sustainability).

For more information on potential adverse conditions caused by specific negative pressure levels in buildings, see ACGIH (2013) and Chapter 28 in the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*.

2. GENERAL COMFORT AND DILUTION VENTILATION

Effective air diffusion in ventilated rooms and the proper quantity of conditioned air are essential for creating an acceptable working environment, removing contaminants, and reducing installation and operating costs of a ventilation system. Ventilation systems must supply air at the proper velocity and temperature, with resulting contaminant concentrations within permissible occupational exposure limits (OELs). For the industrial environment, the most common objective is to provide tolerable (acceptable) working conditions rather than comfort (optimal) conditions.

General ventilation system design is based on the assumption that local exhaust ventilation, radiation shielding, and equipment insulation and encapsulation have been selected to minimize both heat load and contamination in the workplace (see the section on Heat Control). When work operations are generally restricted, such as with equipment operating stations or control booths, spot conditioning of the work environment with clean conditioned air (see the section on Makeup Air) may further reduce the reliance on general ventilation for conditioning or contaminant dilution. In cold climates, infiltration and heat loss through the building envelope may need to be minimized by pressurizing buildings.

For more information on dilution ventilation, see ACGIH (2013).

Quantity of Supplied Air

Sufficient air must be supplied to replace air exhausted by process ventilation and local exhausts, dilute contaminants (gases, vapors, or

airborne particles) not captured by local exhausts, prevent the entry of contaminants or hazardous (ignitable) substances from any surrounding atmosphere during ingress or egress, and provide the required thermal environment. The amount of supplied air should be the largest of the amounts needed for temperature control, dilution, and replacement.

Air Supply Methods

Air supply to industrial spaces can be by natural or mechanical ventilation systems. Although natural ventilation systems driven by gravity forces and/or wind effect are still widely used in industrial spaces (especially in hot premises in cold and moderate climates), they are inefficient in large buildings, may cause drafts, and may not sufficiently solve air contamination problems, because the prerequisite environmental conditions may not be available during all required periods of need or there is no practical filtration method available. Thus, most ventilation systems in industrial spaces are either mechanical (fan-driven) or a combination of mechanical supply with natural exhaust, using louvers or doors for air pressure relief (or for air replacement in exhaust systems).

The most common methods of air supply to industrial spaces are mixing, displacement, and localized.

Mixing Air Distribution. In mixing systems, air is normally supplied at velocities much greater than those acceptable in the occupied zone. Supply air temperature can be above, below, or equal to the air temperature in the occupied zone, depending on the heating/cooling load. The supply air diffuser jet mixes with room air by entrainment, which reduces air velocities and equalizes the air temperature. The occupied zone is ventilated either directly by the air jet or by reverse flow created by the jet. Properly selected and designed mixing air distribution creates relatively uniform air velocity, temperature, humidity, and air quality conditions in the occupied zone and over the room height. Note that supply systems

should introduce air into the workspace in such a way as to not interfere with contaminant control systems such as ventilation hoods. If possible, ventilation hoods (e.g., fume hoods) should have quiescent air conditions (~100 fpm) at their face.

Displacement Ventilation Systems. Conditioned air that is slightly cooler than the desired room air temperature in the occupied zone is supplied from air outlets at low air velocities (~100 fpm or less). Because of buoyancy, the cooler air spreads along the floor and floods the room's lower zone. Air close to the heat source is heated and rises upward as a convective air stream; in the upper zone, this stream spreads along the ceiling. The height of the lower zone depends on the air volume and temperature supplied to the occupied zone and on the amount of convective heat discharged by the sources.

Typically, outlets are located at or near the floor, and supply air is introduced directly into the occupied zone. In some applications (e.g., in computer rooms or hot industrial buildings), air may be supplied to the occupied zone through a raised floor. Exhaust or air returns are located at or close to the ceiling or roof.

Displacement ventilation is common in European countries. It is an option when contaminants are released in combination with surplus heat, and contaminated air is warmer (more buoyant) than the surrounding air. It is not a good choice when air turbulence can interfere with convective conveyance of heat and contaminants. Further information on displacement air distribution systems can be found in Chen and Glicksman (2003) and Goodfellow and Tahti (2001).

Localized Ventilation. Air is supplied locally for occupied regions or a few permanent work areas (Figure 1). Conditioned air is supplied toward the occupants' breathing zone to create comfortable conditions and/or to reduce the concentration of pollutants. These zones may have air that is cleaner than the surrounding air, and should generally be compliant with ASHRAE *Standard* 62.1. In localized ventilation systems, air is supplied through one of the following devices:

Fig. 1 Localized Ventilation Systems

- Nozzles or grilles (e.g., for spot cooling), specially designed low-velocity/low-turbulence devices
- Perforated panels suspended on vertical duct drops and positioned close to the workstation

Local Area and Spot Cooling

In hot workplaces that have few work areas, it is likely impractical to maintain a comfortable environment in the entire space. However, environmentally controlled cabins, individual cooling, and spot cooling and extraction can improve working conditions in occupied areas. Certain applications require minimum distances from supplied air (and natural ventilation points) to ensure airflow in ventilated hoods and cabinets is not affected.

Environmentally controlled cabins (e.g., operating cabs, pulpits, control rooms, enclosures) can provide thermal comfort, and, when pressurized with a dedicated clean-air supply (either dedicated source or through effective filtration), can improve air quality in occupational environments. There usually are significant economic benefits to properly designing, installing, and maintaining worker-protective environmental enclosures.

Spot cooling, probably the most popular method of improving the thermal environment, can be provided by radiation (changing mean radiant temperature), convection (changing air velocity and/or air supply temperatures), or both. Spot-cooling equipment is fixed at the workstation, whereas in **individual cooling**, the worker wears the equipment.

Local exhaust ventilation (spot extraction) is another method to remove excess heat from a process or source of high temperature, and should be the first step considered for energy saving over spot cooling.

Locker Room, Toilet, and Shower Space Ventilation

Ventilation of locker rooms, toilets, and shower spaces is important in industrial facilities to remove odor and reduce humidity. In some industries, control of workroom contamination requires prevention of both ingestion and inhalation routes of exposure, so adequate hygienic facilities, including appropriate ventilation, may be required in locker rooms, changing rooms, showers, lunchrooms, and break rooms. State, provincial, and local regulations should be consulted early in design.

Supply air may be introduced through doors or wall grilles. In some cases, workplace air may be so contaminated that filtration or a dedicated source of clean supply air is required. When control of workroom contaminants is inadequate or not feasible, reduce employee exposure by positively pressurizing locker rooms, lunchrooms, and break rooms to minimize the level of contamination in those areas. Treated supply air may be ineffective in some applications because it can introduce drafts and outdoor contamination or result in excessive condensation in a humid indoor environment.

When mechanical ventilation of supply air is used, the supply system should have adequate ducting and air distribution devices, such as diffusers or grilles, to distribute air throughout the area.

In locker rooms, take exhaust primarily from the toilet and shower spaces as needed and secondarily from the lockers. Exhausting from the room's open ceiling areas should be a last option. ASHRAE *Standard* 62.1 and many local mechanical codes provide requirements for these areas.

Roof Ventilators

Roof ventilators are heat escape ports located high in a building and should be properly enclosed for weathertightness (Goodfellow 1985). Stack effect and some wind induction are the motive forces for gravity- (buoyancy-) driven operation of continuous and round ventilators. Round ventilators can be equipped with a fan barrel and motor, allowing gravity or forced ventilation operation.

Many ventilator designs are available, including the **low ventilator**, which consists of a stack fan with a rain hood, and a **ventilator with a split butterfly closure** that floats open to discharge air and closes by a counterweight. Both use minimum enclosures and have little or no gravity capacity. Split butterfly dampers tend to increase fan airflow noise and are subject to damage from slamming during strong winds. Because noise is frequently a problem in powered roof ventilators, the manufacturer's sound rating should be reviewed. Sound attenuators should be installed where required to meet the design sound ratings.

Continuous ventilation monitors remove substantial, concentrated heat loads most effectively. One type, the **streamlined continuous ventilator**, is efficient, weathertight, and designed to prevent backdraft; it usually has dampers that may be closed in winter to conserve building heat. Its capacity is limited only by the available roof area and the proper location and sizing of low-level air inlets. Continuous ventilation to achieve a slight pressure above the surrounding atmosphere (referred to as **pressurization** by NFPA) also can be used to reduce or declassify the electrical classification of enclosed spaces. Typically, reductions from class I, zone 1 or division 1 to class I, zone 2 or division 2 can be achieved by following the recommendations of NFPA *Standard* 496. This allows using general-purpose electrical devices instead of zone 2 or division 2 devices, or using zone 2 or division 2 electrical devices instead of zone 1 or division 1 devices, which (1) greatly reduces the cost of electrical equipment and (2) provides a sound alternative when particular devices are not available for the higher (more volatile) electrical area classifications.

Gravity ventilators, also highly effective, have low operating costs, do not generate noise, and are self-regulating (i.e., higher heat release increases airflow through the ventilators). Gravity ventilators can be affected by environmental conditions and thus should only be used for heat control rather than for the control of gaseous or aerosol contaminants. Care must be taken to ensure positive pressure at the ventilators, particularly during the heating season. Otherwise, outside air will enter the ventilators.

Next in order of heat removal capacity are (1) round gravity or wind-band ventilators, (2) round gravity ventilators with fan and motor added, (3) low-hood powered ventilators, and (4) vertical upblast powered ventilators. The shroud for the vertical upblast design has a peripheral baffle to deflect air upward instead of downward. Vertical discharge is highly desirable to reduce roof damage caused by hot air if it contains condensable oil or solvent vapor. Ventilators with direct-connected motors are desirable to avoid belt maintenance. Round gravity ventilators are applicable for warehouses with light heat loads and for manufacturing areas with high roofs and light loads.

Streamlined continuous ventilators must operate effectively without mechanical power. To ensure ventilator performance, sufficient low-level openings must be provided for incoming air; insufficient inlet area and significant space air currents are the most common reasons gravity roof ventilators malfunction. A positive supply of air around hot equipment may be necessary in large buildings where external wall inlets are remote from the equipment. Chapter 16 of the 2013 *ASHRAE Handbook—Fundamentals* has additional information on ventilation and infiltration.

The cost of electrical power for mechanical ventilation over that of roof ventilators can be offset by the advantage of constant airflow. Mechanical ventilation can also create the pressure differential necessary for good airflow, even with small inlets. Inlets should be sized correctly to avoid infiltration and other problems caused by high negative pressure in the building. Often, a mechanical system is justified to supply enough makeup air to maintain the work area under positive pressure.

Roof ventilators can comprise either mechanically operated openings or fan-powered mechanical exhaust. Operator-assisted openings

or dampers are usually used in shops with high ceilings, and must be installed when natural ventilation is used to provide air to the space.

3. HEAT CONTROL

Ventilation control alone may frequently be inadequate for meeting heat stress standards for industrial work areas. Optimum solutions may involve additional controls such as spot cooling, changes in work/rest patterns, and radiation shielding.

Ventilation for Heat Relief

Many industrial processes release large amounts of heat and moisture to the environment. In such environments, it may not be economically feasible to maintain comfort conditions (ASHRAE *Standard 55*), particularly during summer. Comfortable conditions are not physiologically necessary: the body must be in thermal balance with the environment, but this can occur at temperature and humidity conditions well above the normal comfort zone. In areas where heat and moisture generated by a process are low to moderate, comfort conditions may not have to be provided if personnel exposures are infrequent and brief. In such cases, ventilation may be the only control necessary to prevent excessive physiological heat stress.

The engineer must distinguish between control needs for hot/dry industrial areas and warm/moist conditions. In hot/dry areas, a process gives off only sensible (primarily convective and radiant) heat without adding moisture to the air. This increases the heat load on exposed workers, but the rate of cooling by evaporation of perspiration may not be significantly reduced. Body heat equilibrium may be maintained, but could cause excessive perspiration. Hot/dry work situations occur around furnaces, forges, metal-extruding and rolling mills, glass-forming machines, etc.

In warm/moist conditions, a wet process may generate a significant latent heat load. The rise in sensible heat load on workers may be insignificant, but the increased moisture content of the air can seriously reduce cooling by evaporation of perspiration, making warm/moist conditions potentially more hazardous than hot/dry. Typical warm/moist operations are found in textile mills, laundries, dye houses, and deep mines, where water is used extensively for dust control.

Industrial heat load is also affected by local climate. Solar heat gain and elevated outdoor temperatures increase the heat load at the workplace, but may be insignificant compared to process heat generated locally. The moisture content of outdoor air is an important factor that can affect hot/dry work situations by restricting an individual's evaporative cooling. For warm/moist working environments, solar heat gain and elevated outdoor temperatures are even more important because moisture contributed by outdoor air is insignificant compared to that released by the process.

Both ASHRAE *Standard 55* and International Organization for Standardization (ISO) *Standard 7730* specify thermal comfort conditions.

Methods for evaluating the general thermal state of the body both in comfort conditions and under heat and cold stress are based on analysis of the heat balance for the human body, as discussed in Chapter 9 of the 2013 *ASHRAE Handbook—Fundamentals*. A person may find the thermal environment unacceptable or intolerable because of local effects on the body caused by asymmetric radiation, air velocity, vertical air temperature differences, or contact with hot or cold surfaces (floors, machinery, tools, etc.).

Heat Stress—Thermal Standards

Another heat stress indicator for evaluating an environment's heat stress potential is the **wet-bulb globe temperature (WBGT)**, defined as follows:

Outdoors with solar load

$$WBGT = 0.7t_{nwb} + 0.2t_g + 0.1t_{db} \quad (1)$$

Indoors, or outdoors with no solar load

$$WBGT = 0.7t_{nwb} + 0.3t_g \quad (2)$$

where

t_{nwb} = naturally ventilated wet-bulb temperature (no defined range of air velocity; different from saturation temperature or psychrometric wet-bulb temperature), °F

t_g = globe temperature (Vernon bulb thermometer, 6 in. diameter), °F

t_{db} = dry-bulb temperature (sensor shaded from solar radiation), °F

Coefficients in Equations (1) and (2) represent the fractional contributions of the component temperatures.

Exposure limits for heat stress for different levels of physical activity are shown in Figure 2 (NIOSH 1986), which depicts the allowable work regime (in terms of rest periods and work periods each hour) for different levels of work over a range of WBGT. When applying Figure 2, assume that the rest area has the same WBGT as the work area. The curves are valid for workers acclimatized to heat. ASHRAE *Standard 62.1* provides some metabolic rates for different activities that can be used with Figure 2. Refer to NIOSH (1986) for recommended WBGT limits for nonacclimatized workers.

The **WBGT index** is an international standard (ISO *Standards 7243, 7730, and 7933*) for evaluating hot environments. The WBGT index and activity levels should be evaluated on 1 h mean values; that is, WBGT and activity are measured and estimated as time-weighted averages on a 1 h basis for continuous work, or on a 2 h basis when exposure is intermittent. Although recommended by NIOSH, the WBGT has not been accepted as the sole legal standard by the Occupational Safety and Health Administration (OSHA), and it may not apply for non-U.S. jurisdictions. The WBGT is generally used in conjunction with other methods to determine heat stress.

Although Figure 2 is useful for evaluating heat stress exposure limits, it is of limited use for control purposes or for evaluation of comfort. Air velocity and psychrometric wet-bulb measurements

Fig. 2 Recommended Heat Stress Exposure Limits for Heat-Acclimatized Workers
[Adapted from NIOSH (1986)]

are usually needed to specify proper controls, and are only measured indirectly in WBGT determinations. Information on other useful tools, including the heat stress index (HSI), can be found in Chapter 9 of the 2013 *ASHRAE Handbook—Fundamentals* and in ISO Standards 7243, 7730, and 7933.

The thermal relationship between humans and their environment is determined by four independent environmental variables:

- Air temperature
- Radiant temperatures
- Moisture content of the air
- Air velocity

Together with the rate of internal heat production (metabolic rate) and clothing variables, these factors may combine in various ways to create different degrees of heat stress. The HSI is defined as the percent of the skin that is wetted by perspiration:

$$\text{HSI} = E_{sk}/E_{max} \times 100 \quad (3)$$

where

E_{sk} = evaporative heat loss from the skin, Btu/h·ft²

E_{max} = maximum possible evaporative heat loss from the skin, Btu/h·ft²

and incorporates relative contributions of metabolism, radiant heat gain (or loss), convective heat gain (or loss), and evaporative (perspiration) heat gain (or loss). For supplemental information on evaluation and control of heat stress using methods such as reduction of radiation, changes in work/rest pattern, spot cooling, and cooling vests and suits, refer to ACGIH (2013), Brief et al. (1983), Caplan (1980), NIOSH (1986), and Ontario MOL (2009).

Heat Exposure Control

Control at Source. Heat exposure can be reduced by providing sufficient insulation to hot equipment or locating it outdoors or in zones with general or local exhaust ventilation, covering steaming water tanks, providing covered drains for direct removal of hot water, and maintaining tight joints and valves where steam may escape.

Local Exhaust Ventilation. Local exhaust ventilation removes heated air generated by a hot process and/or gases emitted by process equipment, while removing a minimum of air from the surrounding space. Local exhaust systems, including heat exposure control using overhead canopy hoods, are discussed in detail in Chapter 32 and McKernan et al. (2014).

Radiation Shielding. In some industries, the major environmental heat load is radiant heat from hot objects and surfaces, such as furnaces, ovens, furnace flues and stacks, boilers, molten metal, hot ingots, castings, and forgings. Because air temperature has no significant effect on radiant heat flow, ventilation is of little help in controlling such exposure. The only effective control is to reduce the amount of radiant heat impinging on the workers by insulating or placing radiation shields around the source.

Radiation shields are effective in the following forms:

- **Reflective shielding.** Sheets of reflective material or insulating board are temporarily attached to the hot equipment or arranged in a semiportable floor stand.
- **Absorptive shielding (water-cooled).** These shields absorb and remove heat from hot equipment.
- **Transparent shields.** Heat-reflective tempered plate glass, reflective metal chain curtains, and close-mesh wire screens moderate radiation without obstructing the view of hot equipment.
- **Flexible shielding.** Aluminum-treated fabrics give a high degree of radiation shielding.
- **Protective clothing.** Reflective garments such as aprons, gauntlet gloves, and face shields provide moderate radiation shielding. For extreme radiation exposures, complete suits with vortex tube cooling may be required.

If the shield is a good reflector, it remains relatively cool in severe radiant heat. Bright or highly polished tinplate, stainless steel, and ordinary flat or corrugated aluminum sheets are efficient and durable. Foil-faced plasterboard, although less durable, reflects well on one side. To be efficient, however, the reflective shield must remain bright. Radiation shields are much more efficient when used in multiple layers; they should reflect the radiant heat back to the primary source, where the resulting hot gases can be removed by local exhaust. However, unless the shield completely surrounds the primary source, some infrared energy is reflected into the cooler surroundings and possibly into an occupied area. The direction of reflected heat should be studied to ensure proper shielding installation.

Spot Cooling. If the workplace is located near a source of radiant heat that cannot be entirely controlled by radiation shielding, spot cooling can be used. See Chapter 20 in the 2013 *ASHRAE Handbook—Fundamentals* and data from spot-cooling diffuser manufacturers for further information.

4. ENERGY CONSERVATION, RECOVERY, AND SUSTAINABILITY

Because of the large air volumes required to ventilate industrial plants, energy conservation and recovery should be practiced, and can provide substantial savings if this practice does not compromise overriding life safety concerns. Therefore, after all critical life safety issues have been adequately addressed, energy recovery should be incorporated into preliminary planning for an industrial plant wherever and whenever it is both safe and practical to deploy. When selecting energy recovery equipment, ensure that materials are compatible with all contaminants and hazardous substances that may be exhausted. Verify the acceptability of the energy recovery method with local codes.

In some cases, it is possible to provide unheated or partially heated makeup air to the building. Although most energy conservation and recovery methods in this section apply to heating, the savings possible with cooling systems are similar. The following are some methods of energy conservation and recovery:

- In the original design phase, process and equipment insulation and heat shields should be provided to minimize heat loads. Vapor-proofing and reducing the glass area may be required. Exhaust requirements for hoods and processes should be reviewed and kept to a practical, safe minimum; for more on local exhaust systems, see Chapter 32.
- Design the supply and exhaust general ventilation systems for optimal operation throughout the year. Provide air as close to the occupied zone as possible without affecting exhaust operation. Clean, recirculated air can be used in winter makeup if it does not increase the levels of contamination in the space (see the following bullet points for more details and restrictions) (ACGIH 2013). Supply and exhaust systems may be interlocked together to avoid overpressurization of the space by the supply unit if intermittent extracts are used.
- Supply air can be passed through air-to-air, liquid-to-air, or hot-gas-to-air heat exchangers to recover building or process heat. Rotary, regenerative, coil energy recovery (runaround), and air-to-air heat exchangers are discussed extensively in Chapters 25 and 26 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*. Energy recovery is also discussed in Chapters 5 and 11 of ACGIH (2013).
- Operate the system for economy if this does not compromise life safety. Although CO₂-based demand control ventilation (DCV) is unsuitable for industrial spaces where human activity is not the main reason for ventilating the space (DOE 2004), industrial spaces may offer their own kind of demand control ventilation for providing makeup air to offset process and exhaust hood exhaust volumes. If the space does not contain a potential source of toxic

contaminants or hazardous (ignitable) substances, shut such systems down at night, on weekends, or whenever possible, and operate makeup air in balance with the needs of process equipment and exhaust hoods. Keep heating supply air temperatures at the minimum, and cooling supply temperatures at the maximum, consistent with process needs and employee comfort. Keep the building in pressure balance so that uncomfortable drafts do not necessitate excessive heating. Increase the deadband/control limits

- If the exhaust air has contaminants that do not pose an unacceptable health risk, and does not contain a potential source of hazardous (ignitable) substances, then recirculation can be considered. However, even then, contaminant concentrations in recirculated air must be determined so that allowable limits in the space are not exceeded. As recirculated air returns to the space, the concentration of contaminants in the partially filtered return air adds to the contaminant levels already existing in the space. It must be determined whether the concentration increases beyond the allowable time-weighted average (TWA) exposure limit during the period for which the worker is exposed. This period is usually assumed to be 8 h for an 8 h work shift, but could be any period of exposure. Once installed, real-time or periodic monitoring is likely required to support this determination. Depending on the contaminant's toxicity, the monitoring system may be required to perform some form of corrective action or shut down once a target level (a percentage of the safe exposure limit) concentration is attained. Predicted energy cost savings from recirculation should be weighed against the necessary costs of air cleaning and monitoring requirements (to include calibration and maintenance of monitoring equipment).

Assuming equilibrium has been established, the predicted TWA concentration at the workers' breathing zone can be calculated (ACGIH 2013):

$$C_B = \frac{Q_B}{Q_A}(C_G - C_M)(1 - f) + (C_O - C_M)f + K_B C_R + (1 - K_B)C_M \quad (4)$$

where

- C_B = TWA worker breathing zone contaminant concentration during recirculation, ppm
- Q_B = total ventilation airflow without considering recirculation, cfm
- Q_A = total ventilation airflow including recirculation, cfm
- C_G = average space concentration if no recirculation, ppm
- f = fraction of time worker spends at workstation
- C_O = TWA contaminant concentration at breathing zone of workstation if no recirculation, ppm
- K_B = fraction of worker breathing zone air that consists of recirculated air, 0 to 1.0
- C_R = recirculated air (after air cleaner) discharge concentration, ppm, or

$$C_R = \frac{(1 - \eta)(C_E - K_R C_M)}{1 - (1 - \eta)K_R} \quad (5)$$

- η = fractional air cleaner efficiency for contaminant
- C_E = (local) exhaust concentration without recirculation, ppm
- K_R = fraction of exhaust air that is recirculated air, 0 to 1.0
- C_M = replacement air contaminant concentration, ppm

Other recirculation system examples are given in Chapter 8 of Goodfellow and Tahti (2001).

Example 1. An industrial space uses 10,000 cfm for ventilation, of which 5000 cfm is general exhaust and 5000 cfm local exhaust (ACGIH 2013). Local exhaust is recirculated through an air cleaner with an efficiency of 0.75. Recirculated air is directed toward the worker spaces, such that $K_B = 0.5$ and $K_R = 0.8$ (more of the recirculated air is locally exhausted than enters the worker's breathing zone). The worker is at the workstation 100% of the time ($f = 1$). The makeup air has a

concentration of 5 ppm (C_M), the local exhaust has a concentration of 500 ppm (C_E), the space has an average concentration of 20 ppm (C_G), and without recirculation the worker's breathing zone is 35 ppm (C_O).

Solution: The concentration C_B at the breathing zone with recirculation is determined from

$$C_R = \frac{(1 - 0.75)[500 - 0.8(5)]}{1 - (1 - 0.75)(0.8)} = 155 \text{ ppm}$$

and

$$C_B = \frac{10,000}{5000}(20 - 5)(1 - 1) + (35 - 5)(1) + 0.5(155) + (1 - 0.5)5 = 110 \text{ ppm}$$

which may or may not exceed the allowable TWA exposure limit of the worker space, depending on the specific contaminant.

CHAPTER 32

INDUSTRIAL LOCAL EXHAUST

<i>Local Exhaust Fundamentals</i>	32.2
<i>Air Movement in Vicinity of Local Exhaust</i>	32.3
<i>Other Local Exhaust System Components</i>	32.6
<i>Operation</i>	32.9

INDUSTRIAL exhaust ventilation systems contain, collect, and remove airborne contaminants consisting of particulate matter (dusts, fumes, smokes, fibers), vapors, and gases that can create a hazardous, unhealthy, or undesirable atmosphere. Exhaust systems can also salvage usable material, improve plant housekeeping, and capture and remove excessive heat or moisture. Industrial exhaust systems must comply with ASHRAE *Standard* 62.1 and other standards as required [e.g., National Fire Protection Agency (NFPA) standards].

Special Warning: Certain industrial spaces may contain flammable, combustible and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), Occupational Safety and Health Administration (OSHA), and American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

Local Exhaust Versus General Ventilation

Local exhaust ventilation systems can be the most performance-effective and cost-effective method of controlling air pollutants and excessive heat. For many operations, capturing pollutants at or near their source is the only way to ensure compliance with occupational exposure limits that are measured within the worker's breathing zone. When properly designed, local exhaust ventilation optimizes ventilation exhaust airflow, thus optimizing system acquisition costs associated with equipment size and operating costs associated with energy consumption and makeup air tempering. Chapters 2 and 3 in ACGIH (2013) also discuss this topic at length.

In some industrial ventilation designs, the emphasis is on filtering air captured by local exhausts before exhausting it to the outdoors or returning it to the production space. As a result, these systems are evaluated according to their filter efficiency or total particulate removal. However, if an insufficient percentage of emissions are captured, the degree of air-cleaning efficiency sometimes becomes irrelevant.

For a process exhaust system in the United States, the design engineer must verify if the system is permitted by the 1990 Clean Air Act. For more information, see the Environmental Protection Agency's web site (<http://www.epa.gov/air/cca/>).

The pollutant-capturing efficiency of local ventilation systems depends on hood design, the hood's position relative to the source of contamination, temperature of the source being exhausted, and the induced air currents generated by the exhaust airflow. Selection and positioning of the hood significantly influence initial and operating costs of both local and general ventilation systems. In addition,

poorly designed and maintained local ventilation systems can cause deterioration of building structures and equipment, negative health effects, and decreased worker productivity.

No local exhaust ventilation system is 100% effective in capturing pollutants and/or excess heat. In addition, installation of local exhaust ventilation system may not be possible in some circumstances, because of the size, mobility, or mechanical interaction requirements of the process. In these situations, general ventilation is needed to dilute pollutants and/or excess heat. Where pollutants are toxic or present a health risk to workers, local exhaust is the appropriate approach, and dilution ventilation should be avoided. Air supplied by the general ventilation system is usually conditioned (heated, humidified, cooled, etc.). Supply air replaces air extracted by local and general exhaust systems and improves comfort conditions in the occupied zone.

Chapter 11 of the 2013 *ASHRAE Handbook—Fundamentals* covers definitions, particle sizes, allowable concentrations, and upper and lower explosive limits of various air contaminants. Chapter 31 of this volume, Goodfellow and Tahti (2001), and Chapter 2 of ACGIH (2013) detail steps to determine air volumes necessary to dilute contaminant concentration using general ventilations.

Sufficient makeup air must be provided to replace air removed by the exhaust system. If replacement air is insufficient, building pressure becomes negative relative to atmospheric pressure and allows air to infiltrate through open doors or window cracks, and can reverse flow through combustion equipment vents. A negative pressure as little as 0.05 in. of water can cause drafts and might cause backdrafts in combustion vents, thereby creating potential health and safety hazards. From the sustainability perspective, a negative plant static pressure can also result in excessive energy use. If workers near the plant perimeter complain about cold drafts, unit heaters are often installed. Heat from these units often is drawn into the plant interior, overheating the interior. Too often, this overheating is addressed by exhausting more air from the interior, causing increased negative pressure and more infiltration. Negative plant pressure reduces the exhaust volumetric flow rate because of increased system resistance, which can also decrease local exhaust efficiencies or require additional energy to overcome the increased resistance. Wind effects on building balance may also play a role, and are discussed in Chapter 24 of the 2013 *ASHRAE Handbook—Fundamentals*.

Positive-pressure plants and balanced plants (those with equal exhaust and replacement air rates) use less energy. However, if there are clean and contaminated zones in the same building, the desired airflow direction is from clean to dirty, and zone boundary construction and pressure differentials should be designed accordingly.

Exhaust system discharge may be regulated under various federal, state, and local air pollution control regulations or ordinances. These regulations may require exhaust air treatment before discharge to the atmosphere. Chapter 30 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* provides guidance and recommendations for discharge air treatment.

The preparation of this chapter is assigned to TC 5.8, Industrial Ventilation Systems.

1. LOCAL EXHAUST FUNDAMENTALS

System Components

Local exhaust ventilation systems typically consist of the following basic elements:

- Hood to capture pollutants and/or excessive heat
- Ducted system to transport polluted air to air cleaning device or building exhaust
- Air-cleaning device to remove captured pollutants from the airstream for recycling or disposal
- Air-moving device (e.g., fan or high-pressure air ejector), which provides motive power to generate the hood capture velocity plus overcome exhaust ventilation system resistance
- Exhaust stack, which discharges system air to the atmosphere

System Classification

Contaminant Source Type. Knowing the process or operation is essential before a local exhaust hood system can be designed.

Hood Type. Exhaust hoods are typically round, rectangular, or slotted to accommodate the geometry of the source. Hoods are either enclosing or nonenclosing (Figure 1). **Enclosing hoods** provide more effective and economical contaminant control because their exhaust rates and the effects of room air currents are minimal compared to those for nonenclosing hoods. Hood access openings for inspection and maintenance should be as small as possible and out of the natural path of the contaminant. Hood performance (i.e., how well it captures the contaminant) should ideally be verified by an industrial hygienist.

A **nonenclosing hood** can be used if access requirements make it necessary to leave all or part of the process open. Careful attention must be paid to airflow patterns and capture velocities around the process and hood (under dynamic conditions) and to the process characteristics to make nonenclosing hoods effective. The use of moveable baffles, curtains, strip curtains, and brush seals may allow the designer to increase the level of enclosure without interfering with the work process. The more of the process that can be enclosed, the less exhaust airflow required to control the contaminant(s).

System Mobility. Local exhaust systems with nonenclosing hoods can be **stationary** (i.e., having a fixed hood position), **moveable**, **portable**, or **built-in** (into the process equipment). Moveable hoods are used when process equipment must be accessed for repair and loading and unloading of materials (e.g., in electric ovens for melting steel).

The portable exhaust system shown in Figure 2 is commonly used for temporary exhausting of fumes and solvents in confined spaces or during maintenance. It has a built-in fan and filter and an exhaust hood connected to a flexible hose. Built-in local exhaust

Fig. 1 Enclosing and Nonenclosing Hoods

(Adapted from ACGIH®, *Industrial Ventilation: A Manual of Recommended Practice*, 27th ed. Copyright 2010. Reprinted with permission.)

systems are commonly used to evacuate welding fumes, such as hoods built into stationary or turnover welding tables. Lateral exhaust hoods, which exhaust air through slots on the periphery of open vessels, such as those used for galvanizing metals, are another example of built-in local exhaust systems.

Effectiveness of Local Exhaust

The most effective hood design uses the minimum exhaust airflow rate to provide maximum contaminant control without compromising operator capability to complete the work task. **Capture effectiveness** should be high, but it is difficult and costly to develop hoods with efficiencies approaching 100%. Makeup air supplied by general ventilation to replace exhausted air can dilute contaminants that are not captured by the hood. Enclosing more of the process reduces the need to protect against contaminant escape through cross drafts, convective currents, or process-generated contaminant momentum. In turn, this reduces the exhaust airflow required to control the contaminant(s).

Capture Velocity. Capture velocity is the air velocity required to entrain contaminants at the point of contaminant generation upstream of a hood. The contaminant enters the moving airstream near the point of generation and is carried along with the air into the hood. Designers use a designated capture velocity V_c to determine a volumetric flow rate to draw air into the hood. Table 1 shows ranges of capture velocities for several industrial operations. These figures are based on successful experience under ideal conditions. Once capture velocity upstream of the hood and hood position relative to the source are known, then the hood flow rate can be determined for the particular hood design. Velocity distributions for specific hoods must be known or determined.

Hood Volumetric Flow Rate. For a given hood configuration and capture velocity, the exhaust volumetric flow rate (the airflow rate that allows contaminant capture) can be calculated as

$$Q_o = V_o A_o \quad (1)$$

where

Q_o = exhaust volumetric flow rate, cfm

V_o = average air velocity in hood opening that ensures capture velocity at point of contaminant release, fpm

A_o = hood opening area, ft²

Low face velocities require that supply (makeup) air be as uniformly distributed as possible to minimize the effects of room air currents. This is one reason replacement air systems must be designed with exhaust systems in mind. Air should enter the hood

Fig. 2 Portable Fume Extractor with Built-in Fan and Filter

Table 1 Range of Capture (Control) Velocities

Condition of Contaminant Dispersion	Examples	Capture Velocity, fpm
Released with essentially no velocity into still air	Evaporation from tanks, degreasing, plating	50 to 100
Released at low velocity into moderately still air	Container filling, low-speed conveyor transfers, welding	100 to 200
Active generation into zone of rapid air motion	Barrel filling, chute loading of conveyors, crushing, cool shakeout	200 to 500
Released at high velocity into zone of very rapid air motion	Grinding, abrasive blasting, tumbling, hot shakeout	500 to 2000

Note: In each category above, a range of capture velocities is shown. The proper choice of values depends on several factors (Alden and Kane 1982):

Lower End of Range

1. Room air currents favorable to capture
2. Contaminants of low toxicity or of nuisance value only
3. Intermittent, low production
4. Large hood; large air mass in motion

Upper End of Range

1. Distributing room air currents
2. Contaminants of high toxicity
3. High production, heavy use
4. Small hood; local control only

Fig. 3 Use of Interior Baffles to Ensure Good Air Distribution

uniformly. Hood flanges, side baffles, and interior baffles are sometimes necessary (Figure 3).

Airflow requirements for maintaining effective capture velocity at a contaminant source also vary with the distance between the source and hood. Chapter 3 of ACGIH (2013) provides methodology for estimating airflow requirements for specific hood configurations and locations relative to the contaminant source.

Airflow near the hood can be influenced by drafts from supply air jets (spot cooling jets) or by turbulence of the ambient air caused by jets, upward/downward convective flows, moving people, mobile equipment, and drafts from doors and windows. Process equipment may be another source of air movement. For example, high-speed rotating machines such as pulverizers, high-speed belt material transfer systems, falling granular materials, and escaping compressed air from pneumatic tools all produce air currents. These factors can significantly reduce the capturing effectiveness of local exhaust systems and should be accounted for in the exhaust system design.

Fig. 4 Influence of Hood Location on Contamination of Air in the Operator's Breathing Zone

(Adapted from ACGIH®, *Industrial Ventilation: A Manual of Recommended Practice*, 28th ed. Copyright 2013.)

Exhausted air may contain combustible pollutant/air mixtures. If it does, the amount by which the exhaust airflow rate should be increased to dilute combustible mixture must be verified to meet the requirements of National Fire Protection Association (NFPA) *Standards* 86 and 329.

Principles of Hood Design Optimization

Numerous studies of local exhaust systems and common practices have led to the following hood design principles:

- Hood location should be as close as possible to the source of contamination.
- The hood opening should be positioned so that it causes the contaminant to deviate the least from its natural path.
- The hood should be located so that the contaminant is drawn away from the operator's breathing zone.
- Hood size must be the same as or larger than the cross section of flow entering the hood. If the hood is smaller than the flow, a higher volumetric flow rate is required.
- Worker position with relation to contaminant source, hood design, and airflow path should be evaluated based on the principles given in Chapters 3 and 10 of ACGIH (2013).
- Canopy hoods (Figure 4) should not be used where the operator must bend over a tank or process (ACGIH 2013).

2. AIR MOVEMENT IN VICINITY OF LOCAL EXHAUST

Air capture velocities in front of the hood opening depend on the exhaust airflow rate, hood geometry, distance from hood face and surfaces surrounding the hood opening. Figure 5 shows velocity contours for an unflanged round duct hood. Studies have established the similarity of velocity contours (expressed as a percentage of the hood entrance velocity) for hoods with similar geometry (Dalla-Valle 1952). Figure 6 shows velocity contours for a rectangular hood with an **aspect ratio** (width divided by length) of 0.333. The profiles are similar to those for the round hood but are more elongated. If the aspect ratio is lower than about 0.2 (0.15 for flanged openings), the flow pattern in front of the hood changes from approximately spherical to approximately cylindrical. Velocity decreases rapidly with distance from the hood; per DallaValle, velocity decreases on the order of 1/(distance from suction inlet squared).

The design engineer should consider side drafts and other sources of air movement close to the capture area of a local exhaust hood. Caplan and Knutson (1977, 1978) found that air movement in front of laboratory hoods can cause contaminants to escape from the

Fig. 5 Velocity Contours for Plain Round Opening
(Alden and Kane 1982; used by permission)

hood and into the operator’s breathing zone. In industrial applications, it is common to see large fans blowing air onto workers who are located in front of an exhaust hood. This can render the local exhaust hood ineffective to the point that no protection is provided for the worker and/or their adjacent co-workers.

Pressure Loss in Hoods and Ducts

A vena contracta forms in the entrance of the hood or duct and produces a pressure loss, which can be described using pressure loss coefficient C_o or a static pressure entry loss (ACGIH 2013). When air enters a hood, the pressure loss, called **hood entry loss**, may have several components, depending on the hood’s complexity. Simple hoods usually have a single pressure loss coefficient C_L specified, defined as

$$C_L = \sqrt{\frac{P_v}{P_{s,h}}} \tag{2}$$

where

C_L = pressure loss coefficient depending on hood type and geometry, dimensionless

$P_v = K\rho V^2/2g_c$, dynamic pressure inside duct caused by moving airstream (constant in duct after vena contracta), where K is proportionality constant, in. of water, ρ is air density in lb/ft^3 , and g_c is the gravitational acceleration constant, $32.2 \text{ lb}_m \cdot \text{ft}/\text{lb}_f \cdot \text{s}^2$

$P_{s,h}$ = static pressure in hood duct because of velocity pressure increase and hood entry loss, in. of water

More information on loss factors and the design of exhaust ductwork is in Chapter 21 of the 2013 *ASHRAE Handbook—Fundamentals*, ACGIH (2013), and Brooks (2001).

The loss coefficient C_L is different from the hood entry loss coefficient. The entry loss coefficient C_o relates duct total pressure loss to duct velocity pressure. From Bernoulli’s equation, hood total pressure is approximately zero at the entrance to the hood, and

Fig. 6 Velocity Contours for Plain Rectangular Opening with Sides in a 1:3 Ratio

(Alden and Kane 1982; used by permission)

therefore the static pressure is equal to the negative of the velocity pressure:

$$P_s = -P_v \tag{3}$$

Static pressure in the hood/duct is the static pressure (velocity pressure) plus the head loss, which is expressed as a fraction of the velocity pressure, as

$$P_{s,h} = P_v + C_o P_v \tag{4}$$

Rearranged, the hood/duct static pressure $P_{s,h}$ (hood suction) for hoods is

$$P_{s,h} = (1 + C_o)P_v \tag{5}$$

and the change in total pressure is

$$\Delta P_t = P_{s,h} - P_v = C_o P_v \tag{6}$$

Loss coefficients C_o for various hood shapes are given in Figure 7. For tapered hoods, Figure 5 shows that the optimum hood entry angle to minimize entry loss is 45° , but this may be impractical in many situations because of the required transition length. A 90° angle, with a corresponding loss factor of 0.25 (for rectangular openings), is typical for many tapered hoods.

Example 1. A nonenclosing side-draft flanged hood (Figure 8) with face dimensions of 1.5 by 4 ft rests on the bench. The required volumetric flow rate is 1560 cfm. The duct diameter is 9 in.; this gives a duct velocity of 3530 fpm. The hood is designed such that the largest angle of transition between the hood face and the duct is 90° . What is the suction pressure (static pressure) for this hood? Assume air density at 72°F .

Fig. 7 Entry Losses for Typical Hoods

Fig. 8 Hood on Bench

Solution: The two transition angles cannot be equal. Whenever this is true, the larger angle is used to determine the loss factor from Figure 7. Because the transition piece originates from a rectangular opening, the curve marked “rectangular” must be used. This corresponds to a loss factor of 0.25. The duct velocity pressure is

$$P_v = \frac{\rho V^2}{2g_c} = \frac{(0.075)(3530)^2}{(2)(32.2)} \times \frac{12}{(62.4)(3600)} = 0.78 \text{ in. of water}$$

From Equation (5),

$$P_{s,h} = (1 + 0.25)(0.78) = 0.98 \text{ in. of water}$$

Compound Hoods. Losses for multislot hoods (Figure 9) or single-slot hoods with a plenum (compound hoods) must be analyzed somewhat differently. The slots distribute air over the hood face and do not influence capture efficiency. Slot velocity should be approximately 2000 fpm to provide required distribution at minimum energy cost; plenum velocities are typically 50% of slot velocities (approximately 1000 fpm). Higher velocities dissipate more energy and can cause hot spots in the face of the hood.

Fig. 9 Multislot Nonenclosing Hood

Losses occur when air passes through the slot and when air enters the duct. Because the velocities, and therefore the velocity pressures, can be different at the slot and at the duct entry locations, the hood suction must reflect both losses and is given by

$$P_{s,h} = P_v + (C_o P_v)_s + (C_o P_v)_d \tag{7}$$

where the first P_v is generally the higher of the two velocity pressures, s refers to the slot, and d refers to the duct entry location.

Example 2. A multislot hood has three slots, each 1 by 40 in. At the top of the plenum is a 90° transition into the 10 in. duct. The volumetric flow rate required for this hood is 1650 cfm. Determine the hood suction (static pressure). Assume air density at 72°F.

Solution: The slot velocity V_s is

$$V_s = \frac{(1650)(144)}{(3)(40)(1)} = 1980 \text{ fpm}$$

which is near the minimum slot velocity of 2000 fpm. Substituting this velocity,

$$P_v = \frac{\rho V^2}{2g} = \frac{(0.075)(1980)^2}{(2)(32.2)} \times \frac{(12)}{(62.4)(3600)} = 0.24 \text{ in. of water}$$

The duct area is 0.5454 ft². Therefore, duct velocity and velocity pressure are

$$V_d = Q/A$$

$$V_d = \frac{1650}{0.5454} = 3025 \text{ fpm}$$

Substituting this velocity,

$$P_v = \frac{(0.075)(3025)^2}{(2)(32.2)} \times \frac{(12)}{(62.4)(3600)} = 0.57 \text{ in. of water}$$

For a 90° transition into the duct, the loss factor is 0.25. For the slots, the loss factor is 1.78 (Figure 7). The duct velocity pressure is added to the sum of the two losses because it is larger than the slot velocity pressure. Using Equation (7),

$$P_{s,h} = 0.57 + (1.78)(0.24) + (0.25)(0.57) = 1.14 \text{ in. of water}$$

Exhaust volume requirements, minimum duct velocities, and entry loss factors for many specific operations are given in Chapter 10 of ACGIH (2013).

Overhead Canopy Hoods

If a hot work process cannot be completely enclosed, place a canopy hood above the process so that the contaminant convectively moves toward the hood. Canopy hoods should be applied and designed with caution to avoid drawing contaminants across the operator's breathing zone (see Figure 4). The hood's height above the process should be minimized to reduce total exhaust airflow rate. Efficiencies in ventilation capture can be gained when ventilating heated processes with canopy hoods, because heated air naturally moves upward because of its reduced density (i.e., buoyancy). Canopy hoods are most effective when contaminant is released over a well-defined area, and the contaminant is entrained in the rising, buoyant plume. Room cross drafts can substantially deflect the rising plume when it is created by a low-temperature process, or when cross drafts are greater than 50 fpm between the process and the canopy inlet. When determining proper hood selection and design parameters, carefully consider process information, such as required worker access to the process, process-related material movement within the plume, and the hazard potential of the contaminants associated with the process.

Canopy hoods without side walls are the least effective and efficient method of controlling hot process plumes. The limitation of any hood design with distance between the hood face and surface of the source is the ability of cross drafts to interfere with capturing contaminants rising from the hot process. Where cross drafts greater than 50 fpm are present, hood designs should include side walls. At a minimum, one side wall should be included in the hood design on the side of the process where the cross draft originates (upstream side).

Canopy Hoods with Sidewalls

When side walls are included, or when the process is close to a structural wall, the plume may attach to the wall. In this event, the plume entrainment volume is reduced compared to that in an unbounded plume, and the resulting flow in the plume is reduced to half the flow of an unbounded plume. If there are two walls attached at a right angle, the flow is reduced to 1/4 of the unbounded plume flow (Nielsen 1993).

Low Canopy Hoods

Whenever the distance between a canopy hood and the hot source is within 3 ft or the source diameter, whichever is smaller, this hood is considered to be a low canopy hood. Its close proximity to the source does not allow sufficient time for the plume to expand; thus, the diameter or cross section of the hot air column is approximately the same as the source. Under this design scenario, the diameter or side dimensions of the hood need only be about 1 ft larger than the source diameter at its widest cross-section (Hemeon 1963, 1999). For rectangular sources, rising plumes may be better controlled if the hood shape reflects that of the source. In this circumstance, perform the hood airflow and design calculations as for a circular source, once for the length and once for the width dimensions.

High Canopy Hood Use as Redundant Control Measure

The high canopy hood without side walls is the least favorable canopy design. The design can be used as a redundant measure for controlling large-volume process plumes. High canopy hoods are not recommended as a primary control measure for heated processes, because of the large volumes of air displaced to remove pollutants from the workplace. For example, arc furnace charging has a limited duration, and restricted canopy hood use while the furnace is being charged reduces the required volume of replacement air. Ideally, high canopy hood faces without walls should be round, because rising air from point sources and compact shapes (i.e., not line sources) becomes circular in cross section as it rises (Bill and

Fig. 10 Sidedraft Hood and Slot Hood on Tank

Gebhart 1975). This occurs because turbulence sweeps the plume edges inward to a minimal volume. However, it is more cost effective to manufacture and install square or rectangular hoods. Baffles are recommended at the face of rectangular canopy hoods to approximate the area of a round hood face.

Ventilation Controls for Large-Scale Hot Processes

Equations to approximate the velocity, area, and volumetric flow of rising air above a large-scale cylindrical heated process with excess air temperatures ($\Delta t < 198^\circ\text{F}$) are available from several sources (ACGIH 2013; Goodfellow 1985; Hemeon 1963, 1999; U.S. Public Health Service 1973). These equations derive from compilation of empirical research by Hemeon and others, and are useful for traditional large-scale, high-temperature processes (e.g., arc furnaces, tapping operations).

Ventilation Controls for Small-Scale Hot Processes

New equations to approximate the velocity, area, and volumetric flow of the rising air above a small-scale heated process have been validated within a range of excess air temperatures ($2^\circ\text{F} < \Delta t < 54^\circ\text{F}$) (McKernan and Ellenbecker 2007; McKernan et al. 2007a, 2007b). These equations are based on modern research applicable to designing engineering controls for heated processes, as well as historic work by Hemeon and others (Goodfellow 1985; Hemeon 1963, 1999; U.S. Public Health Service 1973). They are particularly useful for approximating volumetric flow from discrete low-temperature sources. The historic equations of Hemeon and others continue to be useful for the traditional large-scale, high temperature processes (e.g., arc furnaces, tapping operations).

Sidedraft Hoods

Sidedraft hoods typically draw contaminant away from the operator's breathing zone. With a buoyant source, a sidedraft hood requires a higher exhaust volumetric flow rate than a low canopy hood. If a low canopy hood restricts the work process, a sidedraft hood may be more cost effective than a high canopy hood. Examples of sidedraft hoods include multislotting "pickling" hoods near welding benches (Figure 9) and slot hoods on tanks (Figure 10).

3. OTHER LOCAL EXHAUST SYSTEM COMPONENTS

Duct Design and Construction

Duct Considerations. The second component of a local exhaust ventilation system is the duct through which contaminated air is transported from the hood(s). Round ducts are preferred because they (1) offer more uniform velocity to resist settling of material, (2) can withstand the higher static pressures normally found in industrial exhaust systems, and (3) are easier to seal. When design

Table 2 Contaminant Transport Velocities

Nature of Contaminant Examples		Minimum Transport Velocity, fpm
Vapor, gases, smoke	All vapors, gases, smoke	Usually 1000 to 2000
Fumes	Welding	2000 to 2500
Very fine light dust	Cotton lint, wood flour, litho powder	2500 to 3000
Dry dusts and powders	Fine rubber dust, molding powder dust, jute lint, cotton dust, shavings (light), soap dust, leather shavings	3000 to 4000
Average industrial dust	Grinding dust, buffing lint (dry), wool jute dust (shaker waste), coffee beans, shoe dust, granite dust, silica flour, general material handling, brick cutting, clay dust, foundry (general), limestone dust, asbestos dust in textile industries	3500 to 4000
Heavy dust	Sawdust (heavy and wet), metal turnings, foundry tumbling barrels and shakeout, sandblast dust, wood blocks, hog waste, brass turnings, cast-iron boring dust, lead dust	4000 to 4500
Heavy and moist dust	Lead dust with small chips, moist cement dust, asbestos chunks from transite pipe cutting machines, buffing lint (sticky), quicklime dust	4500 and up

Source: Adapted from ACGIH (2013).

limitations require rectangular or flat oval ducts, the aspect ratio (height-to-width ratio) should be as close to unity as possible.

Minimum transport velocity is the velocity required to transport particles without settling. Table 2 lists some generally accepted transport velocities as a function of the nature of the contaminants (ACGIH 2013). The values listed are typically higher than theoretical and experimental values to account for (1) damage to ducts, which increases system resistance and reduces volumetric flow and duct velocity; (2) duct leakage, which tends to decrease velocity in the duct system upstream of the leak; (3) fan wheel corrosion or erosion and/or belt slippage, which could reduce fan volume; and (4) reentrainment of settled particles caused by improper operation of the exhaust system. Design velocities can be higher than minimum transport velocities but should never be significantly lower.

When particle concentrations are low, the effect on fan power is negligible. Using standard duct sizes and fittings decreases cost and delivery time. Information on available sizes and cost of nonstandard sizes can be obtained from the contractor(s).

Duct Losses. Chapter 21 of the 2013 *ASHRAE Handbook—Fundamentals* covers the basics of duct design and design of metal-working exhaust systems. Loss coefficients are found in the *ASHRAE Duct Fitting Database* CD-ROM (ASHRAE 2008).

For systems conveying particles, elbows with a centerline radius-to-diameter ratio (r/D) greater than 1.5 are the most suitable. If $r/D \leq 1.5$, abrasion in dust-handling systems can reduce the life of elbows. Elbows, especially those with large diameters, are often made of seven or more gores. For converging flow fittings, a 30° entry angle is recommended to minimize energy losses and abrasion in dust-handling systems (Chapter 21 of the 2013 *ASHRAE Handbook—Fundamentals*).

Where exhaust systems handling particles must allow for a substantial increase in future capacity, required transport velocities can be maintained by providing open-end stub branches in the main duct. Air is admitted through these stub branches at the proper pressure and volumetric flow rate until the future connection is installed. Figure 11 shows such an air bleed-in. Using outside air minimizes replacement air requirements, though care must be taken to consider potential adverse effects of temperature or humidity extremes associated with the two air streams. The size of the opening can be calculated by determining the pressure drop required across the orifice from the duct calculations. Then the orifice velocity pressure can be determined from one of the following equations:

$$P_{v,o} = \frac{\Delta P_{t,o}}{C_o} \tag{8}$$

where

$P_{v,o}$ = orifice velocity pressure, in. of water

ΔT_o = total pressure to be dissipated across orifice, in. of water

Fig. 11 Air Bleed-In

C_o = orifice loss coefficient referenced to the velocity at the orifice cross-sectional area, dimensionless (see Figure 7)

Once the velocity pressure is known, orifice velocity and size can be determined.

Occasionally, a counterweighted backdraft damper or spring-loaded air admittance valve, configured to allow airflow into the duct but not out, is used as an air bleed in lieu of an orifice in systems that operate under varying airflow conditions. This ensures the proper quantity of transport airflow inside the duct, helping to eliminate material fallout and subsequent duct blockage.

Integrating Duct Segments. Most systems have more than one hood. If the pressures are not designed to be the same for merging parallel airstreams, the system adjusts to equalize pressure at the common point; however, the resulting flow rates of the two merging airstreams will not necessarily be the same as designed. As a result, the hoods can fail to control the contaminant adequately, exposing workers to potentially hazardous contaminant concentrations. Two design methods ensure that the two pressures will be equal. The preferred design self-balances without external aids. This procedure is described in the section on Industrial Exhaust System Duct Design in Chapter 21 of the 2013 *ASHRAE Handbook—Fundamentals*. The second design, which uses adjustable balance devices such as blast gates or balancing dampers, is not recommended, especially when abrasive material is conveyed.

Duct Construction. Elbows and converging flow fittings should be made of thicker material than the straight duct, especially if abrasives are conveyed. Elbows with $r/D > 2$ with replaceable wear plates (wear backs) in the heel are often used where particulate loading is extremely heavy or the particles are very abrasive. When corrosive material is present, alternatives such as special coatings or different duct materials (fibrous glass or stainless steel) can be used. Cleanout openings should be located to allow access to the duct interior in the event of a blockage. Certain contaminants may require washdown systems and/or fire detection and suppression systems to comply with safety or fire prevention codes. These requirements should be verified with local code officials and insurance

underwriters. NFPA standards provide guidance on fire safety. Industrial duct construction is also described in Chapter 19 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*, and in Sheet Metal and Air Conditioning Contractors' National Association (SMACNA) *Standard* 005-1999.

Air Cleaners

Air-cleaning equipment is usually selected to (1) conform to federal, state, or local emissions standards and regulations; (2) prevent reentrainment of contaminants to work areas; (3) reclaim usable materials; (4) allow cleaned air to recirculate to work spaces and/or processes; (5) prevent physical damage to adjacent properties; and (6) protect neighbors from contaminants.

Factors to consider when selecting air-cleaning equipment include the type of contaminant (number of components, particulate versus gaseous, moisture and heat in the airstream, and pollutant concentration), contaminant characteristics (e.g. volatility, reactivity), required contaminant removal efficiency, disposal method, and air or gas stream characteristics. Auxiliary systems such as instrument-grade compressed air, electricity, or water may be required and should be considered in equipment selection. Specific hazards such as explosions, fire, or toxicity must be considered in equipment selection, design, and location. See Chapters 29 and 30 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for information on equipment for removing airborne contaminants. Consult an applications engineer when selecting equipment.

The cleaner's pressure loss must be added to overall system pressure calculations. In some cleaners, specifically some fabric filters, loss increases as operation time increases. System design should incorporate the maximum pressure drop of the cleaner, or hood flow rates will be lower than designed during most of the duty cycle. Also, fabric collector losses are usually given only for a clean air plenum. A reacceleration to the duct velocity, with the associated entry losses, must be calculated during design. Most other cleaners are rated flange-to-flange with reacceleration included in the loss.

Air-Moving Devices

The type of air-moving device selected depends on the type and concentration of contaminant, the pressure rise required, and allowable noise levels. Fans are usually used. Chapter 21 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* describes available fans; Air Movement and Control Association *Publication* 201 (AMCA 2002) describes proper connection of the fan(s) to the system. The fan should be located downstream of the air cleaner whenever possible to (1) reduce possible abrasion of the fan wheel blades and (2) create negative pressure within the air cleaner and the entire length of dirty duct so that air leaks into the exhaust system throughout its dirty side and control of the contaminant is maintained.

Fans handling flammable or explosive dusts should be specified as spark-resistant. AMCA provides three different spark-resistant fan construction specifications. Consult the fan manufacturer when handling these materials. Multiple NFPA standards give fire safety requirements for fans and systems handling explosive or flammable materials.

When possible, devices such as fans and pollution-control equipment should be located outside classified areas, and/or outside the building, to reduce the risk of fire or explosion.

In some instances, the fan is located upstream from the cleaner to help remove dust. This is especially true with cyclone collectors, for example, which are used in the woodworking industry. If explosive, corrosive, flammable, or sticky materials are handled, an injector (also known as an eductor) can transport the material to the air-cleaning equipment. Injectors create a shear layer that induces airflow into the duct. Injectors should be the last choice because their efficiency seldom exceeds 10%.

Energy Recovery to Increase Sustainability

Energy transfer from exhausted air to replacement air may be economically feasible, depending on the (1) location of the exhaust and replacement air ducts, (2) temperature of the exhausted gas, and (3) nature of the contaminants being exhausted. Heat transfer efficiency depends on the type of heat recovery system used.

If exhausted air contains particulate matter (e.g., dust, lint) or oil mist, the exhausted air should be filtered to prevent fouling the heat exchanger. If exhausted air contains gaseous and vaporous or volatile contaminants, such as hydrocarbons and water-soluble chemicals, their effect on the heat recovery device should be investigated. Chapter 26 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* discusses air-to-air energy recovery systems.

When selecting energy recovery equipment for industrial exhaust systems, cross-contamination from the energy recovery device must be considered. Some types of energy recovery equipment may allow considerable cross contamination (e.g., some heat wheels) from the exhaust into the supply airstream, whereas other types (e.g., runaround coils) do not. The exhaust side of the energy recovery device should be negatively pressured compared to the supply side, so that any leakage will be from the clean side into the contaminated side. This is not acceptable for some applications. The material of the energy recovery device must be compatible with the pollutants being exhausted. If the exhaust airstream destroys the heat exchanger, contamination can enter the supply airstream and cause additional equipment damage as well as increase exposure to workers.

Exhaust Stacks

The exhaust stack must be designed and located to prevent reentraining discharged air into supply system inlets. The building's shape and surroundings determine the atmospheric airflow over it. Chapter 45 covers exhaust stack design. The typical code-required minimum stack height is intended to provide protection for workers near the stack, so discharged air is above their breathing zone. The minimum required stack height does not protect against reentrainment of contaminated exhaust into any outside air intakes.

If rain protection is important, a no-loss stack head design (ACGIH 2013; SMACNA *Standard* 005) is recommended. Weather caps deflect air downward, increasing the chance that contaminants will recirculate into air inlets, have high friction losses, and provide less rain protection than a properly designed stack head. Weather caps should never be used with a contaminated or hazardous exhaust stream.

Figure 12 contrasts flow patterns of weather caps and stack heads. Loss data for stack heads are presented in the *Duct Fitting Database* CD-ROM (ASHRAE 2008). Losses in straight-duct stack heads are balanced by the pressure regain at the expansion to the larger-diameter stack head.

Instrumentation and Controls

Some industrial exhaust systems may require positive verification of system airflow. Indicators of performance failure may require both audible and visual warning indicators. Other instrumentation, such as dust collector level indication, rotary lock valve operation, or fire detection, may be required. Selection of electronic monitoring instruments should consider durability expectations, maintenance, and calibration requirements. Interfaces may be required with the process control system or with the balance of the plant ventilation system. Electrical devices in systems conveying flammable or explosive materials or in a hazardous location may need to meet certain electrical safety and code requirements. These requirements are determined by the owner, process equipment manufacturer, federal and state regulations, local codes, and/or insurance requirements.

Fig. 12 Comparison of Flow Pattern for Stack Heads and Weather Caps

4. OPERATION

System Testing and Balancing

After installation, an exhaust system should be tested and balanced to ensure that it operates properly, with the required flow rates through each hood. If actual flow rates are different from design values, they should be corrected before the system is used. Testing is also necessary to obtain and document baseline data to determine (1) compliance with federal, state, and local codes; (2) by periodic inspections or real-time monitoring, whether maintenance on the system is needed to ensure design operation; (3) whether a system has sufficient capacity for additional airflow; (4) whether system leakage is acceptable; and (5) compliance with testing, adjusting, and balancing (TAB) standards. AMCA (1990) and Chapter 5 of ACGIH (2007) contain detailed information on preferred methods for testing systems.

Operation and Maintenance

Periodic inspection and maintenance are required for proper operation of exhaust systems. System designers should keep this requirement in mind and account for it through the installation of clean-out/inspection doors and through strategic placement of equipment that ensures access for maintenance activities. Systems are often changed or damaged after installation, resulting in low duct velocities and/or incorrect volumetric flow rates. Low duct velocities can cause contaminants to settle and plug the duct, reducing flow rates at affected hoods. Adding hoods to an existing system can change volumetric flow at the original hoods. In both cases, changed hood volumes can increase worker exposure and health risks. The maintenance program should include (1) inspecting ductwork for particulate accumulation and damage by erosion or physical abuse, (2) checking exhaust hoods for proper volumetric flow rates and physical condition, (3) checking fan drives, (4) maintaining air-cleaning equipment according to manufacturers' guidelines, and (5) confirming that the system continues to meet compliance with worker exposure and environmental pollution requirements. These and other details are also discussed in ACGIH (2007).

--	---

THIS chapter focuses primarily on commercial kitchen ventilation (CKV) systems in restaurants and institutional food service facilities, and incorporates the research and experience (including all steps of the design process) amassed by TC 5.10 over the past two decades. Although a brief section on residential kitchen ventilation has been retained, only minor updates have been incorporated over the history of this chapter. Given ongoing debate on residential range hood performance, TC 5.10 anticipates sponsoring research to provide a basis for enhanced design of residential kitchen ventilation (RKV) systems.

1. COMMERCIAL KITCHEN VENTILATION

Kitchen ventilation is a complex web of interconnected HVAC systems. The main components typically include (1) cooling to address heat from cooking appliances, (2) replacement air to provide proper pressurization during cooking operations, and (3) exhaust to remove heat and effluent generated by cooking appliances. System design includes aspects of air conditioning, fire safety, ventilation, building pressurization, refrigeration, air distribution, and food service equipment. Kitchens are in many buildings, including restaurants and retail malls (see Chapter 2), hotels (Chapter 6), hospitals (Chapter 8), single- and multifamily dwellings (Chapter 1), educational facilities (Chapter 7), and correctional facilities. Each building type has special requirements for its kitchens, but many basic needs are common to all. This chapter provides an understanding of the different components of kitchen ventilation systems and where they can be applied. Additionally, background information is included to provide an understanding of the history and rationale behind these design decisions.

Kitchen ventilation has at least two purposes: (1) to provide a comfortable environment in the kitchen and (2) to ensure the safety of personnel working in the kitchen and of other building occupants. Comfort criteria often depend on the local climate, because some kitchens are not air conditioned. Kitchen ventilation ensures safety by providing a means to remove the heat, smoke, and grease (cooking effluent) produced during normal cooking operations.

HVAC system designers are most frequently involved in commercial kitchen applications, in which cooking effluent contains large amounts of grease or water vapor. Residential kitchens typically use a totally different type of hood. The amount of grease produced in residential applications is significantly less than in commercial applications, so the health and fire hazard is much lower.

The centerpiece of almost any kitchen ventilation system is an exhaust hood(s), used primarily to remove cooking effluent from

kitchens. Effluent includes gaseous, liquid, and solid contaminants produced by the cooking process, and may also include products of fuel and even food combustion. These contaminants must be removed for both comfort and safety; effluent can be potentially life-threatening and, under certain conditions, flammable. Finally, note that the arrangement of food service equipment and its coordination with the hood(s) can greatly affect the energy used by these systems, which in turn affects kitchen operating costs. Quite often, the hood selection and appliance layout is determined by a kitchen facility designer. To minimize energy use and ensure a properly designed kitchen ventilation system, the HVAC engineer should reach out to the kitchen designer and share the practices and ideas presented in this chapter.

Sustainability

Kitchens are some of the most intensive users of energy for a given floor area when compared to other commercial or institutional occupancies. In addition to energy used during cooking, the kitchen ventilation system must address the large amount of heat emitted or convected into the kitchen from the cooking equipment, and supply and condition the replacement air needed to support the cooking effluent exhaust system as well as ensure acceptable indoor environmental quality (IEQ). An additional factor to be considered is the cooking effluent, and any treatments that may be required before it is discharged into the atmosphere.

Given these factors, it is imperative that the kitchen ventilation system be designed with careful consideration of both first costs and operating costs. Maintenance costs should also be considered, including scheduled equipment replacement (such as air filters), any corresponding labor, and any production down time as a result of the maintenance.

To ensure all of these criteria are accounted for in the kitchen ventilation design, the integrated building design approach described in Chapter 58 is recommended.

1.1 COMMISSIONING

Because CKV systems are very complex operational environments, it is strongly recommended that ASHRAE *Standard 202* and the recommendations in Chapter 43 for commissioning be followed for any commercial kitchen ventilation project. Sections of this chapter contain the technical information necessary to address all four phases of commissioning. Addressing the following topics is recommended when developing and executing any commissioning plan:

1. Owners project requirements (OPR)
 - a. System manual outline
 - i. System selection: specific kitchen ventilation use requirements (by owner or design team)

The preparation of this chapter is assigned to TC 5.10, Kitchen Ventilation.

- ii. Type of facility (e.g., commissary, quick service, full service, institutional)
 - iii. Cooking appliances selection based on menu, type of cooking, and special/unusual considerations
 - iv. Other considerations
 - 1. System cost
 - 2. Kitchen space comfort targets
 - 3. Energy use and sustainability targets
 - 4. Replacement air requirements
 - 5. Cooking exhaust
 - a. Duct routing and egress
 - b. Effluent control requirements
 - c. Air discharge and outlet restrictions
 - 6. Other mechanical services
 - a. HVAC equipment location
 - b. Utility services
 - 7. Future expansion
 - 8. Ongoing maintenance requirements
2. Design phase
 - a. Systems manual outline (i.e., design intent): the engineer's response to the OPR
 - b. Hood selection based on appliance line up (*very critical because it affects exhaust rate*)
 - c. Replacement air method, and kitchen air movement
 - d. Accounting for kitchen equipment heat gains
 - e. System control strategies, including demand-controlled kitchen ventilation (DCKV) systems
 - f. Exhaust effluent control measures
 - g. Energy saving measures
 - h. Exhaust system requirements
 - i. Fire safety
 - j. Codes and standards
 - i. NFPA *Standard* 96
 - ii. ASHRAE *Standard* 154
 - iii. IMC (ICC 2012)
 - iv. UL *Standard* 710
 - v. UL *Standard* 762
 3. Construction phase
 - a. Submittal review and coordination with all disciplines
 - b. Installation and execution with end use in mind
 - c. Exhaust duct construction
 - d. Air outlet and inlet locations and adjustments
 - e. Technical commissioning of the following:
 - i. System controls for replacement air and exhaust air, including DCKV systems
 - ii. Cooking effluent control equipment
 - iii. Cooking fire suppression systems
 - iv. Air system testing, balancing, and adjustment
 4. Occupancy and operations
 - a. Owner and user training of systems
 - i. Exhaust and replacement air controls, including DCKV systems
 - ii. Cooking effluent control
 - iii. Cooking fire suppression
 - b. Maintenance schedule
 - c. Recommissioning plan
 - d. Consequences of any revision/remodel (e.g., changing cooking equipment)

1.2 VENTILATION DESIGN

Designing a CKV or even a high-end residential kitchen ventilation system requires a different design approach and process than for most traditional HVAC systems. Design considerations include large replacement air requirements, large internal heat gains, kitchen worker comfort, minimizing HVAC system energy use, and

fire safety, all of which are equally high priorities that must be addressed during system design.

Necessary steps to design the ventilation systems for a commercial kitchen are as follows. Details for each step can be found in the subsequent sections in this chapter, or in the other Handbook chapters.

1. **Kitchen facilities design** (including cooking menu and appliance selection and placement). This design is typically performed by the food service consultant (FSC). Additionally, determine which appliances require an exhaust hood.
2. **Exhaust hood selection**, including exhaust air rates. Often overlooked, but one of the most critical design decisions for any CKV system: hood selection directly affects exhaust rates, the corresponding replacement air requirements, CKV system heat gain and loss calculations, and the system's overall energy use. Considerations include
 - a. Appliance thermal plume
 - b. Type I or Type II, based on appliance use or process
 - c. Hood style (e.g., canopy, island, backshelf)
 - d. Energy saving options (e.g., side panels, extra overhang, demand control kitchen ventilation)
 - e. Life-cycle cost analysis
3. **CKV system integration and design**. Determine exactly what the CKV system should accomplish, and how to holistically integrate it into the building.
4. **Replacement air design**. Addresses the need for delivering the replacement air into the kitchen. Considerations include
 - a. Transfer air, comfort supply air, or direct makeup air (or any combination)
 - b. ASHRAE *Standard* 62.1 compliance
 - c. Adjacent zone air classifications
 - d. Replacement and supply air delivery systems
5. **CKV system controls**. Maintain pressurization and comfort for the kitchen, dining area, and if applicable any adjoining zones. Accommodate any demand control systems, including DCKV and adjacent zones' demand-controlled ventilation (DCV) system(s).
6. **Heat gain and loss calculations**. Now is when these should be performed.
 - a. Appliance heat gains
 - b. Replacement air
7. **Exhaust system design**
 - a. Duct selection - type
 - b. Fire safety
 - c. Air discharge
 - d. Effluent control devices
 - e. Fire suppression
8. **HVAC system design**
 - a. Equipment selection
 - b. Diffuser and return grille layout – very critical
9. **Hood and replacement air commissioning specifications** (e.g., air balancing, troubleshooting)

Note: the CKV design engineer is recommended to engage the FSC during steps 1 and 2 to identify areas where both designs can be harmonized for optimal CKV performance.

1.3 SYSTEM INTEGRATION AND DESIGN

Ideally, system integration and balancing bring the many ventilation components together to provide the most comfortable, efficient, and economical performance of each component and of the entire system. In commercial kitchen ventilation, the replacement air system(s) must integrate and balance with the exhaust system and/or facility HVAC system(s). Even optimal system designs

require field testing and balancing once installed. It is important to verify compliance with design, and equally important to confirm that the design meets the needs of the operating facility. Air balance is a critical step in any CKV commissioning process.

The following fundamentals should be considered and applied to all food service facilities, including restaurants, within the constraints of the particular facility and its location, equipment, and systems.

Principles

Although there are exceptions, the following are the fundamental principles of integrating and balancing food service facility systems for comfort, control, and economical operation:

- The building should always be slightly positively pressurized (e.g. +0.005 in. of water) compared to atmosphere to prevent infiltration of outdoor air. Infiltrated air contains contaminants and insects, and adds to the heat load.
- Every kitchen should always be slightly negatively pressurized (−0.001 in. of water) to adjacent rooms or areas immediately surrounding it to help contain odors in the kitchen and to prevent odor migration out of the kitchen.
- System HVAC design should prevent air supplied to the kitchen from being returned and supplied to non-kitchen areas. Odor contamination is an obvious potential problem. In addition, in conditions such as seasonal transitions, when adjacent zones may be in different modes (e.g., economizer versus air conditioning or heating), comfort may be adversely affected. Ideally, the kitchen HVAC system should be separate from all other zones' HVAC systems. Three situations to consider are the following:
 - During seasonal transitions, the kitchen zone may require air conditioning or may be served by ventilation air only, while dining areas require heating. Even in kitchens that require cooling when the adjacent dining areas require heating, it is still important to maintain the pressure differential between these spaces and continue transfer of dining-area air into the kitchen.
 - To limit kitchen personnel discomfort, it is important to control the low-temperature MUA set point and prevent drastic temperature variations between the kitchen space and MUA being introduced. If dedicated kitchen MUA requires heating, thermostatic control of the MUA heating source should ideally be based on kitchen space temperature rather than outdoor air temperature. MUA heating should be interlocked with kitchen HVAC cooling to prevent simultaneous heating and cooling. HVAC thermostat locations in kitchens must consider the potential conflicting temperatures.
 - Ideally, there should be no perceptible drafts in dining areas, and temperature variations of no more than 1°F. Kitchens might not be draft-free; however, velocities at or near exhaust hoods should be no greater than 75 fpm. Kitchen comfort is greatly impacted by radiant heat in work areas, but it is desirable to maintain sensible temperatures within 5°F of design conditions. These conditions can be achieved with even distribution and thorough circulation of air in each zone by an adequate number of registers sized to preclude high air velocities. If there are noticeable drafts or temperature differences, dining customers will be uncomfortable and facility personnel are generally less comfortable and less productive.

Both design concepts and operating principles for proper integration and balance are involved in achieving desired results under varying conditions. The same principles are important in almost every aspect of food service ventilation.

In restaurants with multiple exhaust hoods, or hoods with demand control systems, exhaust airflow volume may vary throughout the day. Replacement air must be controlled to maintain proper

building and kitchen differential pressures to ensure the kitchen remains negative to adjacent areas at all operating points. The more variable the exhaust, or the more numerous and smaller the zones involved, the more complex the design, but the overall pressure relationship principles must be maintained to provide optimum comfort, efficiency, and economy.

A different application is a kitchen with one side exposed to a larger building with common or remote dining. Examples are a food court in a mall or a small restaurant in a hospital, airport, or similar building. Positive pressure at the front of the kitchen might cause some cooking grease, vapor, and odors to spread into the common building space, which would be undesirable. In such a case, the kitchen area is held at a negative pressure relative to other common building areas as well as to its own back room storage or office space. Such spaces that include direct-vent appliances, such as gas-fired water heaters, must maintain the pressure required for safe appliance operation.

Multiple-Hood Systems

Single kitchen exhaust duct/fan systems serving multiple hoods present unique design and balancing challenges not encountered with single-hood/duct/fan systems. Air balance is one of the main challenges. These systems may be designed with bleed ducts and/or balancing dampers. These dampers must be listed for this application. Additionally, most filters come in varying sizes to allow pressure loss equalization at varying airflows. Adjustable filters are available, but should not be used when they can be interchanged between hoods or within the same hood, because this interchange can disrupt the previously achieved balance. Balancing can also be accomplished by changing the number and/or size of filters in some hoods. Note that some multiple-hood systems incorporating DCKV automatically provide real-time balancing. However, the ductwork still needs to be properly designed to allow each hood to achieve design airflows during full-load cooking operations.

In some multitenant installations, the duct design may be completed and installed before the tenants have been identified. In cases such as master kitchen-exhaust systems, which are sometimes used in shopping center food courts, no single group is responsible for the entire design. The base building designer typically lays out ductwork to (or through) each tenant space, and each tenant selects a hood and lays out connecting ductwork. Often, the base building designer has incomplete information on tenant exhaust requirements. Therefore, one engineer must be responsible for defining criteria for each tenant's design and for evaluating proposed tenant work to ensure that tenant designs match the system's capacity. The engineer should also evaluate any proposed changes to the system, such as changing tenancy. Rudimentary computer modeling of the exhaust system may be helpful (Elovitz 1992). Given the unpredictability and volatility of tenant requirements, it may not be possible to balance the entire system perfectly. However, without adequate supervision, it is very probable the system will not achieve proper balance.

For greatest success with multiple-hood exhaust systems, minimize pressure losses in ducts by keeping velocities low, minimizing sharp transitions, and using hoods with relatively high pressure drops. When pressure loss in the ducts is low compared to the loss through the hood, changes in pressure loss in the ductwork because of field conditions or changes in design airflow have a smaller effect on total pressure loss and thus on actual airflow.

Minimum code-required air velocity (500 fpm) must be maintained in all parts of the exhaust ductwork at all times. If fewer or smaller hoods are installed than the design anticipated, resulting in low velocity in portions of the ductwork, the velocity must be brought up to the minimum. One way is to introduce outdoor air, preferably untempered, through a bleed duct system directly into the exhaust duct (Figure 1). The bypass duct should connect to the top or sides (at least 2 in. from the bottom) of the exhaust duct to

Fig. 1 Bleed Method of Introducing Outdoor Air Directly into Exhaust Duct
(Brohard et al. 2003)

prevent backflow of water or grease through the bypass duct when fans are off. This arrangement is also shown in NFPA *Standard 96* and should be discussed with the authority having jurisdiction.

A fire damper is required in the bleed duct, located close to the exhaust duct. Bypass duct construction should be the same as the exhaust duct construction, including enclosure and clearance requirements, for at least several feet beyond the fire damper or as required by the local authority having jurisdiction (AHJ). Means to adjust the bleed airflow must be provided upstream of the fire damper. All dampers must be in the clean bleed air duct so they are not exposed to grease-laden exhaust air. The difference in pressure between bleed and exhaust air duct may be great; the balancing device must be able to make a fine airflow adjustment against this pressure difference. It is best to provide two balancing devices in series, such as an orifice plate or blast gate for coarse adjustment followed by an opposed-blade damper for fine adjustment.

Directly measuring air velocities in the exhaust ductwork to assess exhaust system performance may be desirable. Velocity (pitot-tube) traverses may be performed in kitchen exhaust systems, but holes drilled for the pitot tube must be liquidtight to maintain the fire-safe integrity of the ductwork, per NFPA *Standard 96*. Holes should never be drilled in the bottom of a duct, where they may collect grease. Velocity traverses should not be performed when cooking is in progress because grease collects on the instrumentation.

Dynamic Volumetric Flow Rate Effects

Minimum exhaust flow rates for kitchen hoods are determined either by laboratory tests or by building code requirements. Energy codes specify maximum airflow rates. In either case, the installed system must ensure proper capture and containment under maximum cooking load conditions. The majority of kitchen exhaust systems use fixed-speed fans, which move the same volume of air at a given speed regardless of air density. Although the air volume remains constant, heat and moisture generated by the cooking process affect mass flow.

Exhaust fans for kitchen ventilation systems, like for other high-temperature exhaust processes, must be selected to provide adequate airflow at standard conditions to meet the mass flow needs of the actual cooking process. Testing for hood listing in accordance with UL *Standard 710*, for example, requires capture and containment testing using actual cooking, with cooking appliance heated to controlled surface temperatures and food product cooked, including flare-ups, to determine airflow. This airflow must be converted to standard air conditions to provide proper design ratings for fan selections.

1.4 ENERGY CONSIDERATIONS

Restaurants and commercial kitchens are the largest consumers of energy per unit of floor area when compared to other commercial

or institutional occupancies (Itron and California Energy Commission 2006). Primary drivers of commercial kitchen energy use are the cooking appliances and the HVAC system. The kitchen exhaust ventilation system is often the largest energy-consuming component in a commercial food service facility. However, energy consumption associated with commercial kitchen ventilation (CKV) and HVAC systems, as well the conservation potential, can vary significantly (Fisher 2003). Beyond the design exhaust ventilation rate itself, the magnitude of energy consumption and cost of a CKV system is affected by factors such as geographic location (i.e., climate), system operating hours, static pressure and fan efficiencies, replacement air heating and cooling set points and level of dehumidification, efficiency of heating and cooling systems, level of interaction between kitchen and building HVAC system, appliances under the hood and associated radiant heat gain to space, and applied utility rates. Minimizing the exhaust airflow needed for cooking appliances and reducing radiant load from the appliances are primary considerations in optimizing CKV system design. Because climatic zones vary dramatically in temperature and humidity, energy-efficient designs have widely varying rates of returns on the investment. In new facilities, the designer can select conservation measures suitable for the climatic zone and the HVAC system to maximize the economic benefits.

The operating cost burden has stimulated energy efficiency design concepts and operating strategies discussed in this section and detailed in industry design guidelines (PG&E 2004). It has also impacted changes to ASHRAE *Standard 90.1*.

The Kitchen Exhaust Systems section of ASHRAE *Standard 90.1* states that if a CKV system has a total exhaust airflow rate greater than 5000 cfm, the design must adhere to maximum exhaust rates specified for the different hood types. These rates apply to listed hoods, and are set 30% below the minimum values for unlisted hoods dictated by the *International Mechanical Code*[®] (IMC) (ICC 2012). If a kitchen or dining facility has a total kitchen hood exhaust airflow rate greater than 5000 cfm, it must have one of the following:

- At least 50% of all replacement air is transfer air that would otherwise be exhausted
- Demand ventilation system(s) on at least 75% of the exhaust air, capable of at least 50% reduction in exhaust and replacement air system airflow rates, including controls necessary to modulate airflow in response to appliance operation and to maintain full capture and containment of smoke, effluent, and combustion products during cooking and idle
- Listed energy recovery devices with a sensible heat recovery effectiveness of not less than 40% on at least 50% of the total exhaust airflow

Energy Conservation Strategies

Specifying Exhaust Hoods for Minimal Airflow. The type and style of exhaust hood selected depends on factors such as restaurant type, restaurant menu, and food service equipment installed, as well as flexibility for future kitchen upgrades. Exhaust flow rates are largely determined by the food service equipment and hood style. Wall-mounted canopy hoods function effectively at lower exhaust flow rates than single-island hoods. Single- and double-island canopy hoods are more sensitive to replacement air supply and cross drafts than wall mounted canopy hoods (Swierczyna et al. 2009). Engineered backshelf (proximity) hoods may exhibit the lowest capture and containment flow rates. In some cases, a backshelf hood performs the same job as a wall-mounted canopy hood at one-third the exhaust rate. Cooking appliance type and duty rating must be included in the specification process, because not all hoods (particularly backshelf hoods) are rated or designed for all cooking appliance types or duty ratings.

Threshold exhaust rates for a specific hood and appliance configuration may be determined by laboratory testing under the specifications of ASTM *Standard F1704-09*. Similar in concept to the listed airflow rates derived from UL *Standard 710*, the threshold of containment and capture (C&C) for an ASTM *Standard F1704* test is established under ideal laboratory conditions and is only a reference point for specifying the exhaust airflow rate for a CKV system.

Side Panels and Overhang. In many cases, side (or end) panels allow a reduced exhaust rate because they direct replacement airflow to the front of the hood and cooking equipment. They are a relatively inexpensive way to improve capture and containment and reduce the total exhaust rate. It is important to know that partial side panels can provide almost the same benefit as full panels. Although tending to defy its definition as an “island” canopy, end panels can improve the performance of a double- or single-island canopy hood. A significant benefit of end panels, when hoods are exposed to cross drafts, is mitigation of the negative effect those drafts have on hood performance. However, air distribution designs that eliminate cross drafts are preferred. Increasing overhang is another specification detail that can improve the hood’s ability to capture and allow reduced exhaust rates. It is important that the engineer and food service designers work closely on appliance placement size and type, because they affect hood sizing, which in turn affects lighting, HVAC, and most importantly hood performance. A hood that is too small (i.e., little or no overhang) may often not be capable of working properly at any airflow rate, whereas those with generous overhang may operate well at airflow rates reduced by 30% or more.

Custom-Designed Hoods. Hoods can be custom designed for specific cooking appliances or cooking processes. Customization often reduces exhaust and replacement air quantities and consequently reduces fan sizes, energy use, and energy costs. To operate at flow rates lower than required by code, custom-designed hoods must be either listed or approved by the local code official. The cost involved with custom design makes the process more applicable to chain restaurants, such as quick service, where a specific design may be installed repeatedly. Some single-site establishments may have architectural restrictions that demand a custom solution.

Transfer Air. ASHRAE *Standard 62.1* specifies the quantity of outdoor air that must be provided to ventilate public spaces, such as dining rooms, in food service establishments. *Standard 62.1* allows this ventilation air to be reused by transfer from the ventilated public spaces to the kitchen, where it can be used to replace air exhausted by the hood system and assist kitchen comfort. Transfer air must meet the requirements as prescribed in ASHRAE *Standard 62.1* (section 5.16.3). By maximizing transfer of air from adjoining public spaces to the kitchen, the designer is able to minimize the quantity of dedicated outdoor air supplied to the kitchen as replacement air. This can reduce the energy load on the replacement air system, as well as improve thermal comfort in the kitchen. Most quick-service and fast-casual restaurants do not physically segregate the kitchen from the dining room, so conditioned air can be easily transferred from the dining area to the kitchen. In restaurants where the kitchen and dining room are physically segregated, ducts between the two areas may be required for proper flow of replacement air into the kitchen. Transfer fans may be required to overcome duct losses, because the differential pressure between spaces may be very low (<0.005 in. of water). This design can reduce kitchen replacement air requirements and enhance employee comfort, especially if the kitchen is not air conditioned. Codes may restrict transfer of air from adjoining spaces, other than public dining areas, in buildings such as hospitals. Adjoining spaces should not be overventilated to increase transfer airflow, because the heating and cooling conditions for dining and other public spaces are more energy-intensive than for conditioning replacement air introduced directly into the kitchen.

Demand-Controlled Kitchen Ventilation

Demand-controlled kitchen ventilation (DCKV) refers to any engineered, automated method of modulating (e.g., variable reduction) the amount of air exhausted for a specific cooking operation in response to a part-load or no-load condition (e.g., by duct temperature, opacity, or appliance surface temperatures).

A DCKV system is different from a DCV system in that the controlling demand factor is the kitchen’s cooking operations and not space carbon dioxide (CO_2) levels. In conjunction with this, the amount of replacement air (consisting of makeup, transfer, and outdoor air) is also modulated to maintain the same relative air ratios, airflow patterns, and pressurizations. Failure to integrate systems could cause negative pressure.

The design of all involved ventilation systems must account for DCKV, to create a fully integrated system.

Complete capture and containment of all smoke and greasy vapor must be maintained when a DCKV exhaust system operates at less than 100% of design airflow.

Selection of all components, and design of the DCKV system, must be such that stable operation can be maintained at all modulated and full-flow conditions.

When DCKV is used as the method of compliance with ASHRAE *Standard 90.1* (section 6.5.7.1.4 part b), it must meet all requirements of that section.

When DCKV is used as the method of compliance with ASHRAE *Standard 62.1* it must meet the minimum exhaust air rates per Table 6.5 and minimum ventilation air rates per Table 6.2.2.1, ensuring ventilation during periods of occupancy.

The exhaust system configuration and equipment to be served by a DCKV system must be evaluated to determine the feasibility and cost benefits resulting from its use. An example of a situation where a DCKV system may not be appropriate is when gas-underfired broilers are present.

Evaporative Cooling. Direct evaporative coolers are an alternative to mechanical cooling (or, for that matter, no cooling) of replacement air only in dry climates where dehumidification is not required. Indirect evaporative cooling has a wider range in geographical applications. Water costs, availability, and use restrictions should be considered.

Heat Recovery from Exhaust Hood Ventilation Air. High-temperature effluent, often in excess of 400°F, from the cooking equipment mixes with replacement room air, resulting in exhaust air temperatures well over 100°F. It is frequently assumed that this heated exhaust air is suitable for heat recovery; however, over time, smoke and grease in the exhaust air can foul the heat transfer surfaces. Under these conditions, the heat exchangers require regular maintenance (e.g., automatic washdown) to maintain heat recovery effectiveness and mitigate risk of fire. Because heat recovery systems are expensive, food service facilities with large ventilation rates and relatively light-duty cooking equipment are the best candidates for this equipment. Hospitals are a good example, with large exhaust rates and very low levels of grease production from the cooking equipment. An exhaust hood equipped with heat recovery is more likely to be cost-effective where the climate has very cold winters (well below 32°F). A mild climate is not conducive to use of this conservation measure. See Chapter 26 in the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for more information on air-to-air heat recovery.

Optimized Heating and Cooling Set Points. IMC (ICC 2012) requires that replacement air be conditioned to within 10°F of the kitchen space, except when replacement air is part of the air-conditioning system and does not adversely affect comfort conditions in the occupied space. The exception is important because it allows the design to be optimized to take advantage of the typically lower heating balance points of commercial kitchens. A commercial kitchen may be

considered comfortable at temperatures of up to 85°F when space humidity is $\leq 60\%$. During heating seasons, space humidity is typically not an issue if the kitchen exhaust systems are properly designed and operated. During the heating season, space gains from unhooded appliances and radiant gains from hooded appliances, lighting, refrigeration units, and staff make it possible to maintain comfort using lower supply air temperatures. During cooling seasons, in climatic areas that require dehumidification, consideration must be given to all sources that may introduce moisture into commercial kitchens, including internal cooking, holding, and washing as well as local makeup air (MUA) systems or kitchen HVAC systems not designed for continuous dehumidification. Humidity control ($\leq 60\%$) allows optimization of cooling set points at higher temperatures while maintaining a comfortable working environment.

A dedicated outdoor air system (DOAS) providing conditioned outdoor air for kitchen heating, cooling and dehumidification also optimizes set points by using economizer operation when outdoor air alone (no conditioning) can maintain kitchen set points. Using dedicated outdoor air to heat, cool, and dehumidify outdoor air to control space comfort and humidity and replace air exhausted through the hood has been demonstrated to be an energy-effective design for optimizing heating and cooling set points (Brown 2007).

Accordingly, when local MUA systems are used, it is essential that the heating set point of those units not be set higher than the forecasted heating/cooling balance point (e.g., 55°F) to avoid simultaneous replacement air heating and HVAC cooling. It may be more difficult to control comfort when local MUA (e.g., at 55°F) is introduced into a kitchen being heated by a conventional HVAC system introducing kitchen supply air at temperatures $\geq 80^\circ\text{F}$.

Reduced Exhaust and Associated Duct Velocities

Tempering outdoor replacement air can account for a large part of a food service facility's heating and cooling costs. By reducing exhaust flow rates (and the corresponding replacement air quantity) when little or no product is being cooked, energy cost can be significantly reduced when combined with a DCKV system. Field evaluations by one large restaurant chain suggest that cooking appliances may operate under no-load conditions for 75% or more of an average business day (Spata and Turgeon 1995).

However, it has been difficult to reduce exhaust flow rates in a retrofit situation because of the minimum duct velocity restriction. National Fire Protection Association (NFPA) *Standard 96* had historically required a minimum duct velocity of 1500 fpm. The common belief was that, if duct velocity were lowered, a higher percentage of grease would accumulate on the ductwork, which would then require more frequent duct cleaning. However, no data or research could be identified to support this assumption. Therefore, ASHRAE research project RP-1033 (Kuehn 2000) was undertaken to determine the true effect of duct velocity on grease deposition.

The project analyzed grease deposition as a function of mean duct velocity, using octanoic acid (commonly found in cooking oils and other foods). The results showed that, for design duct velocities below the traditional 1500 fpm threshold, grease deposition was not increased; in fact, in isothermal conditions, as duct velocity decreased, grease deposition on all internal sides of the duct also decreased. These results led to NFPA *Standard 96* and the IMC changing their minimum duct velocity requirements from 1500 fpm to 500 fpm.

Another significant finding in the study was that, if there is a large temperature gradient between exhaust air inside the duct and the external duct wall, the rate of grease deposition increases significantly. Therefore, duct insulation should be considered where there are large temperature variations.

The primary benefit of these code-approved duct velocity changes is the potential for reduced food service energy consumption. By reducing excessive exhaust airflows, while maintaining

necessary capture and containment, energy for fans as well as for heating, cooling and/or dehumidifying air that was previously wasted may now be saved. Previously, if a restaurant remodeled their cooking operation and the remodel resulted in reduced exhaust airflows, the owner had to install new, smaller-diameter ductwork to comply with the 1500 fpm duct velocity requirement. This is often too costly, if not also physically impractical. Now, if a system designed for heavy-duty equipment upgrades to more energy-efficient, lighter-duty equipment, exhaust airflows can be reduced without the expense of modifying ductwork.

Reduced code-approved duct velocity also facilitates application of DCKV systems with less resistance from local code authorities. From a new-facility design perspective, it is recommended that most kitchens be designed for an in-duct velocity between 1500 and 1800 fpm. This allows for reducing the airflows to 500 fpm if needed in the future or as part of a demand-ventilation control strategy.

Designing for High-Performance Green Building Compliance under ANSI/ASHRAE/USGBC/IES Standard 189.1

There are several sections in this standard that any CKV system must comply with in order to be considered a high-performance green building.

Air-Side Economizer Controls for Replacement Air (Makeup Air). Given the large quantities of replacement air typically required for a CKV system, the use of air-side economizers should be evaluated for every location. This evaluation should include comparing the CKV system's typical daily hours of operation to the number of hours of free cooling available in the local climate. Some locations in ASHRAE climate zones 1A and 1B may still benefit from using air-side economizers, especially if they operate enough hours of the year where they can take advantage of free cooling.

ENERGY STAR Appliances. Commercial food service appliances (e.g., fryers, hot food holding cabinets, refrigerators and freezers, steam cookers, ice machines, dishwashers, griddles, ovens) should bear the ENERGY STAR label. Equipment selection guidance and specifications can be found at <http://www.energystar.gov/>.

DCKV for Facilities Greater than 2000 cfm. Kitchen/dining facilities with total kitchen hood exhaust airflow rates above 2000 cfm must comply with at least one of the following:

- At least 50% of all replacement air must be transfer air that would otherwise be exhausted.
- At least 75% of kitchen hood exhaust air must be controlled by a demand ventilation system(s), which must (1) be able to reduce exhaust and replacement air system airflow rates by no more than the larger of 50% of total design exhaust and replacement air system airflow rate, or the outdoor airflow and exhaust rates required to meet the ventilation and exhaust requirements of Sections 6.2 and 6.5 of ANSI/ASHRAE *Standard 62.1* for the zone; (2) include controls to modulate airflow in response to appliance operation and to maintain full capture and containment of smoke, effluent, and combustion products during cooking and idle; (3) include controls that result in full flow when the demand ventilation system(s) fail to modulate airflow in response to appliance operation; and (4) allow occupants to temporarily override the system(s) to full flow.
- Listed energy recovery devices with a sensible heat recovery effectiveness of not less than 40% must be applied on at least 50% of the total exhaust airflow.
- In climate zones 1B, 2B, 3B, 4B, 5B, 6B, 7B, and 8B, when replacement air is uncooled or cooled without mechanical cooling, the capacity of any nonmechanical cooling system(s) (e.g., natural or evaporative cooling) must be demonstrated to be no less than the system capacity of a mechanical cooling system(s) necessary to meet the same loads under design conditions.

Outdoor Airflow Measuring. Each mechanical ventilation system shall have a permanently installed device to measure the minimum outdoor airflow rate that meets the following requirements:

- The device must use methods described in ASHRAE *Standard* 111.
- The device's accuracy must be $\pm 10\%$ of the minimum outdoor airflow. Where the minimum outdoor airflow varies, as in demand control ventilation systems, the device must maintain this accuracy over the entire range of occupancy and system operation.
- The device must be able to notify the building operator, either by activating a local indicator or by sending a signal to a building monitoring system, whenever an outdoor air fault condition exists. This notification requires manual reset.

Exception: Constant-volume air supply systems that do not use demand control ventilation and use an indicator to confirm that the intake damper is open to the position needed to maintain design minimum outdoor airflow do not require notification ability.

Energy Measurement Devices. Energy consumption must be measured by devices to track and record energy profiles so that periodic assessments can be made to assure continued future performance. In addition to whole-building monitoring, submetering may be required on specific appliance lineups depending upon capacity. See section 7 of ANSI/ASHRAE/USGBC/IES *Standard* 189.1 for additional information.

Commissioning. Facilities with a gross floor area over 5000 ft must be commissioned. Commissioning is essential to ensure that the building, including the kitchen exhaust and HVAC systems, functions as intended. For additional information on high performance building commissioning requirements, see section 10 of ANSI/ASHRAE/USGBC/IES *Standard* 189.1.

1.5 COMMERCIAL EXHAUST HOODS

The design, engineering, construction, installation, and maintenance of commercial kitchen exhaust hoods are governed by nationally recognized standards (e.g., NFPA *Standard* 96) and model codes [e.g., the IMC (ICC 2009a), *International Fuel Gas Code* (IFGC; ICC 2009b)]. In some cases, local codes may prevail. Before designing a kitchen ventilation system, the designer should identify governing codes and consult the AHJ. Local authorities with jurisdiction may have amendments or additions to these standards and codes.

The type of hood required, or whether a hood is required, is determined by the type and quantity of emissions from cooking. Hoods are not typically required over electrically heated appliances such as microwave ovens, toasters, steam tables, popcorn poppers, hot dog cookers, coffee makers, rice cookers, egg cookers, holding/warming ovens (as mentioned in ASHRAE *Standard* 154), or heat lamps. Appliances can be unhooded only if the additional heat and moisture loads have been considered in a thorough load calculation and accounted for in design of the HVAC system. Temperature and humidity in the kitchen space should be based on recommendations of ASHRAE *Standard* 55.

Hood Types

Many types, categories, and styles of hoods are available, and selection depends on many factors. Hoods are classified by whether they are designed to handle grease; Type I hoods are designed for removing grease and smoke, and Type II hoods are not. Model codes distinguish between grease-handling and non-grease-handling hoods, but not all model codes use Type I/Type II terminology. A Type I hood may be used where a Type II hood is required, but the reverse is not allowed. However, characteristics of the equipment and processes under the hood, and not necessarily the hood type,

determine the requirements for the entire exhaust system, including the hood.

A **Type I hood** is used for collecting and removing grease particulate, condensable vapor, and smoke. It includes (1) listed grease filters, baffles, or extractors for removing the grease and (2) fire-suppression system. Type I hoods are required over cooking equipment, such as ranges, fryers, griddles, gas underfired and electric broilers, and ovens, that produce smoke or grease-laden vapors.

A **Type II hood** collects and removes steam and heat where grease or smoke is not present. It may or may not have grease filters or baffles and typically does not have a fire-suppression system. It is usually used over dishwashers. A Type II hood is sometimes used over ovens, steamers, or kettles if they do not produce smoke or grease-laden vapor and as authorized by the AHJ.

Type I Hoods

Categories. Type I hoods fall into two categories: unlisted and listed. **Unlisted hoods** are no longer allowed under ASHRAE *Standard* 154. However, if they are used, they must meet the design, construction, and performance criteria of applicable national and local codes and are not allowed to have fire-actuated exhaust dampers. **Listed hoods** are listed in accordance with Underwriters Laboratories (UL) *Standard* 710 and are constructed in accordance with the terms of the hood manufacturer's listing, and are required to be installed in accordance with either NFPA *Standard* 96 or the model codes. Model codes include exceptions for listed hoods to show equivalency with the model code requirements.

The two subcategories of Type I listed hoods, as covered by UL *Standard* 710, are exhaust hoods with and without exhaust dampers. UL listings also distinguish between water-wash and dry hoods.

All listed hoods are subjected to electrical (if applicable), temperature, and cooking smoke and flare-up (capture and containment) tests. A listed exhaust hood with exhaust damper includes a fire-actuated damper, typically at the exhaust duct collar. In the event of a fire, the damper closes to prevent fire from entering the duct. Fire-actuated exhaust dampers are permitted only in listed hoods. Also, listed hoods that incorporate an integral supply air plenum include a fire-actuated damper in that plenum; the damper's location in the supply air plenum depends on plenum configuration. Refer to NFPA *Standard* 96 and UL *Standard* 710 for examples of the damper in exhaust hood supply air plenum.

Grease Removal. Most grease removal devices in Type I hoods operate on the same general principle: exhaust air passes through a series of baffles that create a centrifugal force to throw grease particles out of the airstream as the exhaust air passes around the baffles. The amount of grease removed varies with baffle design, air velocity, temperature, type of cooking, and other factors. NFPA *Standard* 96 does not allow use of mesh-filter as primary grease filter. To date, stand-alone mesh filters have not met the requirements of UL *Standard* 1046, and therefore cannot be used as primary grease filters. ASTM *Standard* F2519 provides a test method to determine the grease particle capture efficiency of grease filters and extractors. Grease removal devices generally fall into the following types:

- **Baffle filters** have a series of vertical baffles designed to capture grease and drain it into a container. The filters are arranged in a channel or bracket for easy insertion and removal for cleaning. Each hood usually has two or more baffle filters, which are typically constructed of aluminum, steel, or stainless steel and come in various standard sizes. Filters are cleaned by running them through a dishwasher or by soaking and rinsing. NFPA *Standard* 96 requires that grease filters be listed. Listed grease filters are tested and certified by a nationally recognized test laboratory in accordance with UL *Standard* 1046.
- **Removable extractors** (also called **cartridge filters**) have a single horizontal-slot air inlet. The filters are arranged in a channel

or bracket for easy insertion and removal for cleaning. Each hood usually has two or more removable extractors, which are typically constructed of stainless steel and contain a series of horizontal baffles designed to remove grease and drain it into a container. Available in various sizes, they are cleaned by running them through a dishwasher or by soaking and rinsing. Removable extractors may be classified by a nationally recognized test laboratory in accordance with UL *Standard* 1046, or may be listed as part of the hood in accordance with UL *Standard* 710. Hoods that are listed with removable extractors cannot have those extractors replaced by other extractors.

- **Stationary extractors** are integral to the listed water-wash exhaust hoods and are typically constructed of stainless steel and contain a series of horizontal baffles that run the full length of the hood. The baffles are not removable for cleaning, though some have doors that can be removed to clean the extractors and plenum.
- **Water-wash hoods** fall into two classifications: clean-in-place and cold-water mist styles. Clean-in-place hoods reduce or eliminate the need for kitchen staff to manually clean the hood components; these hoods may have fixed stationary or removable grease extractors. These systems may automate the removal of the grease load on the filters, hood plenums, and ductwork. Typical hoods include one or more manifolds with spray nozzles that, when activated, wash out the collected grease with hot, detergent-injected water. The wash cycle is activated periodically, typically after cooking equipment and fans have been turned off. Washdown cycles can last 3 to 10 min, depending on the hood manufacturer, type of cooking, duration of operation, water temperature, and pressure. Most water-wash hood manufacturers recommend a water temperature of 130 to 180°F and water pressure of 20 to 80 psi. Average water consumption varies from 0.50 to 1.50 gpm per linear foot of hood, depending on manufacturer. Most water-wash hood manufacturers provide an optional automatic means of activating the water-wash system in the event of a fire.

Some water-wash hood manufacturers provide continuous cold water mist as an option. The cold water runs continuously during cooking and may or may not be recirculated, depending on the manufacturer. Typical cold-water usage is 1 gph per linear foot of hood. The advantage of this method is that it improves grease extraction and removal, partly through condensation of the grease. Many hood manufacturers recommend continuous cold water in hoods located over solid-fuel-burning cooking equipment, because the water acts as a spark arrestor to satisfy code requirements.
- **Multistage filters** use two or more stages of filtration to remove a larger percentage of grease. They typically consist of a baffle filter or removable extractor followed by a higher-efficiency filter, such as a packed bead bed. Each hood usually has two or more multistage filters, which are typically constructed of aluminum or stainless steel and are available in standard sizes. Filters are cleaned by running them through a dishwasher or by soaking and rinsing. NFPA *Standard* 96 requires that grease filters be listed, so these multistage filters must be tested and certified by a nationally recognized test laboratory in accordance with UL *Standard* 1046.

UL *Standards* 710 and 1046 do not include grease extraction efficiency tests. Historically, grease extraction efficiency rates published by filter and hood manufacturers were usually derived from tests conducted by independent test laboratories retained by the manufacturer. Test methods and results therefore have varied greatly.

In 2005, however, a new grease filter and extractor test standard, ASTM *Standard* F2519, was published, which determines the grease particle capture efficiency of both removable filters and fixed extractors such as those used in water-wash hoods. The filters are evaluated by pressure drop as well as particulate capture efficiency.

The test generates a controlled quantity of oleic acid particles in size ranging from 0.3 to 10 μm that are released into a hood to represent the cooking effluent. The particles are then sampled and counted downstream in the duct with an optical particle counter, with and without the filter or extractor in place. The difference in the counts is used to calculate the particulate capture efficiency graphed versus particle size. ASTM *Standard* F2519 measures particulate capture efficiency only, not vapor removal efficiency. A more detailed explanation is available in the Exhaust Systems section of this chapter.

Styles. Figure 2 shows the six basic styles for Type I hood applications. These style names are not used in all standards and codes but are well accepted in the industry. The styles are as follows:

- **Wall-mounted canopy**, used for all types of cooking equipment located against a wall.
- **Single-island canopy**, used for all types of cooking equipment in a single-line island configuration.
- **Double-island canopy**, used for all types of cooking equipment mounted back-to-back in an island configuration.
- **Back shelf/proximity**, used for counter-height equipment typically located against a wall, but possibly freestanding.
- **Eyebrow**, used for direct mounting to ovens and some dishwashers.
- **Pass-over**, used over counter-height equipment when pass-over configuration (from cooking side to serving side) is required.

Sizing. The size of the exhaust hood relative to cooking appliances is important in determining hood performance. Usually the hood must extend horizontally beyond the cooking appliances (on all open sides on canopy-style hoods and over the ends on back shelf and pass-over hoods) to capture expanding thermal currents rising from the appliances. For unlisted hoods, size and overhang requirements are dictated by the prevailing code; for listed hoods, by the terms of the manufacturer's listing. **Overhang** varies with hood style, distance between hood and cooking surface, and characteristics of cooking equipment. With back shelf and pass-over hoods, the front of the hood may be kept behind the front of the cooking equipment (**set-back**) to allow head clearance for the cooks. These hoods may require a higher front inlet velocity to capture and contain expanding thermal currents. ASHRAE research (Swierczyna et al. 2006, 2010) indicates an appliance front overhang of 9 to 18 in. for canopy style and a 10 in. setback for back shelf/proximity style are preferable to current code minimums. All styles may have full or partial side panels to close the area between appliances and the hood. This may eliminate the side overhang requirement and generally reduces the exhaust flow rate requirement.

Exhaust Flow Rates. Exhaust flow rate requirements to capture, contain, and remove effluent vary considerably depending on hood style, overhang, distance from cooking surfaces to hood, presence and size of side panels, cooking equipment, food, and cooking processes involved. The hot cooking surfaces and product effluent create thermal air currents that are captured by the hood and then exhausted. The velocity of these currents depends largely on surface temperature and tends to vary from 15 fpm over steam equipment to 150 fpm over charcoal broilers. The required flow rate is determined by these thermal currents, a safety allowance to absorb cross-currents and flare-ups, and a safety factor for the style of hood.

Overhang and the presence or absence of side panels help determine the safety factor for different hood styles. Gas-fired cooking equipment may require an additional allowance for exhaust of combustion products and combustion air.

Because it is not practical to place a separate hood over each piece of equipment, general practice (reflected in ASHRAE *Standard* 154) is to categorize equipment into four groups, as shown in Table 1. Table 2 lists the required hood type by duty level.

These categories apply to unlisted and listed Type I hoods. ASHRAE *Standard* 154-2011 requires that all Type I hoods be

Fig. 2 Styles of Commercial Kitchen Exhaust Hoods

Table 1 Appliance Types by Duty Category

Light duty (400°F)	Electric or gas	Ovens (including standard, bake, roasting, revolving, retherm, convection, combination convection/steamer, conveyor, deck or deck-style pizza, pastry) Steam-jacketed kettles Compartment steamers (both pressure and atmospheric) Cheesemelters Rethermalizers
Medium duty (400°F)	Electric Electric or gas	Discrete element ranges (with or without oven) Hot-top ranges Griddles Double-sided griddles Fryers (including open deep-fat fryers, donut fryers, kettle fryers, pressure fryers) Pasta cookers Conveyor (pizza) ovens Tilting skillets/braising pans Rotisseries
Heavy duty (600°F)	Gas Electric or gas	Open-burner ranges (with or without oven) Gas underfired broilers Chain (conveyor) broilers Wok ranges Overfired (upright) salamander broilers
Extra-heavy duty (700°F)	Appliances using solid fuel such as wood, charcoal, briquettes, and mesquite to provide all or part of the heat source for cooking.	

listed; unlisted hoods are not allowed. The exhaust flow rate requirement is based on the group of equipment under the hood. If there is more than one group, the flow rate is based on the heaviest-duty

group unless the hood design allows different rates over different sections of the hood.

Though considered obsolete based on laboratory tests and research, some local codes may still require exhaust flow rates for unlisted canopy hoods to be calculated by multiplying the horizontal area of the hood opening by a specified air velocity. Some jurisdictions may use the length of the open perimeter of the hood times the vertical height between hood and appliance instead of the horizontal hood area. Swierczyna et al. (1997) found that these methods of calculation result in higher-than-necessary exhaust flow rates for deeper hoods, because the larger reservoirs of deeper hoods typically increase hood capture and containment performance.

Table 3 lists typical exhaust flow rates for listed hoods. Typical design rates for listed hoods are based on published rates for listed hoods serving single categories of equipment, which vary from manufacturer to manufacturer. Rates are usually lower for listed hoods than for unlisted hoods, and it is generally advantageous to use listed hoods. Actual exhaust flow rates for hoods with internal short-circuit replacement air are typically higher than those in Table 3, although net exhaust rates (actual exhaust less internal makeup air quantity) are lower, which seriously compromises the hood's capture and containment performance (Brohard et al. 2003).

Listed hoods are allowed to operate at their listed exhaust flow rates by exceptions in the model codes. The exhaust flow rates for listed hoods are established by conducting tests per UL *Standard* 710. Typically, exhaust flow rates are much lower than those dictated by the model codes. Note that listed flow rate values are established under draft-free laboratory conditions, and actual operating conditions may compromise listed performance. Thus, manufacturers may recommend design values above their listed values.

Hoods listed in accordance with UL 710 cover one or more cooking duty ratings: light, medium, heavy, and extra heavy. These duty ratings correspond to minimum cooking surface temperatures during tests of 200, 400, 600, and 700°F respectively. In application,

these temperature ratings correspond to duty ratings (see Table 2). The total exhaust flow rate is calculated by multiplying the hood exhaust flow rate by hood length.

ASTM Standard F1704 details a laboratory flow visualization procedure for determining the capture and containment threshold of an appliance/hood combination. This procedure can be applied to all hood types and configurations installed over any cooking appliances. ASTM Standard F2474 also provides a laboratory test procedure for determining heat gain of specific combinations of exhaust hood, cooking equipment, type of foods, and cooking processes. Results from a series of interlab heat gain tests (Fisher 1998; Swierczyna et al. 2008) have been incorporated in Chapter 18 of the 2013 ASHRAE Handbook—Fundamentals.

Table 3 Typical Exhaust Flow Rates by Cooking Equipment Category For Listed Type I Hoods

Type of Hood	Exhaust Flow Rate, cfm per linear foot of hood			
	Light	Medium	Heavy	Extra-Heavy
	Duty	Duty	Duty	Duty
Wall-mounted canopy	150 to 200	200 to 300	200 to 400	350+
Single-island canopy	250 to 300	300 to 400	300 to 600	550+
Double-island canopy (per side)	150 to 200	200 to 300	250 to 400	500+

Back shelf/proximity/pass-over	100 to 200	200 to 300	300 to 400	Not recommended

Island Canopy Hoods

Island canopy hoods, particularly single-island style, have become popular in open cafeteria operations such as those found in university food service. In many cases, the food service consultant specifies gas underfired broilers and other heavy-duty cooking equipment as part of the design. For a given line of appliances, a single-island canopy hood requires significantly more exhaust than a wall-mounted canopy hood. Single-island canopy hoods present the most difficult capture and containment challenge in hood applications, and are often the source of the “hood” problem in a kitchen with display cooking. To address the lack of reliable performance data on island canopy hoods, ASHRAE research project RP-1480 (Swierczyna et al. 2010) was undertaken to determine appropriate exhaust airflow rates. The objective was to expand the database for the exhaust rates required for capture and containment of standardized cook lines under four island canopy hood configurations: rear filter single island, V-bank single island, and 8 ft deep and 10 ft deep double-island hoods. Four side panel designs, four supply air strategies, and two makeup air temperature set points were also evaluated to quantify the effects of these features on island hood performance.

Swierczyna et al. (2010) confirmed that single-island canopy hoods need significantly higher exhaust airflow rates than their wall-mounted counterparts to effectively ventilate cooking equipment for a given duty class. For example, although an exhaust rate of 300 to 400 cfm/ft can be adequate for complete capture and containment with a wall-mounted canopy hood over a heavy-duty appliance line (ASHRAE Standard 154; PG&E 2010), a single-island canopy hood may require an exhaust rate in excess of 500 cfm/ft in many situations (measured along one side of the canopy hood). In fact, there were several test scenarios for single-island hoods where an exhaust rate in excess of 700 cfm/ft was required to achieve capture and containment. This contradicts common design practice, where the specified ventilation rates are often much closer to those for wall-canopy hoods.

Single-island hood performance was improved by the larger hood’s V-bank filter configuration over the smaller hood’s rear filter configuration for most test configurations. The plume was better aligned with the filters and was drawn toward the center, relative to the front and rear of the hood. The larger V-bank hood was found to be less sensitive to local air replacement. However, aggressive appliance plumes that focused on the flat bottom of the V-bank, or replacement air strategies that were focused at the side of the V-bank, proved challenging and indicated that a change of filter bank profile may improve hood performance.

The performance of a double-island canopy hood, with balanced replacement air, can be comparable to back-to-back wall-mounted canopy hoods for a given duty class of appliances. For example, a heavy-duty front line and a light-duty back line under the double-island hood required an exhaust airflow rate approximately 300 cfm/ft (measured along both sides of the hood). This rate is comparable to the ventilation rate for similar appliance duty classes under wall-mounted canopy hoods (Swierczyna et al.

2006). The double-island hood configuration performed as if a wall existed between them. Furthermore, the back-to-back appliance lines created a converging thermal plume that helped direct the plume toward the filter bank. However, without a wall between them, the double-island hood system was more susceptible to cross drafts than a wall-mounted hood configuration.

The configuration, volume, and temperature of makeup air was critical to the performance of the double-island canopy hood. Consistent with previous research (Brohard et al. 2003), reducing local makeup airflow rates and velocities corresponded with reduced capture and containment exhaust rates, in most cases. When air volume and associated velocity and turbulence near the hood was minimized, the appliance plumes were more stable and the hood was able to capture and contain at a lower exhaust rate. However, when local makeup air was introduced aggressively through four-way diffusers, perforated diffusers, or a high-flow perforated perimeter supply system, hood performance degraded severely. For double-island configurations, a perforated perimeter supply system operated at a low-flow, low-velocity condition was the best of the local makeup air configurations tested. When the perforated perimeter supply system delivered low-flow, low-velocity air adjacent to the hood (i.e., less than 60% of replacement air requirement), hood performance improved significantly over the high-flow, high-velocity introduction (i.e., greater than 60% of replacement air requirement), and in some cases, better than the exhaust-only configuration with displacement supply. Higher replacement air temperatures from ceiling diffusers also degraded the performance of island hoods. Unbalanced replacement air distribution was extremely detrimental to the performance of the double-island hoods.

Other research highlighted the advantages of using side panels for wall-mounted canopy hoods and a variety of replacement air conditions (Brohard et al. 2003; Swierczyna et al. 2006). However, results from the double-island canopy hood testing regarding side panels were inconclusive. A more extensive side panel (and center partition) investigation would need a larger laboratory where replacement air was introduced more uniformly around the hood to eliminate the effect of relatively high, directional local velocities.

A partition between the two appliances lines improved performance of a double-island hood when coupled with a balanced supply on both sides of the hood. However, if as little as 1000 cfm was exhausted from the side opposite from the supply air delivery, performance of the double-island hood degraded. This was contrary to the expectation that the partition would be more of a benefit with unbalanced replacement air and its ability to mitigate the effect of cross drafts.

Increased hood overhang was shown to be one of the most effective performance enhancements for island canopy hoods. With a heavy-duty three-broiler appliance line centered front-to-rear under the single island hoods, rather than at a minimum prescriptive front overhang dimension, a 14% exhaust reduction was possible for the smaller rear filter hood, and a 40% exhaust reduction was possible for the larger V-bank hood. Likewise, when side overhang was increased to 24 in. from the minimum of 6 in., a 41% exhaust rate reduction was found for both single-island hoods. However, the results did not show a significant performance difference between the 8 ft and 10 ft deep double-island hoods. Increased side overhang was found to be one of the most effective performance enhancements for double-island canopy hoods. Increasing the side overhang to 24 in. resulted in a 160 cfm/ft reduction in exhaust flow rate.

Tailored exhaust bias for double-island hoods may improve hood performance. With more exhaust volume focused over the more challenging appliances, the exhaust rate can be reduced for a given configuration. However, application of a specific bias for other applications or hood dimensions may yield different performance results and should be verified.

Specification of enhanced hood edge geometry should be considered by manufacturers and end-users. Although each design needs to be properly evaluated for its effect on hood performance, the design tested in this project was effective and was typical of edge design currently found in the industry.

Performance in the field should be verified to ensure proper hood capture and containment operation. As shown by RP-1480 (Swierczyna et al. 2010), many factors interact in the kitchen and affect hood performance. These interactions cannot be perfectly predicted for each installation. Therefore, a field test is best to verify proper kitchen ventilation and hood performance.

Wall Canopy Hoods, Appliance Positioning, and Diversity

ASHRAE research project RP-1202 (Swierczyna et al. 2006) quantified the effect of the position and/or combination of appliances under a wall canopy exhaust hood on the minimum C&C exhaust rate. Effects of side panels, front overhang, and rear seal were also investigated. The scope of this laboratory study was to investigate similar and dissimilar appliances under a 10 ft wall-mounted canopy hood. The appliances included three full-sized electric convection ovens, three two-vat gas fryers, and three 3 ft gas underfired broilers, representing the light, medium, and heavy-duty appliance categories, respectively. In addition to various physical appliance configurations, appliances were also varied in their usage: either off, at idle conditions, or at cooking conditions. A supplemental study investigated the effect of appliance accessories (including shelving and a salamander) and hood dimensions (including hood height, depth, and reservoir volume) on the minimum exhaust rate required for complete capture and containment.

The study demonstrated that subtle changes in appliance position and hood configuration could dramatically affect the exhaust rates required for complete capture and containment, regardless of appliance duty and/or usage. The wide range in C&C values for a given hood/appliance setup explains why a similar hood installed over virtually the same appliance line may perform successfully in one kitchen and fall short of expectations in another facility. The following conclusions are specific to the conditions tested by Swierczyna et al. (2006).

Airflow Requirements for Like-Duty Appliance Lines. Evaluation supported widely accepted commercial kitchen ventilation (CKV) design practices: higher ventilation rates are required for progressively heavier-duty appliances (Table 4). For a 10 ft wall-mounted canopy hood, at a defined median or good-case installation, the light-duty oven line required 1100 cfm (110 cfm/ft), the medium-duty fryer line required 2400 cfm (240 cfm/ft), and the heavy-duty broiler line required 4400 cfm (440 cfm/ft) to achieve C&C. Simply increasing front overhang as noted between the worst- and good-case installations in Table 4 reduced the C&C exhaust rate by 10 to 27%. Installing side panels in addition to the increased front overhang (best-case scenario) reduced the exhaust requirements by an additional 18 to 33%.

Appliance position testing confirmed the exhaust rate of an appliance line was most dependent on the duty of the end appliance. The end appliance drove the exhaust rate more than additional volume from the other two appliances, as they changed from off to cooking conditions or were varied in duty class. In most cases, the lowest exhaust requirements for particular appliance lines were achieved when the lowest-duty appliance was at the end of the appliance line. In other words, hood performance was optimized when the heaviest-duty appliance was in the middle of the appliance line.

Appliance Positioning (Front-to-Back) and Rear Seal. Increasing the front overhang by pushing appliances toward the back wall significantly decreased the required exhaust rates, not only because of the increased distance from the hood to the front of the appliance, but also because of the decreased distance between the

Table 4 Capture and Containment Exhaust Rates for Three Like-Duty Appliance Lines at Cooking Conditions with Various Front Overhang and Side Panel Configurations under 10 ft Wall-Mounted Canopy Hood

	Best Case	Good Case	Worst Case
Three electric full-sized convection ovens	9 in. front overhang full side panels 85 cfm/ft	9 in. front overhang 110 cfm/ft	6 in. front overhang 120 cfm/ft
Three two-vat gas fryers	18 in. front overhang partial side panels 160 cfm/ft	18 in. front overhang 240 cfm/ft	6 in. front overhang 330 cfm/ft
Three gas underfired broilers	12 in. front overhang partial side panels 330 cfm/ft*	12 in. front overhang 440 cfm/ft	0 in. front overhang (6 in. cook surface) 510 cfm/ft

*Adding a rear seal between back of appliance and wall to best-case configuration (6 in. of front overhang and partial side panels) further improved hood performance to an exhaust rate of 2800 cfm (280 cfm/ft).

Source: Swierczyna et al. (2006).

Fig. 4 Exhaust Capture and Containment Rates for One or Three Appliances Cooking from Like-Duty Classes under a 10 ft Wall-Canopy Hood (Swierczyna et al. 2006)

back of the appliance and the wall. With a rear seal in place, some of the replacement air, which would have otherwise been drawn up from behind the appliances, was instead drawn in along the perimeter of the hood, helping guide the plume into the hood, as shown in Figure 3.

Diversity in Appliance Usage. Operation diversity was evaluated with cook lines of three similar appliances and included combinations of *cook* and *off* conditions. In most cases, operation correlated directly with the required exhaust rate, with an emphasis on the operation of the end appliances (Figure 4). The capture and containment rate for the end appliance cooking and the other two like-duty appliances off was nearly the same rate as all three appliances cooking.

Changing the condition of end appliances from *off* to cooking had the greatest effect for medium-duty fryers, which required a 950 cfm increase in the exhaust rate. Because the fryers were thermostatically controlled, they responded to cooking operations by firing the burners. This, combined with an aggressive cooking plume, required a significantly increased exhaust rate for C&C. An aggressive thermal plume was present for the three heavy-duty gas underfired broilers; the exhaust rate increased 850 cfm. For the light-duty electric convection oven, there was a 200 cfm difference in turning the end appliances from off to cook. Figure 4 also shows that cooking with only the center appliance, with the two end appliances turned off, greatly reduced the exhaust requirement.

Diversity in Appliance Duty and Position (Side-to-Side). The study found that the capture and containment rate of a multiduty

Fig. 5 Capture and Containment Exhaust Rates for Cooking Conditions on Multiduty Appliance Lines (Compared with Single-Duty Lines with Only One Appliance Operating) under 10 ft Wall Canopy Hood (Swierczyna et al. 2006)

appliance line was less than the rate of the heaviest duty appliance in that line, applied over the length of the hood (Figure 5).

Hood Side Panels. Side panels installed on the 10 ft hood improved hood performance dramatically, by preventing the plume

Fig. 6 Exhaust Capture and Containment Rates for Three Two-Vat Gas Fryers with Various Side Panel and Overhang Configurations under 10 ft Wall Canopy Hood (Swierczyna et al. 2006)

Fig. 7 Exhaust Capture and Containment Rates for Heavy-Duty Gas Underfired Broiler Line under 10 ft Wall Canopy Hood with 4 and 5 ft Hood Depths and Front Various Front Overhangs (Swierczyna et al. 2006)

from spilling at the side of the hood and by increasing velocity along the front of the hood. Combining side panels (measuring 1 by 1 ft by 45°, 2 by 2 ft by 45°, 3 by 3 ft by 45°, 4 by 4 ft by 45°, or full) with the maximum hood overhang resulted in the lowest exhaust requirement for all cases tested. The example of the three two-vat gas fryer line is shown in Figure 6.

Effect of Shelving on Hood Capture and Containment Performance. Neither solid nor tubular shelving over the six-burner range required an increase in the exhaust rate. In fact, tubular shelving mounted to the back of the appliance showed a slight enhancement compared to having no shelving installed.

Effect of Hood Depth, Reservoir, and Mounting Height on Capture and Containment Performance. Comparing the 4 and 5 ft deep hoods, the deeper hood reduced capture and containment exhaust rates when appliances were positioned with maximum front overhang and minimum rear gap. The deeper hood had a negative effect when appliances remained in the minimum front overhang position. The effect of hood depth in conjunction with front overhang, side panels, and rear seal is shown in Figure 7.

Another advantage of the 5 ft over the 4 ft hood was its ability to capture and contain the plume when an oven door was opened. For a 4 ft hood and a 6 in. front overhang, an exhaust rate of 1200 cfm was required for the three electric ovens with the doors closed and 5200 cfm with the doors open. Similarly, for a 5 ft deep hood with an 18 in. front overhang, 1200 cfm was required for three ovens with the doors closed and 3400 cfm with the doors open. The setup and schlieren views are shown in Figure 8.

The reservoir volume of the hood was increased by changing the hood height from 2 to 3 ft. When the gas underfired broiler was operated in the left appliance position, the increased hood volume marginally improved capture and containment performance. In contrast, a significant improvement was found for the appliance in the center position. This improvement indicated the plume was well located in the hood, and the increased hood volume may have allowed the plume to roll inside the hood and distribute itself more evenly along the length of the filter bank.

Minimizing hood mounting height had a positive effect on capture and containment performance. In most cases, a direct correlation could be made between the required exhaust rate and hood height for a given appliance line. The typical 6.5 ft mounting height (for a canopy hood) was increased to 7 or 7.5 ft. For the gas underfired broiler installed at the end of the hood, increasing the hood height by 1 ft required a 14% increase in exhaust. However, when the broiler was in the center position, the increased hood height did not compromise capture and containment performance and required a reduced exhaust rate. The dramatic reduction in the exhaust requirement as the hood-to-appliance distance was reduced below the 6.5 ft mounting height illustrated the potential for optimizing CKV systems by using close-coupled or proximity-style hoods. This effect is shown in Figure 9.

Design Guidelines. Swierczyna et al. (2006) illustrated the potential for large variations in the airflow requirements for a specified appliance line and hood configuration. Best-practice design considerations that became evident included the following:

- Position heavy-duty appliances (e.g., broilers) in middle of the line.
- Position light-duty appliances (e.g., ovens) on the end of the line.
- Push back appliances (maximize front overhang, minimize rear gap).
- Seal area between rear of appliance and wall.
- Use side panels, end panels, and end walls.
- Installing shelving or ancillary equipment (e.g., salamander) behind or above a range should not negatively affect C&C performance, if other best practices (e.g., maximizing hood overhang) are observed.
- Use larger hoods, both deeper and taller.
- Installing hoods at lowest height practical (or allowed by code) to minimize distance from cooking surface to hood improves C&C performance.
- Introduce replacement air at low velocity. Do not locate four-way diffusers near hood, and minimize use of air curtains.

Replacement (Makeup) Air Options. Air exhausted from the kitchen must be replaced. Replacement air can be brought in through traditional methods, such as **ceiling diffusers**, or through systems built as an integral part of the hood. It may also be introduced using low-velocity displacement diffusers or transfer air from other zones. For further information, see the section on Replacement (Makeup) Air Systems.

Static Pressure. Static pressure drop through hoods depends on the type and design of the hood and grease removal devices, size of duct and duct connections, and flow rate. Table 5 provides a general guide for determining static pressure loss depending on the type of grease removal device and exhaust flow rate. Manufacturers' data

Fig. 8 Three Ovens under Wall-Mounted Canopy Hood at Exhaust Rate of 3400 cfm

(Swierczyna et al. 2006)

Table 5 Exhaust Static Pressure Loss of Type I Hoods for Various Exhaust Airflows*

Type of Grease Removal Device	Hood Static Pressure Loss, in. of water			
	150 to 250 cfm/ft	250 to 350 cfm/ft	350 to 450 cfm/ft	500+ cfm/ft
Baffle filter	0.25 to 0.50	0.50 to 0.75	0.75 to 1.00	1.00 to 1.25
Extractor	0.80 to 1.35	1.30 to 1.70	1.70 to 3.00	2.90 to 4.20
Multistage	0.55 to 1.10	1.10 to 1.70	1.70 to 2.90	2.90 to 4.00

*Values based on 20 in. high filters and 1500 fpm through hood/duct collar.

should be consulted for actual values. Static pressure losses for exhaust ducts should be calculated for each installation.

Type II Hoods

Type II hoods (Figure 10) can be divided into the following two application categories:

Fig. 10 Type II Hoods

- **Condensate hood.** For applications with high-moisture exhaust, condensate forms on interior surfaces of the hood. The hood is designed to direct the condensate toward a perimeter gutter for collection and drainage, allowing none to drip onto the appliance below. Hood material is usually noncorrosive, and filters are usually installed.
- **Heat/fume hood.** For hoods over equipment producing heat and fumes only. Filters are usually not installed.

ASHRAE *Standard 154* sets minimum exhaust airflow requirements for Type II hoods based on the duty rating of the appliance underneath the hood. Table 6 classifies Type II appliances as either

Table 6 Type II Hood Duty Classification by Appliance Type

Appliance Description	Size	Type II Hoods	
		Light Duty	Medium Duty
Cheesemelter, gas	All	X	
Dishwasher, conveyor rack, chemical sanitizing	All	X	
Dishwasher, conveyor rack, hot water sanitizing	All	X

light or medium duty, and Table 7 gives minimum net airflow requirements.

Recirculating Systems

A recirculating system, previously called a **ductless hood**, consists of a cooking appliance/hood assembly designed to remove grease, smoke, and odor and to return the treated exhaust air directly back into the room. HVAC design must consider that recirculating systems discharge the total amount of heat and moisture generated by the cooking process back into the kitchen space, adding to the cooling load.

These hoods typically contain the following components in the exhaust stream: (1) a grease removal device such as a baffle filter, (2) a high-efficiency particulate air (HEPA) filter or an electrostatic precipitator (ESP), (3) some means of odor control such as activated charcoal, and (4) an exhaust fan. NFPA Standard 96, Chapter 13, is devoted entirely to recirculating systems and contains specific requirements such as (1) design, including interlocks of all critical components to prevent operation of the cooking appliance if any of the components are not operating; (2) fire extinguishing system, including specific nozzle locations; (3) maintenance, including a specific schedule for cleaning filters, ESP, hood, and fan; and (4) inspection and testing of the total operation and interlocks. In addition, NFPA Standard 96 requires that all recirculating systems be listed by a testing laboratory. The recognized standard for a recirculating system is UL Standard 710B. Recirculating systems should not be used over gas-fired or solid-fuel-fired cooking equipment.

Designers should thoroughly review NFPA Standard 96 requirements and contact a manufacturer of recirculating systems to obtain specific information needed for the design and listing information before incorporating this type of system into a food service design.

Table 7 Minimum Net Exhaust Airflow Requirements for Type II Hoods

Type of Hood	Minimum Net Exhaust Flow Rate per Linear Hood Length, cfm/ft	
	Light-Duty Equipment	Medium-Duty Equipment
Wall-mounted canopy	200	300
Single island	400	500
Double island (per side)	250	300
Eyebrow	250	250
Back shelf/pass-over	200	300

Downdraft Appliance Ventilation Systems

These systems are intended to remove smoke, grease-laden vapors, odors, and other impurities from the air by drawing the cooking effluents away from cooking appliances and downward into ventilation systems. According to UL Standard 710B, these systems are used with electric cooking appliances only. A downdraft system listed to UL Standard 710B, for recirculating applications, consists of a fire extinguishing system unit, grease filters, interlocks, etc., all contained within a suitable enclosure.

Downdraft systems operate on a different principle than typical exhaust hoods. With a customary exhaust hood, the buoyant thermal plume from cooking rises into the exhaust hood by gravity, provided overhang is sufficient, cross drafts do not interfere, etc., as explained previously. Thereafter, one or more exhaust fans create a low pressure in the hood plenum, and the exhaust contents are carried outdoors from the hood.

In contrast, downdraft ventilation systems include an exhaust fan that creates a low pressure at an inlet beside or behind a cooking surface, or between two cooking surfaces. The exhaust fan draws cooking effluents, possibly including combustion products, through a grease filter in the exhaust inlet, to be transported outdoors or recirculated into the cooking space.

Downdraft appliance ventilation systems are described and covered by NFPA Standard 96, Chapter 15, and if used for recirculation, are listed to UL Standard 710B. If used to ventilate processes producing smoke or grease laden vapor, these systems must comply with NFPA Standard 96, Chapter 15, which references other requirements in NFPA Standard 96:

- Clearance requirements in Section 4.2
- Hood requirements of Chapter 6
- Grease removal device requirements of Chapter 7
- Special-purpose filters listed in accordance with ANSI/UL Standard 1046
- Exhaust duct requirements of Chapter 7
- Air movement requirement of 8.2.1.2 and 8.2.2.3
- Fire-extinguishing requirements of Chapter 10 and Section 15.2
- Maintenance requirements of Chapter 11
- Safety requirements of Chapter 12

Important additional requirements are provided by NFPA Standard 96, sections 15.1.2 through 15.4.

Caution is advised for application of downdraft ventilation systems to commercial kitchens. Pulling effluent away from a flat-surface griddle is one popular application of these systems, particularly in Asian-style steakhouses, where the griddles are used intermittently and the exhaust inlet is slightly close to the edges of the cooking surface. More challenging is trying to pull vapors from the tops of commercial cooking vessels, such as on range tops, because cooking effluents might be emitted above and out of reach of the downdraft inlet suction. For gas appliances, also remember

that air movement created by downdraft inlet suction might be sufficient to interfere with the operation of nearby gas burners

Field Performance Testing

Once kitchen ventilation systems have been installed, it is important to verify that they operate correctly. ASHRAE *Standard* 154-2011 describes performance testing for both Type I and Type II hood applications. For Type II hoods, the requirement is that the hood must be operating at the minimum airflow shown in Table 7. For Type I hoods, all appliances must be turned on and either actual or simulated cooking must be performed to verify that the hood system has achieved proper capture and containment.

1.6 COOKING EFFLUENT GENERATION AND CONTROL

Air quality, fire safety, labor cost, and maintenance costs are important concerns about emissions from a commercial cooking operation. Cooking emissions have also been identified as a major component of smog particulate. This has led to regulation in some major cities, requiring reduction of emissions from specific cooking operations.

In a fire, grease deposits in duct act as fuel. Reducing this grease can help prevent a small kitchen fire from becoming a major structural fire. In the past, the only control of grease build-up in exhaust ducts was frequent duct cleaning, which is expensive and disruptive to kitchen operation. It also depends on frequent duct inspections and regular cleaning. Grease build-up on fans, fire nozzles, roofs, and other ventilation equipment can be costly in additional maintenance and replacement costs. From an energy and sustainability perspective, it is desirable to reduce the atmospheric

emissions and achieve the highest grease extraction or destruction with the lowest energy costs possible. For mechanical extractors, the pressure drop of the filters is the predominant driver for energy usage, whereas for other control systems there may be electrical components or water use that needs to be evaluated. Figure 11 presents some design guidance for what filtration may be desirable under various exhaust temperature and/or duty level situations.

Another issue that commonly comes up during kitchen design and operation is how often ductwork needs to be cleaned in restaurants. Table 8 presents inspection schedules adapted from Table 11.4 of NFPA *Standard* 96.

Effluent Generation

During cooking operations on appliances, effluent is generated. This effluent includes water vapor and organic material (in both particulate and vapor form) released from the food. If the energy source for the appliance involves combustion additional contaminants may also be released.

Particle Size Comparisons (from Exhaust Systems). Effluent from five types of commercial cooking equipment has been

Table 8 Recommended Duct-Cleaning Schedules

Type or Volume of Cooking	Inspection Frequency
Solid fuel	Monthly
High-volume cooking (gas charbroiler or wok cooking)	Quarterly
Moderate-volume	Semiannually
Low-volume (churches, day camps, seasonal businesses)	Annually

Fig. 11 Typical Filter Guidelines Versus Appliance Duty and Exhaust Temperature

measured under a typical exhaust hood (Kuehn et al. 1999). Foods that emit relatively large amounts of grease were selected. Figures 12A and 12B shows the measured amount of grease in the plume entering the hood above different appliances and the amount in the vapor phase, particles below 2.5 μm in size (PM 2.5), particles less than 10 μm in size (PM 10), and the total amount of particulate grease. Ovens and fryers generate little or no grease particulate emissions, whereas other processes generate significant amounts. However, gas underfired broilers (referred to as “gas broilers” in Figures 12A and 12B) generate much smaller particulates compared to the griddles and ranges, and these emissions depend on the broiler design. The amount of grease in the vapor phase is significant and varies from 30% to over 90% by mass; this affects the design approach for grease removal systems.

Carbon monoxide (CO) and carbon dioxide (CO₂) emissions are present in solid fuel and natural gas combustion processes but not in processes from electrical appliances. Additional CO and CO₂ emissions may be generated by gas underfired boilers when grease drippings land on extremely hot surfaces and burn. Nitrogen oxide (NO_x) emissions appear to be exclusively associated with gas appliances and related to total gas consumption.

Figure 12C shows the measured plume volumetric flow rate entering the hood. In general, gas appliances have slightly larger flow rates than electric because additional products of combustion must be vented. Gas underfired and electric broilers have plume flow rates considerably larger than the other appliances shown. Effluent flow rates from gas underfired and electric broilers are approximately 100 times larger than the actual volumetric flow rate created by vaporizing moisture and grease from food. The difference is caused by ambient air entrained into the effluent plume before it reaches the exhaust hood.

Thermal Plume Behavior

The most common method of contaminant control is to install an air inlet device (a hood) where the plume can enter it and be conveyed away by an exhaust system. The hood is generally located above or behind the heated surface to intercept normal upward flow. Understanding plume behavior is central to designing effective ventilation systems.

Effluent released from a noncooking cold process, such as metal grinding, is captured and removed by placing air inlets so that they catch forcibly ejected material, or by creating airstreams with

sufficient velocity to induce the flow of effluent into an inlet. This technique has led to an empirical concept of capture velocity that is often misapplied to hot processes. Effluent (such as grease and smoke from cooking) released from a hot process and contained in a plume may be captured by locating an inlet hood so that the plume flows into it by buoyancy. Hood exhaust rate must equal or slightly exceed plume volumetric flow rate, but the hood need not actively induce capture of the effluent if the hood is large enough at its height above the cooking operation to encompass the plume as it expands during its rise. Additional exhaust airflow may be needed to resist cross currents that carry the plume away from the hood.

A heated plume, without cross currents or other interference, rises vertically, entraining additional air, which causes the plume to enlarge and its average velocity and temperature to decrease. If a surface parallel to the plume centerline (e.g., a back wall) is nearby, the plume will be drawn toward the surface by the Coanda effect. This tendency may also help direct the plume into the hood. Figure 13 illustrates a heated plume with and without cooking effluent as it rises from heated cooking appliances. Figure 13A shows two gas underfired broilers cooking hamburgers under a wall-mounted, exhaust-only, canopy hood. Note that the hood is mounted against a clear back wall to improve experimental observation. Figures 13B and 13C show the hot-air plume without cooking, visualized using a

schlieren optical system, under full capture and spillage conditions, respectively.

Effluent Control

Effluents generated by cooking include grease in particulate (solid or liquid) and vapor states, smoke particles, and volatile organic compounds (VOCs or low-carbon aromatics, which are significant contributors to odor). Grease vapor is condensable and may condense into grease particulate in the exhaust airstream when diluted with room-temperature air or when it is exhausted into the cooler outdoor atmosphere.

Effluent controls in the vast majority of kitchen ventilation systems are limited to removing solid and liquid grease particles by mechanical grease removal devices in the hood. More effective devices reduce grease build-up downstream of the hood, lowering the frequency of duct cleaning and reducing the fire hazard.

The reported grease extraction efficiency of mechanical filtration systems (e.g., baffle filters and slot cartridge filters) may reflect the particulate removal performance of these devices. These devices are listed for their ability to limit flame penetration into the plenum and duct. Grease extraction performance can be evaluated using ASTM Standard F2519. Smaller aerodynamic particles (<2.5 μm) are not easily removed by mechanical extractors. If these particles must be removed, a pollution control unit is typically added, which removes a large percentage of the grease that escaped the grease removal device in the hood, as well as smoke particles.

ASHRAE research project RP-745 (Gerstler et al. 1998) found that a significant proportion of grease effluent may be in vapor form (Figure 14), which is not removed by mechanical extractors.

Grease Extraction

The particulate range from cooking operations ranges from 0.01 to 100 μm. Different cooking operations have different ranges of particle sizes in the cooking plume and have been measured for many appliances (Gerstler et al. 1998; Kuehn et al. 2008). Grease particulates larger than 20 μm are too heavy to remain airborne and drop out of the airstream. Figure 15 compares the size of particles from kitchen exhaust to common items.

Fig. 14 Particulate Versus Vapor-Phase Emission Percentage per Appliance (Average)
(Gerstler et al. 1998)

Each combination of food product, cooking equipment, and cooking temperature creates a unique particle emissions profile, these profiles change over time during the cooking process. For example, the initial drop of French fries into a fryer gives off a short blast of large particles, whereas cooking a hamburger on a griddle gives off a continuous stream of particles and vapor. Burgers cooked on a broiler tend to burn and emit very small particles (< 1 μm in size).

Variations in the food product itself can also change the emissions of a cooking process. Hamburger with 23% fat content produces more grease than a 20% fat burger. Chicken breast may have a different effluent characteristic than chicken legs or thighs. Even cooking chicken with or without the skin changes the properties of emissions.

Figures 16 and 17 show typical particle emission profiles for a gas griddle and gas underfired broiler both cooking hamburgers (Kuehn et al. 1999).

ASTM *Standard F2519-05* can be used to determine fractional filter efficiency for grease particulate. A fractional efficiency curve is a graph that gives a filter's efficiency over a range of particle sizes. Fractional efficiency curves are created by subjecting a test filter to a controlled distribution of particles and measuring the quantity of particles at each given size before and after the filter. The amount of reduction of particles is used to calculate the efficiency at each given size. The fractional efficiency curve for a typical 20 by 20 in. baffle filter tested at 350 cfm/ft is shown in Figure 18.

Fig. 15 Size Distribution of Common Particles

Fig. 16 Gas Griddle Mass Emission Versus Particle Size (Kuehn et al. 1999)

Fig. 17 Gas Underfired Broiler Mass Emission Versus Particle Size (Kuehn et al. 1999)

Extraction efficiencies must be compared at the same airflow per linear length of filter. This gives a consistent way of comparing performance of extraction devices that may be built very differently, such as hoods with removable extractors and with stationary extractors. This is also consistent with the way exhaust flow rates for hoods are commonly specified. The airflow rate through a hood changes hood efficiency by changing the velocity at which the air travels through a filter.

To demonstrate what a filter fractional efficiency means with an actual cooking process, the gas underfired broilers (referred to as "charbroiler") emissions curve and the baffle filter efficiency curve have been plotted on one graph in Figure 19. The area under each emission curves is representative of the total particulate emissions for the gas underfired broiler. As can be seen by comparing the graph before and after the baffle filter, there is very little reduction in the amount of grease exhausted to the duct. The area under the "charbroiler after baffle" curve represents the amount of grease particulate exhausted into the duct.

The graphs and efficiencies shown here are only for particulate grease. There is also a vapor component of the grease that is exhausted, which cannot be removed by filtration. Some of the vapor condenses and is removed as particulate before reaching the filter. Some condenses in the duct and accumulates on the duct and fan. However, with elevated temperatures in the exhaust airstream, vapor may pass through and exit to the atmosphere.

Higher efficiency at a specific particle size may not be the only selection criteria for grease extraction. From an energy and sustainability standpoint, the ideal goal would be to have the highest grease

Fig. 18 Baffle Filter Particle Efficiency Versus Particle Size (Kuehn et al. 1999)

Fig. 19 Baffle Filter Particle Efficiency Versus Particle Size (Kuehn et al. 1999)

extraction at the lowest pressure drop possible. Smaller particles can only be removed by shifting the efficiency curve towards the left.

More effective devices reduce grease build-up downstream of the hood, lowering the frequency of duct cleaning and reducing the fire hazard. Having higher-efficiency grease removal devices in the hood reduces the maintenance of downstream control equipment.

Concerns about air quality also emphasize the need for higher-efficiency grease extraction from the exhaust airstream than can be provided by filters or grease extractors in exhaust hoods. Cleaner exhaust discharge to the outdoors may be required by increasingly stringent air quality regulations or where the exhaust discharge configuration is such that grease, smoke, or odors in discharge would create a nuisance. In some cases, exhaust air is cleaned so that it can be discharged inside (e.g., through recirculating systems). Several systems have been developed to clean the exhaust airstream, each of which presents special fire protection issues.

Where odor control is required in addition to grease removal, activated charcoal, other oxidizing bed filters, or deodorizing agents are used downstream of the grease filters. Because much cooking odor is gaseous and therefore not removed by air filtration, filtration upstream of the charcoal filters must remove virtually all grease in the airstream to prevent grease build-up on the charcoal filters. See Chapter 12 of the 2013 *ASHRAE Handbook—Fundamentals* for more information.

The following technologies are applied to varying degrees for control of cooking effluent. They are listed by order of use in the exhaust stream after a mechanical filtration device, with particulate control upstream of VOC control. After the description of each technology are qualifications and concerns about its use. There is no consensus test protocol for evaluating these technologies in kitchen applications.

Electrostatic Precipitators (ESPs). Particulate removal is by high-voltage ionization, then collection on flat plates.

- Condensed grease can block airflow, especially when mounted outdoor.
- As the ionizer section becomes dirty, efficiency drops because the effective ionizer surface area is reduced.
- Under heavy loading, the unit may shut down because of voltage drop.

Ultraviolet (UV) Destruction. This system uses ultraviolet light to chemically convert the grease into an inert substance and ozone. Construction (not performance) is evaluated for safety in accordance with UL *Standard* 710C.

- Requires adequate exposure time for chemical reactions.
- Personnel should not look at light generated by high-intensity UV lamps.
- Exhaust fans should operate when UV lights are on because some forms of UV generate ozone.
- UV is more effective on very small particles and vapor.
- The required frequency of duct cleaning is reduced.
- Lamps need to be replaced periodically; as lamps become dirty, efficiency drops.

Water Mist, Scrubber, and Water Bath. Passage of the effluent stream through water mechanically entraps particulates and condenses grease vapor.

- High airflow can reduce efficiency of water baths.
- Water baths have high static pressure loss.
- Spray nozzles need much attention; water may need softening to minimize clogging.
- Drains tend to become clogged with grease, and grease traps require more frequent service. Mist and scrubber sections need significant length to maximize exposure time.

Pleated, Bag, and HEPA Filters. These devices are designed to remove very small particles by mechanical filtration. Some types also have an activated-carbon face coating for odor control.

- Filters become blocked quickly if too much grease enters.
- Static loss builds quickly with extraction, and airflow drops.
- Almost all filters are disposable and very expensive.

Activated-Carbon Filters. VOC control is through adsorption by fine activated charcoal particles.

- Require a large volume and thick bed to be effective.
- Are heavy and can be difficult to replace.
- Expensive to change and recharge. Many are disposable.
- Ruined quickly if they are grease-coated or subjected to water.
- Some concern that carbon is a source of fuel for a fire.

Oxidizing Pellet Bed Filters. VOC and odor control is by oxidation of gaseous effluent into solid compounds.

- Require a large volume and long bed to be effective.
- Are heavy to handle and can be difficult to replace.
- Expensive to change.
- Some concern about increased oxygen available in fire.

Incineration. Particulate, VOC, and odor control is by high-temperature oxidation (burning) into solid compounds.

- Must be at system terminus and clear of combustibles.
- Are expensive to install with adequate clearances.
- Can be difficult to access for service.
- Very expensive to operate.

Catalytic conversion. A catalytic or assisting material, when exposed to relatively high-temperature air, provides additional heat adequate to decompose (oxidize) most particulates and VOCs.

- Requires high temperature (450°F minimum).
- Expensive to operate because of high temperature requirement if integrated into the hood (can be cost-effective at the appliance level).

1.7 REPLACEMENT (MAKEUP) AIR SYSTEMS

In hood systems, where air exhausted through the hood is discharged to the outdoors, the volume of air exhausted must be replaced with uncontaminated outdoor air. Outdoor air must be introduced into the building through properly designed replacement air systems. Proper replacement air volume and distribution allow the hood exhaust fan to operate as designed and facilitate proper building pressurization, which is required for safe operation of direct-vent gas appliances (such as water heaters), prevention of kitchen odors migrating to adjacent building spaces, and/or maintaining a comfortable building environment. Proper pressurization enhances the building environment by preventing suction of unfiltered and/or unconditioned outdoor air into the building envelope through doors, windows, or air handlers. IMC (ICC 2009a) requires neutral or negative pressurization in rooms with mechanical exhaust. NFPA *Standard* 96 requires enough replacement air to prevent negative pressures from exceeding 0.02 in. of water, which may still be excessive for proper drafting of some direct vent appliances. To ensure pressure control, IMC also requires electrical interlock between exhaust and replacement air sources. This electrical interlock prevents excessive negative or positive pressures created by the exhaust fan or replacement air unit operating independently.

Indoor Environmental Quality

Traditionally, the primary purpose of replacement air has been to ensure proper operation of the hood. Kitchen thermal comfort and indoor environmental quality (IEQ) have been secondary. In some applications, thermal comfort and IEQ can be improved through

Table 9 Outdoor Air Requirements for Dining and Food Preparation Areas

Facility Type	Airflow Rate, cfm/person	Maximum Occupancy, persons/1000 ft ²
Restaurant dining area	7.5	70
Cafeterias and fast food dining area	7.5	100
Bars/cocktail lounges	7.5	100
Kitchen (cooking) spaces	7.5	20

Note: All areas are assumed nonsmoking.
Source: ASHRAE Standard 62.1.

adequate airflow and proper introduction of replacement air. In many of today's applications, outdoor air that meets IEQ standards is the most energy-efficient source for kitchen hood replacement air. Table 9 gives ASHRAE Standard 62.1 requirements for outdoor air per person; these requirements may be increased or decreased in certain areas if approved by the authority having jurisdiction. Outdoor air requirements affect HVAC system sizing and may require another means of introducing outdoor air. A further requirement of Standard 62.1, that outdoor air be sufficient to provide for an exhaust rate of at least 0.70 cfm per square foot of kitchen space, is generally easily met due to cooking ventilation rates.

Replacement Air Introduction

Replacement air may be introduced into the building through dedicated makeup air units, conventional HVAC apparatus, dedicated hood-system makeup air units (discussed in the section on Air Distribution), or in very limited climates, ventilators that include no conditioning means.

Dedicated Makeup Air Units. These units are specifically designed to heat, dehumidify, or cool 100% outdoor air. These dedicated units typically include modulating, heating, dehumidification, and cooling systems that react to outdoor air conditions and prevent cycling of these conditioning systems. Cycling leads to space discomfort and higher unit energy consumption. Hot-gas reheat (HGRH) may also be included to aid in continuous dehumidification (when required by outdoor air conditions) while maintaining space comfort. See Chapter 28 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for more information on makeup air units.

Using enthalpy or temperature control for determining dedicated makeup air unit operation is recommended. These controls turn compressor(s), water supply, or heat sources off when outdoor air conditions warrant, while maintaining kitchen comfort, thus conserving energy and saving money without the use of additional economizer damper systems.

Conventional HVAC Units. Conventional HVAC units require fixed outdoor air intakes or economizer-controlled outdoor air dampers when they (1) supply outdoor air to meet spaces' ventilation requirements, (2) are adjacent to the kitchen area, and (3) only secondarily transfer the outdoor component of the total airflow to the kitchen. To alleviate any potential overpressurization occurrences, HVAC units with economizers should have a barometric relief damper either in the return ductwork or in the HVAC unit itself. As the amount of outdoor air increases, the increasing pressure in the system opens the relief damper, so that the return air volumetric rate is only enough to maintain approximately the amount of design supply air. The amount of air required for dedicated replacement air becomes the minimum set point for the economizer damper when the hoods are operating. Fixed outdoor air intakes must be set to allow the required amount of replacement air. Outdoor air dampers should be interlocked with hood controls to open to a preset minimum position when the hood system is energized.

If the zone controls call for cooling, and outdoor conditions are within economizer range, the outdoor damper may be opened to

allow greater amounts of outdoor air. The maximum setting for outdoor air dampers in unitary HVAC units is typically 25 to 30% of total unit air volume when the units are operating in their heating or cooling (i.e., noneconomizer) mode. Field experience has shown that large increases in air discharge velocities or volumes can occur at diffusers when HVAC units go into economizer mode. This is because the static loss through the fresh-air intake is considerably less than through the return air duct system, and thus a change from return air to fresh air reduces the overall static through the system, resulting in a relative increase in the total system flow. This can create air balance problems that negatively affect hood performance because of interference with capture and containment supply flow patterns at the hoods.

A large increase in air velocity or volume from supply diffusers indicates a need for better balance between the fresh air and return air static losses. Some HVAC manufacturers state that a relief fan is required to ensure proper air balance if economizer controls call for outdoor air greater than 50% during economizer operation mode. A relief fan addresses static losses in the return duct system, thus helping minimize the static difference with the fresh-air intake. Lack of a barometric relief damper, or constrictions in the return ductwork, also may be the source of the problem.

In smaller commercial buildings, including restaurants and strip centers, individual unitary rooftop HVAC equipment is common. This unitary equipment may not be adequate to supply 100% of the replacement air volume. Outdoor air must be considered during initial unit selection to obtain desired unit operation and space comfort. The space in which the hood is located should be kept at a neutral or negative pressure relative to adjacent spaces. Therefore, HVAC economizers are not recommended for equipment supplying air directly to the space in which the hood is located, unless the economizer installation includes equipment and controls to maintain overall system air balance and to prevent excessive air discharge velocities or volumes.

In climates with higher summer dew-point design conditions, consider adding active dehumidification (such as hot-gas reheat) for units supplying outdoor air for ventilation at rates greater than 10% of unit total airflow.

Replacement Air Categories

Three categories of replacement air have been defined for design of energy-efficient replacement air systems: supply, makeup, and transfer. IAQ engineers must design outdoor air systems to meet total building ventilation requirements. Replacement air for kitchen ventilation must integrate into the total building IAQ design. Total kitchen ventilation replacement air may consist of only dedicated makeup air; however, in many energy-efficient designs, outdoor air required for ventilating the kitchen or adjacent spaces is used as supply or transfer air to augment or even eliminate the need for dedicated makeup air. Typically, replacement air will be a combination of categories from multiple sources. The source of replacement air typically determines its category.

Kitchen supply air is outdoor air introduced through the HVAC or ventilating apparatus, dedicated to the comfort conditioning of the space in which the hood is located. In many cases this may be an ideal source of replacement air because it also provides comfort conditioning for the occupants.

Makeup air is outdoor air introduced through a system dedicated to provide replacement air specifically for the hood. It is typically delivered directly to or close to the hood. This air may or may not be conditioned. When conditioned, it may be heated only; generally only in extreme environments will it be cooled. When included, makeup air typically receives less conditioning than space supply air. The IMC (ICC 2009a) requires makeup air be conditioned to within 10°F of the kitchen space, except when introducing replacement air that does not decrease kitchen comfort (see

the section on Energy Considerations for additional information). This can be accomplished with proper distribution design. Typical sources of makeup air heating include direct and indirect gas-fired units, hot-water coils (with freeze protection), and, in some cases or geographic areas, electric resistance heating. When cooling is provided, the outdoor air design conditions must be considered. A low-dew-point design is required for effective use of evaporative coolers. Higher-dew-point design temperatures may require water or direct exchange (DX) coils for cooling and/or dehumidification. Temperature of makeup air introduced varies with distribution system and type of operation.

Transfer air is outdoor air, introduced through the HVAC or ventilating apparatus, dedicated to comfort conditioning and ventilation requirements of a space adjacent to the area in which the hood is located. The device providing transfer air must operate and supply outdoor air whenever the hood is operating. Air must not be transferred from spaces where airborne contaminants such as odors, germs, or dust may be introduced into the food preparation or serving areas. Air may be transferred through wall openings, door louvers, or ceiling grilles connected by duct above the ceiling. Depending on grille and duct pressure drop, a transfer fan(s) may be required to avoid drawing transfer air through lower-pressure-drop openings at velocities that may be detrimental to food service processes. When using openings through which food is passed, transfer velocities should not exceed 50 fpm to avoid excessive cooling of the food. Transfer air is an efficient source of replacement air because it performs many functions, including ventilating and/or conditioning the adjacent space, replacing air for the hood, and additional conditioning for the space in which the hood is located. Only the portion of air supplied to the adjacent space that originated as outdoor air may be transferred for replacement air. The IMC (ICC 2009a) recognizes the use of transfer air as a replacement air source. In large buildings such as malls, supermarkets, and schools, adequate transfer air may be available to meet 100% of hood replacement air requirements. Malls and multiple-use-occupancy buildings may specify a minimum amount of transfer air to be taken from their space to keep cooking odors in the kitchen, or they may specify the maximum transfer air available. Code restrictions may prevent the use of corridors as spaces through which transfer air may be routed. Conditions of transfer air are determined by conditioning requirements of the space into which the air is initially supplied.

Air Distribution

The design of a replacement air distribution system may enhance or degrade hood performance. Systems that use a combination of kitchen supply, makeup, and transfer air include various components of distribution. Distribution from each source into the vicinity of the hood, must be designed to eliminate high velocities, eddies, swirls, or stray currents that can interrupt the natural rising of the thermal plume from cooking equipment into the hood, thus degrading the performance of the hood. Methods of distribution may include conventional diffusers, compensating hood designs, transfer devices, and simple openings in partitions separating building spaces. Regardless of the method selected, it is important to always deliver replacement air to the hood (1) at proper velocity and (2) uniformly from all directions to which the hood is open. This minimizes excessive cross-currents that could cause spillage. Proper location and/or control of HVAC return grilles is therefore critical. The higher air velocities typically recommended for general ventilation or spot cooling with unconditioned air (75 to 200 fpm at worker) should be avoided around the hood. Hood manufacturers offer a variety of compensating hoods, plenums, and diffusers designed to introduce replacement air effectively.

Hood-Supplied Replacement Air (Compensating Hoods).

A common way of distributing replacement air is through compensating systems that are integral with the hood. Figure 20 shows

four typical compensating hood configurations. Because actual flows and percentages may vary with hood design, the manufacturer should be consulted about specific applications. The following are typical descriptions of configurations that include perimeter supply.

Brohard et al. (2003) investigated the effects of six methods of introducing replacement air on three hood styles. Three hood types were tested: (1) wall-mounted canopy, (2) island-mounted canopy, and (3) proximity (backshelf). Gas underfired broilers and gas griddles, respectively representing heavy-duty and medium-duty appliances, were tested. Idle and emulated cooking conditions also were tested. The MUA strategies included (1) displacement ventilation (base case), (2) ceiling diffuser, (3) hood face diffuser, (4) air curtain diffuser, (5) back wall supply, and (6) short-circuit supply. The influences of air mass disturbances (drafts) and tapered side panels were also investigated. Each replacement air strategy and specific configuration tested compromised the exhaust hood's ability to completely capture and contain the thermal plume and/or effluents at higher replacement airflow rates (expressed as a percentage of the threshold exhaust rate). Temperature of locally supplied makeup air also affected hood performance, because air density affects the dynamics of air movement around the hood. Generally, hotter makeup air temperatures (e.g., greater than 90°F) affect hood performance more adversely than cooler air (e.g., less than 75°F).

Air Curtain Supply. This method is typically used for spot-cooling the cooking staff to counter the severe radiant heat generated from equipment such as gas or electric broilers. The air must be heated and/or cooled, depending on local climate. Air curtain discharge can be along the length of the hood front only or along all open sides of the hood. When discharge velocity is too low, air tends to enter the hood directly and may have little effect on hood performance. When discharge velocity is too high, air entrains the cooking plume and spills it into the room. Ideal velocity and throw can improve hood performance and redirect the thermal plume toward the filters. Discharge velocities must be carefully selected to avoid discomfort to personnel and cooling of food.

Limit the percentage of makeup air supplied through an air curtain to less than 20% of the hood's exhaust flow. At these low air velocities, an air curtain may enhance capture and containment, depending on design details. However, at higher makeup airflow rates, the air curtain is one of the worst performing makeup air strategies. The negative effect of an air curtain is clearly illustrated in Figure 21 by the schlieren flow visualization recorded during a test of a wall-mounted canopy hood operating over two gas underfired broilers.

Fig. 20 Compensating Hood Configurations

Introducing makeup air through an air curtain is a risky option. An air curtain (by itself or in combination with another pathway) is not recommended, unless velocities are minimized and the designer has access to performance data on the actual air curtain configuration being specified. Typical air curtains are easily adjusted, which could cause cooking effluent to spill into the kitchen by inadvertently creating higher-than-specified discharge velocities.

Back-Wall Supply. A makeup air plenum is installed between the back of the hood and wall. The full-length plenum typically extends down the wall to approximately 6 in. below the cooking surface or 2 to 3 ft above the floor. The depth of the plenum is typically 6 in. Makeup air is discharged behind and below the cooking equipment. The bottom of the plenum is provided with diffusers and may also include a balancing damper. As with front-face discharge, air volume and discharge velocity dictate how far into the space the makeup air will travel. The amount of travel and local climate dictate the amount of heating and/or cooling needed. Support for wall shelves, salamander broilers, or cheesemelters mounted under the hood must be considered. The plenum structure typically does not provide sufficient support for mounting these items.

Back-wall supply can be an effective strategy for introducing makeup air (Figure 22). In most cases, it allows significant amounts of air to be locally supplied without a detrimental effect on hood C&C performance. Local makeup air mostly enters the kitchen space, rather than remaining contained in the cooking zone. This potentially creates an additional heat and moisture load on the kitchen, particularly because most replacement air supplied is mixed with room air before being exhausted.

To help ensure proper performance, the discharge of the back-wall supply should be at least 12 in. below cooking surfaces of appliances, to prevent the relatively high-velocity makeup air from interfering with gas burners and pilot lights. Back-wall plenums with larger discharge areas may provide increased airflow rates as long as discharge velocities remain below maximum thresholds. The quantity of air introduced through the back-wall supply should be no more than 60% of the hood's exhaust flow.

Front-Face Supply. Supplying air through the front face of the hood is a configuration recommended by many hood manufacturers. In theory, air exits the front-face unit horizontally into the kitchen space. However, a front-face discharge with louvers or perforated face can perform poorly, if its design does not consider discharge air velocity and direction. Figure 23 presents a poorly designed perforated face supply, which can negatively affect hood capture performance in the same way as an air-curtain or four-way diffuser. To

Fig. 22 Schlieren Image Showing Thermal Plume Being Captured with Back-Wall Supply
(Brohard et al. 2003)

Fig. 21 Schlieren Image Showing Thermal Plume Being Pulled Outside Hood by Air Curtain
(Brohard et al. 2003)

Fig. 23 Schlieren Image Showing Thermal Plume Being Pulled Outside Hood by Front Face
(Brohard et al. 2003)

improve front-face performance, internal baffling and/or a double layer of perforated plates may be used improve the uniformity of airflow. In addition, greater distance between the lower capture edge of the hood and the bottom of the face discharge area may decrease the tendency of the replacement air supply to interfere with hood capture and containment. In general, face discharge velocities should not exceed 150 fpm (i.e., replacement air flow rate divided by gross discharge area) and should exit the front face in a horizontal direction.

Internal Makeup Air. This method, also known as **short-circuit**, introduces makeup air directly into the exhaust hood cavity. This design has limited application, and the amount of air that can be introduced varies considerably with the type of cooking equipment and exhaust flow rate. As noted previously, thermal currents from cooking equipment create a plume of a certain volume that the hood must remove. The hood must therefore draw at least this volume of air from the kitchen, in addition to any internal makeup. If the net exhaust flow rate (total exhaust less internal makeup air) is less than the plume volume, part of the plume may spill out of the hood. Internal makeup air is typically not conditioned; however, depending on local climate, manufacturer's design, type of cooking equipment, and local codes, conditioning may be required. Some local authorities approve internal discharge hoods, and some do not. For unlisted hoods, IMC (2009a) requires the net quantity of exhaust air to be calculated by subtracting any airflow supplied directly to a hood cavity from the total exhaust flow rate of a hood. Listed hoods are operated in accordance with the terms of the listing. All applicable codes must be consulted to ensure proper criteria are followed.

When short-circuit hoods are operated with excessive internal makeup air, they typically fail to capture and contain the cooking effluent (Figure 24). ASHRAE *Standard* 154 limits the quantity of internal replacement air to no more than 10% of the exhaust airflow. Additionally, the introduction of untempered makeup air results in uncomfortable kitchen conditions. Independent research (Brohard et al. 2003) recommends not using this compensating hood design; therefore, there is no additional design information in this chapter.

Fig. 24 Schlieren Image Showing Thermal Plume Being Displaced by Short-Circuit Supply, Causing Hood to Spill
(Brohard et al. 2003)

Multiple Discharge. This method may combine internal, perimeter, air curtain, and/or front face. Each may be served by a separate or common plenum. Balancing dampers may be provided for one or both discharge arrangements. These dampers may be used to fine-tune the amount of air discharged through the air curtain or front face. However, this method inherits the performance problems of each of the individual types, and combining them tends to compound these problems.

Perforated Perimeter Supply. Perforated perimeter supply is similar to a front-face supply, but the air is directed downward, as in Figure 25, toward the hood capture area. This may be advantageous under some conditions, because air is directed downward into the hood capture zone.

For proper hood performance, discharge velocities should not exceed 150 fpm (i.e., makeup airflow rate divided by gross discharge area) from any section of the diffuser, and the distance to lower edge of the hood should be no less than 18 in., or the system begins to act like an air curtain. An increase in the plenum discharge area lowers the velocity for a given flow of replacement air and reduces the chance of it affecting capture and containment. If the perforated perimeter supply is extended along the sides of the hood as well as the front, the increased area allows proportionally more makeup air to be supplied. In all cases, the velocity downward 2 in. above the lower edge of the hood should not exceed 75 fpm.

Room-Supplied Makeup Air (Diffusers and Grilles). There are various ways to distribute replacement air in the vicinity of the hood to avoid cross currents that degrade hood performance. Non-aspirating diffusers are recommended, especially adjacent to the hood. For more information on diffusers, see Chapter 20 of the 2013 *ASHRAE Handbook—Fundamentals*, Chapter 20 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*, and Chapter 57 of this volume. Typical devices include the following.

Directional Ceiling Diffusers. Air from these two- or three-way diffusers should not be directed toward exhaust hoods,

Fig. 25 Schlieren Image Showing Effective Plume Capture with Replacement Air Supplied Through 16 in. Wide Perforated Perimeter Supply, Shown with Additional Front Overhang
(Brohard et al. 2003)

where it might disturb the thermal plume and adversely affect hood performance. The diffuser should be located so that the jet velocity at the lip of the hood does not exceed 75 fpm.

Four-Way Directional Ceiling Diffusers. Four-way directional diffusers located close to kitchen exhaust hoods (Figure 26) can have a detrimental effect on hood performance, particularly when flow through the diffuser approaches its design limit. They are not recommended within 15 ft of the hood.

Perforated Ceiling Diffusers. These nonaspirating, perforated-face diffusers may have internal deflecting louvers, but should not be capable of directing the airflow toward the hood. The diffuser should be located so that the jet velocity at the lip of the hood does not exceed 75 fpm. In some code jurisdictions, when conventional ceiling diffusers are used, only perforated diffusers are allowed in commercial kitchens. Perforated ceiling diffusers can be used near the hood, although a greater number of these diffusers may be required to reduce air velocities for a given supply rate. To help ensure proper hood performance, air from a perforated diffuser near the hood should not be directed toward the hood. If ceiling-supplied air must be directed toward a hood, air discharge velocity at the diffuser face should be selected so that the terminal velocity does not exceed 75 fpm at the edge of the hood capture area.

Slot Diffusers. Because the slot opening of these devices is generally small compared to air volume, air velocity is often higher than that which would be obtained with two-, three-, and four-way diffusers. Also, because airflow is mostly downward, the potential for negatively affecting hood performance is quite high if outlets are near the hood. If used with relatively high ceilings, the potential for negative impact is less because the velocity diminishes as air diffuses downward. Slot diffusers are usually nonaspirating.

Displacement Diffusers. These devices, designed to provide low-velocity laminar flow over the diffuser surface, typically supply air from 50 to 70°F in a kitchen, depending on equipment loads. Hotter, stratified air is removed from the ceiling through exhaust ducts or returned to the HVAC system to be conditioned. In contrast with

ceiling diffusers, which require complete mixing to be effective, stratification is the desired effect with displacement diffusers.

Displacement diffusers were used to determine the baseline for Brohard et al.'s (2003) replacement air study, because they provided a uniform, nearly laminar bulk airflow. This low-velocity bulk airflow is optimal for attaining C&C with the lowest exhaust rate. Therefore, supplying replacement air through displacement diffusers (Figure 27) may be an effective strategy for introducing replacement air. Adequate wall or floor space is required to accommodate displacement diffusers.

Other Factors That Influence Hood Performance.

Hood Style. Wall-mounted canopy hoods function effectively with a lower exhaust flow rate than single-island hoods. Island canopy hoods are more sensitive to makeup air supply and cross drafts than wall-mounted canopy hoods. Back-shelf/proximity hoods generally exhibit lower capture and containment exhaust rates, and in some cases, perform the same job at one-third of the exhaust rate required by a wall-mounted canopy hood.

Cross Drafts. Cross drafts have a detrimental effect on all hood/appliance combinations. Cross drafts adversely affect island canopy hoods more than wall-mounted canopy hoods. A fan in a kitchen, especially pointing at the cooking area, severely degrades hood performance and may make capture impossible. Cross drafts required at least a 37% increase in exhaust flow rate; in some cases, C&C could not be achieved with a 235% increase in exhaust rate (Brohard et al. 2003). Cross drafts can result from portable fans, movement in the kitchen, or an unbalanced HVAC system, which may pull air from open drive-through windows or doors.

Side Panels. Side (or end) panels allow a reduced exhaust rate in most cases, because they direct replacement airflow to the front of the hood. Installing side panels improved C&C performance for static conditions an average 10 to 15% and up to 35% for dynamic (cross-draft) conditions. They are a relatively inexpensive way to enhance performance and reduce the total exhaust rate. Partial side panels can provide virtually the same benefit as full panels. One of

Fig. 26 Schlieren Image Showing Thermal Plume Being Pulled Outside Hood by Air Discharged from Four-Way Diffuser
(Brohard et al. 2003)

Fig. 27 Schlieren Image Showing Plume Being Effectively Captured when Replacement Air Is Supplied at Low Velocity from Displacement Diffusers
(Brohard et al. 2003)

the greatest benefits of side panels is to mitigate the negative effect of cross drafts.

Brohard et al. (2003) recommend reducing the impact that locally supplied makeup air may have on hood performance by minimizing makeup air velocity as it is introduced near the hood. This can be accomplished by minimizing the volume of makeup air through any single distribution system or by distributing through multiple configurations. The chances of makeup air affecting hood performance increase as the percentage of the locally supplied makeup air (relative to the total exhaust) is increased. In fact, the 80% rule of thumb for sizing airflow through a makeup air system may be a recipe for trouble.

Effective introduction of replacement air (whether supplied through displacement ventilation diffusers, perforated diffusers located in the ceiling, and/or as transfer air from adjacent spaces) should be designed to limit velocities approaching the hood to less than 75 fpm.

Design Recommendations. The first step to reducing the replacement air requirement is lowering the design exhaust rate, which can be accomplished by prudent selection and application of UL *Standard* 710 listed hoods. Using side panels on canopy hoods may increase effectiveness and mitigate cross drafts, and is highly recommended where applicable. The next step is to take credit for outdoor air that must be supplied by the HVAC system to meet code requirements for space or occupant ventilating. Depending on the architectural layout, it may be practical to transfer most of this air to the kitchen. Assuming the transfer air is conditioned and properly introduced, it may enhance hood performance and improve the kitchen environment. For more information, see the sections on Energy Considerations and Commercial Exhaust Hoods in this chapter.

1.8 HVAC SYSTEM DESIGN

As mentioned previously, one purpose of kitchen ventilation is to provide a comfortable environment for employees. Engineers who are used to designing HVAC loads for more traditional spaces (e.g., offices) may not realize how different the kitchen environment can be: kitchens require a much greater quantity of outdoor air as makeup, and have much higher internal loads (including sensible radiated heat gain from appliances underneath hoods, sensible and latent loads from unhooded equipment including warewashers, and sometimes outdoor air loads).

Hooded and Unhooded Appliance Loads

One of the challenges in performing cooling and heating load calculations for a kitchen is determining the space heat gains from the cooking appliances. Given that many of the largest cooking appliances include exhaust hoods to remove the smoke, grease, and heat, determining the heat gain can be challenge. There may also be a large number of smaller appliances that do not include exhaust hoods and which reject all their heat directly to the space.

Tables 5A to 5E in Chapter 18 of the 2013 *ASHRAE Handbook—Fundamentals* list typical equipment and the heat rejected into the kitchen. The data contained in these tables were updated as part of ASHRAE research project RP-1362 (Swierczyna et al. 2008). Table 10 summarizes which tables to use for what type of equipment.

For the majority of appliances, table heat gain values were determined during idle or standby condition: that is, the appliance was fully warmed up and in its ready-to-cook condition. (Typically, an appliance is in standby for as much as 70% of the day.) For appliances installed under an exhaust hood, the amount of heat emitted as radiation is listed, because this heat ends up heating nearby objects. For the appliances that are not installed under a hood because of their low energy consumption or lack of cooking effluent, the

Table 11 Heat Gain from Outdoor Air Infiltration

Type of Heat Gain	Equation	Chapter 18,
		2013 <i>ASHRAE Handbook—Fundamentals</i> Equation Reference
Sensible	$q_s = 1.10Q_s \Delta t$	(10)
Latent	$q_l = 4840Q_s \Delta W$	(11)
Total (Sensible + Latent)	$q_t = 4.5Q_s \Delta h$	(8)

Notes: Q_s is flow in cfm, t is °F, W is lb_m water per lb_m air, h is Btu/lb_m, and q is heat gain in Btu. Δ is the difference between outdoor and space-neutral (room design) conditions.

amount of both sensible and latent heat is listed, in addition to the radiation.

The greatest challenge with using these data is determining the diversity or usage factor of the appliances. It may be difficult to anticipate how often the appliance will be at full cooking or at some standby condition. Any assumptions made can be rendered incorrect by a change in kitchen throughput or sales. Determining the correct heat gain is an involved procedure that requires input from the entire kitchen design team.

Outdoor Air Loads

If the outdoor air is not conditioned to a space-neutral (or space design) condition, then the sensible and latent loads from this volume of air will impact the existing HVAC system at least to some extent because however the air is introduced into the kitchen some of it will enter the kitchen space especially if that air is hot and humid. Table 11 summarizes the relevant equations from Chapter 18 of the 2013 *ASHRAE Handbook—Fundamentals*. It is recommended that the load from at least 50% of the outdoor air brought into the kitchen to replace the exhaust air be used in the heat gain calculations.

The remaining heat gains from lighting, envelope, and people can be calculated following the procedure described in Chapter 18 of the 2013 *ASHRAE Handbook—Fundamentals*.

Thermal Comfort Research Results

ASHRAE research project RP-1469 (Stoops et al. 2013) conducted a large field survey on kitchens in the United States to identify how well engineers are satisfying design kitchen conditions. During the summer, 105 kitchens had their space conditions monitored. Figures 28 to 30 show the resulting temperatures in three areas of the restaurant (kitchen, food preparation, and warewashing) as a function of height above the floor.

Stoops et al. found that temperature increases with height above the floor: although floor-level temperatures ranged from approximately 75 to 83°F, at head level for staff temperatures ranged from 86 to 99°F. Higher temperatures at increasing heights can be

Fig. 28 Summer Temperatures by Height and Kitchen Zone in Casual Kitchens

Fig. 30 Summer Temperatures by Height and Kitchen Zone in Quick-Service Restaurant Kitchens

Fig. 29 Summer Temperatures by Height and Kitchen Zone in Institutional Kitchens

partially attributed to radiated heat gain from the appliances underneath hood(s), but there is no question that the space conditions were not being met on average for most of the kitchens monitored in this study, even at the floor level. See Chapter 9 of the 2013 *ASHRAE Handbook—Fundamentals* for more information.

1.9 EXHAUST SYSTEMS

Exhaust systems remove effluent produced by appliances and cooking processes to provide fire and health safety, comfort, and aesthetics. Typical exhaust systems simultaneously incorporate fire prevention designs and fire suppression equipment. In most cases, these functions complement each other, but in other cases they may seem to conflict. Designs must balance these functions. For example, fire-actuated dampers may be installed to minimize the spread

of fire to ducts, but maintaining an open duct might be better for removing smoke of an appliance fire from the kitchen.

Duct Systems

Exhaust ducts convey exhaust air from the hood to the outdoors, along with any grease, smoke, VOCs, and odors that are not extracted from the airstream along the way. These ducts may also be used to exhaust smoke from a fire. To be effective, ducts must be greasetight; it must be clear of combustibles, or combustible material must be protected so that it cannot be ignited by a fire in a duct; and ducts must be sized to convey the volume of airflow necessary to remove the effluent.

Model building codes, such as the IMC (ICC 2009a), and standards, such as NFPA *Standard 96*, set minimum air velocity for exhaust ducts at 500 fpm. Maximum velocities are limited by pressure drop and noise and typically do not exceed 2500 fpm. Until recently, NFPA *Standard 96* and the IMC had set the minimum air velocity through the duct at 1500 fpm. However, based on ASHRAE research (Kuehn 2000) that indicated that there is no basis for specifying 1500 fpm minimum duct velocity for commercial kitchen ventilation and that grease deposition in ducts does not increase when duct velocity is lowered to 500 fpm, NFPA and IMC requirements were changed to 500 fpm. This allows flexibility for design of variable-speed exhaust systems and retrofitting older systems, though because of spatial and cost constraints, current design practice for new single-speed systems generally is to design duct velocity between 1500 and 1800 fpm.

Ducts should have no traps that can hold grease, which would be an extra fuel source in the event of a fire, and ducts should pitch toward the hood or an approved reservoir for constant drainage of liquefied grease or condensates. On long duct runs, allowance must be made for possible thermal expansion because of fire, and the slope back to the hood or grease reservoir must conform to local code requirements.

Single-duct systems carry effluent from a single hood or section of a large hood to a single exhaust termination. In multiple-hood systems, several branch ducts carry effluent from several hoods to a single master duct that has a single termination. See the section on Multiple-Hood Systems for more information.

Ducts may be round or rectangular. Standards and model codes contain minimum specifications for duct materials and construction, including types and thickness of materials, joining methods, and minimum clearance of 18 in. to combustible materials. Listed factory-built modular grease duct systems are available as an alternative to code-prescribed welded systems. These listed systems typically incorporate stainless steel liners and double-wall, insulated construction, allowing reduced clearances to combustibles and non-welded joint construction.

When fire-rated enclosures are required for grease ducts, either fired-rated enclosures are built around the duct or the newer listed, field-applied grease duct enclosures can be used directly on the grease duct, or the newer listed, factory-built, modular grease ducts with insulated construction can be used as an integral fire-rated enclosure. Most of these listed systems allow zero clearance to combustibles and also provide 1 h or 2 h fire resistance rating, and can be used in lieu of a fire-rated enclosure required in NFPA *Standard 96* and IMC (ICC 2009a). See Chapter 19 in the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* and the Fire Safety section in this chapter for more information on grease duct construction.

1.10 EXHAUST FANS

Types of Exhaust Fans

Exhaust fans for kitchen ventilation must be capable of handling hot, grease-laden air. The fan should be designed to keep the motor out of the airstream and should be effectively cooled to prevent premature failure. To prevent roof damage, the fan should contain and properly drain all grease removed from the airstream. See Chapter 21 in the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* and the Fire Safety section in this chapter for more information on fans.

The following types of exhaust fans are commonly used; all have centrifugal wheels with backward-inclined blades:

- **Power roof ventilator (PRV).** Also known as **upblast fans**, PRVs are designed for mounting at the exhaust duct outlet (Figure 31), and discharge upward or outward from the roof or building. Aluminum upblast fans must be listed for the commercial kitchen exhaust application in compliance with UL *Standard 762*, and must include a grease drain, grease collection device, and integral hinge kit to permit access for duct cleaning.
- **Centrifugal fan.** Also known as a **utility set**, this is an AMCA Arrangement 10 centrifugal fan, including a field-rotatable blower housing, blower wheel with motor, drive, and often a motor/drive weather cover (Figure 32). These fans are typically constructed of steel and roof-mounted. Where approved, centrifugal fans can be

Fig. 31 Power Roof Ventilator (Upblast Fan)

mounted indoors and ducted to discharge outdoors. The inlet and outlet are at 90° to each other (single width, single inlet), and the outlet can usually be rotated to discharge at different angles around a vertical circle. The lowest part of the fan must drain to an approved container. When listed in accordance with UL *Standard 762*, a grease drain, grease collection device, and blower housing access panel are required.

- **Tubular centrifugal.** These fans, also known as **inline fans**, have the impeller mounted in a cylindrical housing discharging the gas in an axial direction (Figure 33). Where approved, these fans can be located in the duct inside a building if exterior fan mounting is not practical for wall or roof exhaust. They are always constructed of steel. The gasketed flange mounting must be greasetight yet removable for service. The lowest part of the fan must drain to an approved container. When listed in accordance with UL *Standard 762*, a grease drain, grease collection device, and blower housing access panel are required.
- **High-plume fan.** These fans may be used for kitchen applications when the requirements for a high exhaust plume are required (Figure 34). These fans generate a high nozzle exit velocity, which forces the exhaust plume to higher elevations and thus discharges smoke and grease laden vapors into the atmosphere. This fan is applicable when the intent is to prevent re-entraining smoke and grease-laden kitchen exhaust into the building makeup air system, or to discharge it over neighboring buildings or structures. When listed in accordance with UL *Standard 762*, a grease drain, grease collection device, and blower housing access panel are required. Because of the size and weight of these fans, the installation should be verified for structural integrity by a structural engineer. Items to be evaluated may include roof load, wind load, and seismic conditions.

Exhaust Terminations

Rooftop. Rooftop terminations are preferred because discharge can be directed away from the building, the fan is at the end of the

Fig. 32 Centrifugal Fan (Utility Set)

Fig. 33 Tubular Centrifugal (Inline) Fan

Fig. 34 High-Plume Fan

system, and the fan is accessible. Common concerns with rooftop terminations are as follows:

- Exhaust system discharge should be arranged to minimize reentry of effluent into any fresh-air intake or other opening to any building. This requires not only separating the exhaust from intakes, but also knowledge of the direction of the prevailing winds. Some codes specify a minimum distance to air intakes. See Chapter 45 for more information on exhaust discharge principles and considerations.
- In the event of a fire, neither flames, radiant heat, nor dripping grease should be able to ignite the roof or other nearby structures.
- All grease from the fan or duct termination should be collected and drained to a remote closed container to preclude ignition.
- Rainwater should be kept out of the exhaust system, especially out of the grease container. If this is not possible, then the grease container should be designed to separate water from grease and drain the water back onto the roof. Figure 35 shows a rooftop utility set with a stackhead fitting, which directs exhaust away from the roof and minimizes rain penetration. Discharge caps should not be used because they direct exhaust back toward the roof and can become grease-fouled.

Outside Wall. Wall terminations are less common today but are still occasionally used in new construction. The fan may or may not be the terminus of the system, located on the outside of the wall. Common concerns with wall terminations are as follows:

- Discharge from the exhaust system should not be able to enter any fresh-air intake or other opening to any building.
- Adequate clearance to combustibles must be maintained.
- To avoid grease draining down the side of the building, duct sections should pitch back to the hood inside, or a grease drain should be provided to drain grease back into a safe container inside the building.
- Discharge must not be directed downward or toward any pedestrian areas.
- Louvers should be designed to minimize their grease extraction and to prevent staining of the building facade.

Recirculating Systems. With these units, it is critical to keep components in good working order to maintain optimal performance.

Fig. 35 Rooftop Centrifugal Fan (Utility Set) with Vertical Discharge

Otherwise, excessive grease, heat, and odors will accumulate in the premises.

As with other terminations, containing and removing grease and keeping the discharge as far as possible from combustibles are the main concerns. Some units are fairly portable and could be set in an unsafe location. The operator should be made aware of the importance of safety in locating the unit. These units are best for large, unconfined areas with a separate outdoor exhaust to keep the environment comfortable.

1.11 FIRE SAFETY

The combination of flammable grease vapor and particulates carried by kitchen ventilation systems and the potential of cooking equipment to be an ignition source creates a higher hazard level than normally found in HVAC systems. Design of an exhaust system serving commercial cooking equipment that may produce grease-laden vapors (i.e., a Type I exhaust system) must include a fire suppression system, as required by NFPA *Standard* 96 and the International Mechanical Code (IMC; ICC 2009a). The IMC further requires that the fire suppression system comply with the International Building Code (IBC; ICC 2009c) and the International Fire Code (IFC; ICC 2009d). By further reference, these codes and standards require that automatic fire suppression systems for Type I hoods must be listed to UL *Standard* 300.

Replacement air systems, air-conditioning systems serving a kitchen, and exhaust systems serving cooking equipment that does not produce grease-laden vapor have no specific fire protection requirements beyond those applicable to similar systems not located in kitchens. However, an exhaust system serving any grease-producing cooking equipment must be considered a grease exhaust system even if it also serves non-grease-producing equipment.

Fire safety starts with proper design, followed by proper operation and maintenance of the cooking equipment and the exhaust system, including frequent and thorough cleaning of grease deposits in the area of appliances, and exhaust filters, hoods, and ducts. After that, the three primary aspects of fire protection in a grease exhaust system are (1) to extinguish a fire quickly once it has started, (2) to prevent the spread of fire from or to the grease exhaust system, and (3) to prevent heat transfer to building components from a grease duct fire if the fire-extinguishing system fails. Additionally, UL

Standard 300 requires that the fire suppression system not disperse burning grease outside the fire zone, and that, after a fire is suppressed by a fire suppression system, it must remain suppressed for at least 20 min.

Fire Suppression Systems

NFPA *Standard 96* requires that exhaust systems serving grease-producing equipment must include a fire-extinguishing system that protects the cooking equipment, hood interior, hood filters or grease extractors, ducts, and any other grease-removal devices in the system.

Actuation of any fire-extinguishing system must not depend on building electricity. If actuation relies on electricity, it must be supplied with standby power, usually in the form of battery backup.

Listed fire suppression systems must also automatically shut off all supplies of fuel and energy to all equipment protected by that system. Any gas appliance not requiring protection but located under the same ventilating equipment must also be shut off. On operation of an extinguishing system, all electrical sources located under the ventilating equipment, if subject to exposure to discharge from the fire-extinguishing system, must be shut off. If the exhaust system is in a building with a fire alarm system, actuation of the fire-extinguishing system should send a signal to the fire alarm system.

Dry and Wet Chemical Systems. Wet chemical and combinations of wet chemical and water fire-extinguishing systems have comprised the majority of fire suppression systems since the publication of *UL Standard 300* in 1994 and its subsequent citation by codes and standards. Dry chemical systems were popular through the early 1990s, but their use declined because they do not meet the requirements of *UL Standard 300* and must be replaced with *UL Standard 300* listed systems. Wet chemical systems are covered in NFPA *Standard 17A*, and though obsolete since *UL Standard 300* was published, dry chemical systems are covered in NFPA *Standard 17*. Both standards provide detailed application information.

Fire suppression systems are tested for their ability to extinguish fires in cooking operations in accordance with *UL Standard 300*. Wet chemical systems extinguish fires by reacting with fats and grease to **saponify**, or form a soapy foam layer, which prevents oxygen from reaching the burning surface. This suppresses the fire and prevents reignition. Saponification is particularly important with deep fat fryers, where the frying medium may be hotter than its autoignition temperature for some time after the fire is extinguished. If the foam layer disappears or is disturbed before the frying medium has cooled below its autoignition temperature, the fat can reignite.

Frying media commonly used today, which contain a high percentage of vegetable oils, have autoignition points of about 685 to 710°F when new. Contamination and deterioration through normal use lowers the autoignition point. In addition to the formation of a foam blanket instead of a thin layer of powder, another advantage of wet chemical systems over dry chemical systems is that the former cools the frying media, bringing it below the autoignition point more quickly.

For a chemical system protecting the entire exhaust system, fire-extinguishing nozzles are located over the cooking equipment being protected, in the hood to protect grease-removal devices and the hood plenum, and at the duct collar (downstream from any fire dampers and pointing in the direction of effluent flow) to protect the grease duct.

Two types of nozzle arrangements are common for protecting appliances. Appliance specific coverage is provided by nozzles that are usually directed at the centers of individual appliances. Overlapping coverage is provided by a generally greater number of evenly spaced nozzles. Although overlapping coverage is slightly more expensive to install and maintain, this arrangement solves the common problem of appliances being periodically rearranged under hoods to meet operational needs.

The duct nozzle is rated to protect an unlimited length of duct, so additional nozzles are not required further downstream in the duct. Additional nozzles and piping in ducts would also make periodic duct cleaning more difficult.

Listed fire-extinguishing systems are available as preengineered (packaged) systems, installed by authorized exhaust hood manufacturers or local authorized fire suppression system distributors/dealers. In either case, required periodic maintenance of fire suppression systems is performed by local authorized fire suppression system distributors/dealers.

Chemical systems typically consist of one or more tanks of chemical agent, a propellant gas cartridge, piping to the suppression nozzles, fire detectors, and auxiliary equipment. Auxiliary equipment may include manual actuation ("pull") stations, gas shutoff valves (spring-loaded or solenoid-actuated), and auxiliary electric contacts.

Fire detection is required at the entrance to each duct (or ducts, in hoods with multiple duct takeoffs). The fire detectors are typically fusible links that melt at a set temperature associated with a fire, although electronic detection with battery back-up is also available.

Actuation of chemical suppression systems is typically mechanical, requiring no electric power, by means of a spring-loaded device that pierces the seal on a propellant canister. Fire detectors are typically interconnected with the system actuator by steel cables in tension, so that melting of any fusible links, in series configuration, releases the tension on the steel cables, causing the spring-loaded actuator to release the propellant and force suppressant through pipes and nozzles.

The total length of the steel cable and number of pulley elbows allowed in the detection system are limited. A manual pull station is typically connected to the system actuator by steel cable. If a mechanical gas shutoff valve is used, it is also typically connected to the system actuator by steel cable. System actuation also switches auxiliary dry electrical contacts, which can be used to shut off electrical cooking equipment, operate an electric gas valve, shut off a replacement air fan, keep the related exhaust fan running, and/or send an alarm signal to the building fire alarm system. With electrically actuated fire suppression systems, detection is by electronic temperature sensors, and manual pulls are electric, in place of fusible links, cables, pipes, and pulleys.

Manual pull stations are generally required to be at least 10 ft from the cooking appliance and in a path of egress. Some code authorities may prefer that the pull station be installed closer to the cooking equipment for faster response; however, if it is too close, it may not be possible to approach it once a fire has started. Refer to the applicable code requirements for each jurisdiction to determine specific requirements for location and mounting heights of pull stations.

Water Systems. Water can be used for protecting cooking equipment, hoods, and exhaust systems. Standard fire sprinklers may be used throughout the system, except over deep-fat fryers, where special automatic spray nozzles specifically listed for the application must be used. These nozzles must be aimed properly and supplied with the correct water pressure. Many hood manufacturers market a preengineered water spray system that typically includes a cabinet containing the necessary plumbing and electrical components to monitor the system and initiate fuel shutoff and building alarms.

Application of standard fire sprinklers for protection of cooking equipment, hoods, and exhaust systems is covered by NFPA *Standard 13*. NFPA *Standards 25* and *96* cover maintenance of sprinkler systems serving an exhaust system. The sprinklers must connect to a wet-pipe building sprinkler system installed in compliance with NFPA *Standard 13*.

One advantage of a sprinkler system is that it has virtually unlimited capacity, whereas chemical systems have limited chemical supplies. Where sprinklers are used in ducts, the duct should be

pitched to drain safely. NFPA *Standard* 13 requires that sprinklers used to protect ducts be installed every 10 ft on center in horizontal ducts, at the top of every vertical riser, and in the middle of any vertical offset. Any sprinklers exposed to freezing temperatures must be protected.

Combination Systems. Hoods that use water either for periodic cleaning (water-wash) or for grease removal (cold-water mist) can use this feature in conjunction with the fire-extinguishing system to protect the hood, grease-removal devices, and/or ducts in the event of a fire, if listed to UL *Standard* 300. The water supply for these systems may be from the kitchen water supply if flow and pressure requirements are met. Examples include (1) an approved water-wash or water-mist system to protect the hood in combination with a listed wet chemical system to protect ducts and the cooking appliances (2) a listed chemical fire suppression system in the hood backed up by water sprinklers in the duct, or (3) a listed wet chemical system for appliances, with simultaneous use of a hood water-wash system, with foam-forming chemical injected into the water, for hood plenum and duct.

Multiple-Hood Systems. All hoods connected to a multiple-hood exhaust system must usually meet several requirements. In the IMC (ICC 2009a), for example, the hoods must be on the same floor of the building, all interconnected hoods must be in the same room or in adjoining rooms, interconnecting ducts must not penetrate assemblies required to be fire-resistance rated, and the grease duct system must not serve solid-fuel-fired appliances.

The multiple-hood exhaust system must be designed to (1) prevent a fire in one hood or in the duct from spreading through the ducts to another hood and (2) protect against a fire starting in the common duct system. Of course, the first line of protection for the ducts is keeping them clean. Especially in a multiple-tenant system, a single entity must assume responsibility for cleaning the common duct frequently.

Each hood must have its own fire-extinguishing system to protect the hood and cooking surface. A single system might serve more than one hood, but in the event of fire under one hood, the system would discharge its suppressant under all hoods served, resulting in unnecessary cleanup expense and inconvenience. A water-mist system could serve multiple hoods if sprinkler heads were allowed to operate independently.

Because of the possibility of a fire spreading through ducts from one hood to another, the common duct must have its own fire extinguishing system. The appendices of NFPA *Standards* 17 and 17A present detailed examples of how common ducts can be protected, either by one system or by a combination of separate systems serving individual hoods. Different types of fire-extinguishing systems may be used to protect different portions of the exhaust system; however, in any case where two different types of system can discharge into the common duct at the same time, the agents must be compatible.

As mentioned earlier, actuation of the fire-extinguishing system protecting any hood must shut off fuel or power to all cooking equipment under that hood. When a common duct, or portion thereof, is protected by a chemical fire-extinguishing system that activates from a fire in a single hood, NFPA *Standards* 17 and 17A require shutoff of fuel or power to the cooking equipment under every hood served by that common duct, or every portion of it protected by the activated system, even if there is no fire in the other hoods served by that duct.

From an operational standpoint, it is usually most sensible to provide one or more fire-extinguishing systems to detect and protect against fire in common ducts and a separate system to protect each hood and its connecting ducts. This prevents a fire in the common duct from causing discharge of fire suppressant under an unaffected hood and it allows unaffected hoods to continue operation in the event of a fire under one hood unless the fire spreads to the common duct.

Preventing Fire Spread

The exhaust system must be designed and installed both to prevent a fire starting in the exhaust system from damaging the building or spreading to other building areas, and to prevent a fire in one building area from spreading to other parts of the building through the exhaust system. This protection has two main aspects: (1) maintaining clearance from the duct to other portions of the building, and (2) either enclosing the duct in a fire-resistance-rated enclosure, or wrapping the duct with a listed fire-rated product. These methods are sometimes addressed by a listed insulated grease duct system that incorporates an integral fire resistance.

Clearance to Combustibles. A grease fire can generate gas temperatures of 2000°F or greater in the exhaust hood and duct. In such a grease fire, heat radiating from the hot surface can ignite combustible materials near the hood or duct. Additionally, if the hood or duct is not fully welded and liquidtight as required by codes and standards, grease liquid or vapor leaking from the hood or duct can ignite and spread fire to nearby combustible structure. Most codes require a minimum clearance of 18 in. from the hood and grease duct to any combustible material. However, even 18 in. may not be sufficient clearance to prevent ignition of combustibles in the case of a major grease fire, especially with large volumes of grease in larger ducts.

Several methods to protect combustible materials from the radiant heat of a grease fire and allow reduced clearance to combustibles are described in NFPA *Standard* 96 and the IMC (ICC 2009a). Based on testing and listing of grease ducts provided with integral insulation or wrapped with insulation, NFPA *Standard* 96 and other codes now allow listed insulation to be applied to the duct or a listed factory-built grease duct with integral insulation. For hoods, the clearance can be reduced as prescribed.

Listed grease ducts, typically with insulation between double walls or on the outside of single-wall ducts, may be installed with reduced clearance to combustibles in accordance with locally adopted codes and standards, if installed per manufacturers' instructions, which should include specific information regarding the listing. Listed grease ducts are tested and evaluated in accordance with UL *Standard* 1978.

NFPA *Standard* 96 requires a minimum clearance of 3 in. to "limited combustible" materials (e.g., gypsum wallboard on metal studs). The IMC (2009a) allows reduced clearance of ducts to 3 in. in proximity to noncombustibles on noncombustible structure, such as gypsum wallboard on metal studs. Clearance reduction is also available for hoods, but may differ by local code, so local codes and standards should be consulted accordingly.

Note that clearance-to-combustible issues are often seen in inspections of restaurant sites after grease fires. Many instances of inappropriate clearance reduction have been seen in which gypsum wallboard was mistakenly applied to wood studs and joists. In many of these cases, surrounding structure was ignited by heat from a grease fire, in spite of the gypsum wallboard barrier. The issue here is autoignition of the combustible material behind the gypsum wallboard from the high heat of the grease fire, even in cases where the gypsum wallboard layer is intact after the fire.

Enclosures. Normally, when a HVAC duct penetrates a fire-resistance-rated wall or floor, a fire damper is used to maintain the integrity of the wall or floor. Because fire dampers cannot be installed in a grease duct unless specifically approved for such use, there must be an alternative means of maintaining the integrity of rated walls or floors. Therefore, grease ducts that penetrate a fire-resistance-rated wall or floor/ceiling assembly must be continuously enclosed in a fire-rated enclosure from the point the duct penetrates the first fire barrier until the duct leaves the building. Listed grease ducts are also subject to these enclosure requirements. The requirements are similar to those for a vertical shaft (typically 1 h rating if

the shaft penetrates fewer than three floors, 2 h rating if it penetrates three or more floors), except that the shaft can be both vertical and horizontal. In essence, the enclosure extends the room containing the hood through all the other compartments of the building without creating any unprotected openings to those compartments.

Where a duct is enclosed in a rated enclosure, whether vertical or horizontal, clearance must be maintained between the duct and the shaft. NFPA *Standard* 96 and the IMC (2009a) require a minimum 6 in. clearance and that the shaft be vented to the outdoors. IMC requires that each exhaust duct have its own dedicated enclosure.

Some listed grease ducts are designed and tested for use without shaft enclosure. Listed grease ducts of this type use fire barrier insulation and provide integral fire-rated resistance, which serves the same function as the shaft enclosure. These products are tested and listed in accordance with UL *Standard* 2221. They must be installed in accordance with the manufacturer's installation instructions.

Some insulation materials are listed to serve as a fire-resistance-rated enclosure for a grease duct when used to cover a duct. These insulations are tested and listed in accordance with ASTM *Standard* E2336. These listed insulations must be applied in accordance with the manufacturer's installation instruction.

Insulation materials that have not been specifically tested and approved for use as fire protection for grease ducts should not be used in lieu of rated enclosures or to reduce clearance to combustibles. Even insulation approved for other fire protection applications, such as to protect structural steel, may not be appropriate for grease ducts because of the high temperatures that may be encountered in a grease fire.

Exhaust and Supply Fire-Actuated Dampers. Because of the risk that the damper may become coated with grease and become a source of fuel in a fire, balancing and fire-actuated dampers are not allowed at any point in an exhaust system except where specifically listed for use or required as part of a listed device or system. Typically, fire dampers are found only at the hood collar and only if provided by the hood manufacturer as part of a listed hood.

Opinions differ regarding whether any fire-actuated dampers should be provided in the exhaust hood. On one hand, a fire-actuated damper at the exhaust collar may prevent a fire under the hood from spreading to the exhaust duct. However, like anything in the exhaust airstream, the fire-actuated damper and fusible link may become coated with grease if not properly maintained, which may impede damper operation. On the other hand, without the fire-actuated damper, the exhaust fan draws smoke and fire away from the hood. Although this cannot be expected to remove all smoke from the kitchen during a fire, it can help to contain smoke in the kitchen and minimize migration of smoke to other areas of the building.

A fire-actuated damper will generally close only in the event of a severe fire; most kitchen fires are extinguished before enough heat is released to trigger the fire-actuated damper. Thus, the hood fire-actuated damper remains open during relatively small fires, allowing the exhaust system to remove smoke, but can close in the event of a severe fire, helping to contain the fire in the kitchen area.

Fan Operations. If replacement air flow rates exceed 2000 cfm, the replacement air supply to the kitchen is generally required by codes and standards to be shut down during fire to avoid feeding air to the fire. However, if the exhaust system is intended to operate during a fire to remove smoke from the kitchen (as opposed to just containing it in the kitchen), the replacement air system must operate as well. If the hood has an integral replacement air plenum, a fire-actuated damper must be installed in the replacement air plenum to prevent a fire in the hood from entering the replacement air duct. NFPA *Standard* 96 details the instances where fire-actuated dampers are required in a hood replacement air plenum.

Regardless of whether fire-actuated dampers are installed in the exhaust system, NFPA *Standard* 96 calls for the exhaust fan to continue to run in the event of a fire unless fan shutdown is required by

a listed component of the exhaust system or of the fire-extinguishing system. Listed fire-extinguishing systems protecting ducts are tested both with and without airflow, and exhaust airflow is not necessary for proper operation.

Control Systems. The IMC (2009a) requires that Type I (grease and smoke) hoods be designed and installed to automatically activate related exhaust fans whenever cooking operations occur. Further, the exhaust fan(s) must occur be activated through an interlock with the cooking appliances by means of a heat sensor or other approved means. An example of such an interlock is a listed electronic temperature sensor using a listed hood and duct accessory penetration in the duct collar and connecting the sensor electrically in parallel with fan control switches.

1.12 SYSTEM COMMISSIONING AND AIR BALANCING

ANSI/ASHRAE/IES *Standard* 202 defines commissioning as “a quality-focused process for enhancing delivery of a project. The process focuses upon verifying and documenting that all of the commissioned systems and assemblies are planned, designed, installed, tested, operated, and maintained to meet the owner's project requirements.”

For commercial kitchen ventilation (CKV), commissioning may involve validation of system components that are designed, supplied, and/or installed by multiple design professionals, vendors and building trades. This chapter's sections on Commissioning and Ventilation Design include steps that may be used to develop the owner's project requirements (OPR), including system design and installation.

It is not unusual for CKV systems to be treated as independent building systems, even though these systems can affect the safety and IEQ (including comfort and odor control) of the entire facility. Some locations may limit the effects the CKV system is allowed to have on the outdoor environment surrounding the facility. Given the CKV system's potential impacts, it is critical the OPR identifies responsibilities for system performance and its impacts on the facility and its environments. Refer to the System Integration and Design section of this chapter for more information.

Air Balancing

Kuehn (2010) demonstrated that a high degree of correction is required to achieve accurate airflow measurements with many of the instruments commonly used in the field to balance hood systems. Because of the level of correction required, hot-wire anemometers are not recommended. Therefore, balancing is best performed when the manufacturers of all system components provide a certified reference method of measuring the airflow of their equipment, rather than depending on generic measurements of duct flows or other forms of measurement in the field, which again can be erroneous. The equipment manufacturer should be able to develop a reference method of measuring airflow in a portion of the equipment that is dynamically stable in the laboratory as well as in the field. This method should relate directly to airflow by graph or formula.

Basic tools for balancing include the following:

- Volumetric flow hood
- Rotating vane anemometer
- Velocity grid
- Pitot tube/anemometers
- Manometer/pressure meter
- Voltage/ampere meter(s)
- Tachometer

Using instruments with current calibration certification or new instruments is recommended. The general steps for air balancing in restaurants are as follows:

1. Verify all exhaust and HVAC equipment is installed correctly and operating correctly, including (but not limited to) verifying that exhaust ducts are fully welded and inspection doors are in place, HVAC and supply ducts are complete and sealed, fans are rotating the correct direction, and thermostats are set up correctly and set to *on* or occupied mode.
2. Tabulated results of measurements should be kept and used to create a balance chart to show the building's net exfiltration or infiltration.
3. Exhaust hoods should be set to their proper flow rates, with supply and exhaust fans on.
4. Next, supply airflow rate, whether part of combined HVAC units or separate replacement air units, should be set to design values through the coils and the design supply flows from each outlet, with approximately correct settings on the outdoor airflow rate. Then, correct outdoor and return airflow rates should be set proportionately for each unit, as applicable. These settings should be made with exhaust on, to ensure adequate relief for the outdoor air. Where outdoor air and return air flows of a particular unit are expected to modulate, there should ideally be similar static losses through both airflow paths to preclude large changes in total supply air from the unit. Such changes, if large enough, could affect the efficiency of heat exchange and could also change airflows within and between zones, thereby upsetting air distribution and balance. See Chapter 38 for general HVAC testing, adjusting, and balancing information.
5. Next, outdoor air should be set with all fans (exhaust and supply) operating. Pressure difference between indoors and outdoors should be checked to confirm that (1) nonkitchen zones of the building are at a positive pressure compared to outdoors and (2) kitchen-zone pressure is negative compared to the surrounding zones, and positive or neutral compared to outdoors.
6. For applications with DCKV systems, proper capture and containment, as well as differential pressures between zones and atmosphere, should be confirmed at minimum and at maximum flow rates. This requires that the replacement airflow rate compensate automatically with each increment of exhaust. It may require some adjustments in controls or in damper linkage settings to get the correct proportional response.

System Tests

Cooking Exhaust Duct Leakage. ASHRAE *Standard* 154 outlines methods of test for exhaust system duct leakage. In most installations, the hood, exhaust fans, and replacement air equipment will be listed and labeled for its intended use. Exhaust duct systems may be field fabricated or Listed factory-built systems. Either system requires joining sections in the field and may include field-installed cleanouts and inspections ports. It is critical to the fire safety of the facility and the performance of the CKV system that these duct systems be tested to assure they are properly installed. See Chapter 19 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for information on HVAC duct construction and leakage criteria.

Fire Suppression. Like the duct system, the hood fire suppression system requires some field work to complete the system installation. Typically, the local AHJ requires an operating test of the installed suppression system. Test requirements vary. If the local AHJ does not require such a performance test of the completed system, the OPR should specify that such a test be conducted.

DCKV. When a DCKV system is installed to control the CKV systems, a system test should be conducted. This test should include the full range of the DCKV modulation, including the effects on exhaust and replacement air system performance throughout that full range. Examples include, at DCKV modulation extremes, (1) heating/cooling performance, (2) effective airflow distribution, and

(3) maintaining proper pressure balance between the kitchen, adjacent spaces, and atmosphere.

Building Automation System. The CKV system for controlling the temperature and proper pressurization of food preparation spaces and zones must be tested to ensure it operates properly as designed. If other spaces and zones outside of the food preparation zone provide replacement air for the CKV system, then they must also be tested to ensure their proper operation.

Performance Test

After initial airflows are verified to be at design values and the building is balanced, a performance evaluation of all exhaust hoods should be performed to verify capture and containment (C&C) at the design conditions.

Conduct Type I hood field testing with all appliances under the hood at operating temperatures, with all sources providing replacement air for the hood operating, and with all sources of recirculated air in the space operating. C&C is verified visually by observing smoke or steam produced by actual cooking operation or by simulating devices such as smoke candles or smoke puffers.

Note that smoke bombs should not be used, because they typically create new effluent from a point source and do not necessarily show whether cooking effluent is being captured. Actual cooking at the normal production rate is the most reliable method of generating smoke. Note that health department rules for new facilities typically do not allow food to be brought into the facility until all safety and health inspections are complete and approved. Actual cooking may require special arrangements with the AHJ.

Systems with DCKV should be tested at both minimum and maximum airflow settings. Hood systems with demand control should be tested at both minimum and maximum airflow settings.

If hoods fail the performance test, examine the systems and correct any capture problems. Close attention should be given to the design considerations and guidelines in this chapter to correct any performance problems.

Follow-Up: Records

1. A punch list of any remaining issues encountered during installation, air balancing, or performance testing should be recorded and submitted to the facility management and any affected contractors so that these items can be corrected.
2. When the preceding steps are complete, the system is properly integrated and balanced. At this time, all fan speeds and damper settings (at all modes of operation) should be permanently marked on the equipment and in the test and balance report. Air balance records of exhaust systems, replacement air systems, HVAC supply and return serving the hood area, and individual diffuser and/or grille airflows must also be completed. If the unit includes a fan, records must include fan or unit model(s) and size(s), fan wheel and motor rpm, and fan motor amp draw. These records should be kept by the food service facility for future reference.
3. For new facilities, after two or three days in operation, all belts in the system should be checked and readjusted to correct new belt run-in wear. This examination should take place no longer than a week after initial operation, and before the facility opens if possible. Obviously, direct-drive systems do not require this inspection or replacement.
4. Once the facility is operational, check performance of the ventilation system to verify that the design is adequate for actual cooking operation, particularly at maximum cooking and at outdoor environmental extremes. Any necessary changes should be made, and all the records should be updated to show the changes.
5. Rechecking the air balance should not be necessary more than once every two years unless basic changes are made in facility operation. If there are any changes, such as adding a new type of

cooking equipment or deleting exhaust connections, the system should be modified accordingly. Modifications should be recorded, added to owner's records, and marked on affected equipment.

6. All final operational measurements and recording shall be retained as a reference for future energy audit field surveys.

1.13 OPERATIONS AND MAINTENANCE

Sustainability Impact

Proper operation and maintenance of all kitchen ventilation systems is an often overlooked requirement, but is one of the most critical, especially given the large amount of resources used CKV operation. Typically, most attention is focused on the production of food, which is the primary role of any commercial kitchen. Given the kitchen ventilation system's role in providing replacement air, heating and cooling, and cooking effluent extraction, ensuring it is properly operated and maintained is critical for minimizing both overall system energy use and any environmental impacts both inside and outside the restaurant caused by effluent produced during cooking. Systems that are not operated or maintained correctly are likely to consume excessive energy, may create uncomfortable conditions in the kitchen area, may create an environmentally hazardous condition in the kitchen (e.g., hoods that do not capture and contain cooking effluent), and may affect outdoor environmental conditions (e.g., when pollution control devices are not operating properly). Additionally, given the fire hazards associated with commercial cooking, improper operation and maintenance of a kitchen's ventilation system(s) can even create a life safety hazard. Maintaining a proper air balance is part of a kitchen ventilation system's necessary maintenance. See Chapter 39 for more information on the costs associated with building operations and maintenance.

Finally, as part of any total commissioning process, the impact of operations and maintenance must be taken into account, especially ensuring that any related tasks can be performed with minimal disruption to food service production. If the system's proper operations and associated maintenance are not easily performed, they will most likely be deferred or not performed at all.

Operation

All components of the kitchen's ventilation system, and in some instances the entire building's ventilation system, are designed to operate in balance with each other, even under variable loads, to properly capture, contain, and remove cooking effluent and heat and maintain proper space temperature control in the most efficient and economical manner. Deterioration in any of these components unbalances the system, affecting one or more of its design concepts.

The ventilation system's design intent should be fully understood by the owners and operators so that any deviations in operation can be noted and corrected. *This is especially critical when a DCKV system is used.* In addition to creating health and fire hazards, normal cooking effluent deposits can also unbalance the system, so they must be regularly removed.

All components of exhaust and replacement air systems affect proper capture, containment, and removal of cooking effluent. In the exhaust system, this includes the cooking equipment itself, exhaust hood, all filtration devices, ducts, exhaust fan, and any dampers. In the replacement air system, this includes the air-handling unit(s) with intake louvers, dampers, filters, fan wheels, heating and cooling coils, ducts, and supply registers. In systems that obtain their replacement air from the general HVAC system, this also includes return air registers and ducts.

When the system is first set up and balanced in new condition, these components are set to optimum efficiency. In time, all components become dirty; filtration devices, dampers, louvers, heating and cooling coils, and ducts become restricted; fan blades change shape

as they accumulate dirt and grease; and fan belts loosen. In addition, dampers can come loose and change position, even closing, and ducts can develop leaks or be blocked if internal insulation sheets fall down.

All these changes deteriorate system performance. The operator should know how the system performed when it was new, to better recognize when it is no longer performing the same way. This knowledge allows problems to be found and corrected sooner and the peak efficiency and safety of system operation to better be maintained.

Maintenance

Maintenance may be classified as preventive or emergency (breakdown). **Preventive maintenance** keeps the system operating as close as possible to optimal performance, including maximum production and least shutdown. It is the most effective maintenance and is preferred.

Preventive maintenance can prevent most emergency shutdowns and emergency maintenance. It has a modest ongoing cost and fewer unexpected costs. Clearly the lowest-cost maintenance in the long run, it keeps the system components in peak condition, maximizes the system's energy efficiency, and extends the operating life of all components.

Emergency maintenance must be applied when a breakdown occurs. Sufficient staffing and money must be applied to the situation to bring the system back on line in the shortest possible time. Such emergencies can be of almost any nature. They are impossible to predict or address in advance, except to presume the type of component failures that could shut the system down and keep spares of these components on hand or readily accessible, so they can be quickly replaced. Preventive maintenance, which includes regular inspection of critical system components, is the most effective way to avoid emergency maintenance.

Following are brief descriptions of typical operations of various components of kitchen ventilation systems and the type of maintenance and cleaning required to bring the abnormally operating system back to normal. Many nontypical operations are not listed here. Any maintenance should include a check of the building automation system (BAS) as it relates to the kitchen ventilation system to ensure it is operating per its original design.

Cooking Equipment

Normal Operation. Produces properly cooked product, of correct temperature, within expected time. Minimum smoke during cooking.

Abnormal Operation. Produces undercooked product, of lower temperature, with longer cooking times. Increased smoke during cooking.

Cleaning/Maintenance. Clean solid cooking surfaces between each cycle if possible, or at least once a day. Baked-on product insulates and retards heat transfer. Filter frying medium daily and change it on schedule recommended by supplier. Check that (1) fuel source is at correct rating, (2) thermostats are correctly calibrated, and (3) conditioned air is not blowing on cooking surface.

Solid-fuel appliances are listed as "Extra-Heavy Duty" (see Table 2) and require additional attention. A hood over a solid-fuel appliance must be individually vented and therefore not be combined at any point with another duct and fan system. Using a UL *Standard* 762 upblast, in-line, or utility set fan listed to 400 or 500°F is suggested because the airstream temperature may be hotter without cooler air combining from other, typically lower-temperature cooking appliances. Design, installation, and maintenance precautions for the use of and emissions from solid fuel include monthly duct cleaning with weekly inspections, spark arrestors, and additional spacing to fryers. Refer to NFPA *Standard* 96, Chapters 5 to 10 and 14, and IMC, sections 507 and 906, for additional direction.

Exhaust Systems (e.g., Hoods)

Normal Operation. All cooking vapors are readily drawn into the exhaust hood, where they are captured and removed from the space. The environment immediately around the cooking operation is clear and fresh.

Abnormal Operation. Many cooking vapors do not enter the exhaust hood at all, and some that enter subsequently escape. The environment around the cooking operation, and likely in the entire kitchen, is contaminated with cooking vapors and a thin film of grease.

Cleaning/Maintenance. Clean all grease removal devices in the exhaust system. Hood filters should be cleaned at least daily. High-efficiency grease extractors may require frequent cleanings during each shift. For other devices, follow the minimum recommendations of the manufacturer; even these may not be adequate at very high flow rates or with products producing large amounts of effluent. Check that (1) all dampers are in their original position, (2) fan belts are properly tensioned, (3) the exhaust fan is operating at the proper speed and turning in the proper direction, (4) the exhaust duct is not restricted, and (5) the fan blades are clear.

NFPA *Standard 96* design requirements for access to the system should be followed to facilitate cleaning the exhaust hood, ductwork, and fan. Cleaning should be done if the combustibles' depth is greater than 0.08 in. in any part of the system, and by a method that leaves no more than a 0.002 in. depth deposit of combustibles. Cleaning agents should be thoroughly rinsed off, and all loose grease particles should be removed, because they can ignite more readily. Agents should not be added to the surface after cleaning, because their textured surfaces merely collect more grease more quickly. Fire-extinguishing systems may only be disarmed by properly trained and qualified service personnel before cleaning, to prevent accidental discharge, and then reset by authorized personnel after cleaning. All access panels removed must be reinstalled after cleaning, with proper gasketing in place to prevent grease leaks and escape of fire.

Supply, Replacement, and Return Air Systems

Normal Operation. The environment in the kitchen area is clear, fresh, comfortable, and free of drafts and excessive air noise.

Abnormal Operation. The kitchen is smoky, choking, hot, and humid, and perhaps very drafty with excessive air noise.

Cleaning/Maintenance. Check that the replacement air system is operating and is providing the correct amount of air to the space. If it is not, the exhaust system cannot operate properly. Check that dampers are set correctly, filters and exchangers are clean, the belts are tight, the fan is turning in the correct direction, and supply and return ductwork and registers are open, with supply air discharging in the correct direction and pattern. If drafts persist, the system may need to be rebalanced. If noise persists in a balanced system, system changes may be required.

Filter cleaning or changing frequency varies widely depending on the quantity of airflow and contamination of local air. Once determined, the cleaning schedule must be maintained.

With replacement air systems, the air-handling unit, coils, and fan are usually cleaned in spring and fall, at the beginning of the seasonal change. More frequent cleaning or better-quality filtering may be required in some contaminated environments. Duct cleaning for the system is on a much longer cycle, but check local codes because stricter requirements are sometimes invoked. Ventilation systems should be cleaned by professionals to ensure that none of the expensive system components are damaged. Cleaning companies should be required to carry adequate liability insurance. The Power Washers of North America (PWNA) and the International Kitchen Exhaust Cleaning Association (IKECA) provide descriptions of proper cleaning and inspection techniques and lists of their members.

2. RESIDENTIAL KITCHEN VENTILATION

Although commercial and residential cooking processes are similar, their ventilation requirements and procedures are different. Differences include exhaust airflow rate and installation height. In addition, residential kitchen ventilation is less concerned with replacement air, and energy consumption is comparatively insignificant because of lower airflow, smaller motors, and intermittent operation.

Equipment and Processes

Although the physics of cooking and the resulting effluent are about the same, residential cooking is usually done more conservatively. Heavy-duty and extra-heavy-duty equipment, such as upright broilers and solid-fuel-burning equipment (described in Table 1), is not used. Therefore, the high ventilation rates of commercial kitchen ventilation and equipment for delivering these rates are not often found in residential kitchens. However, some residential kitchens are designed to operate with commercial-type cooking equipment, with higher energy inputs rates than usually found. In these cases, the hood may be similar to a commercial hood, and the required ventilation rate may approach that required for small commercial facilities.

Cooking effluent and by-products of open-flame combustion must be more closely controlled in a residence than in a commercial kitchen, because any escaping effluent can be dispersed throughout a residence, whereas a commercial kitchen is designed to be negatively pressurized compared to surrounding spaces. A residence also has a much lower background ventilation rate, making escaped contaminant more persistent. This situation makes residential kitchen ventilation a different kind of challenge, because problems cannot be resolved by simply increasing the ventilation rate at the cooking process.

Residential cooking always produces a convective plume that carries with it cooking effluent, often including grease vapor and particles, as well as water vapor, and by-products of combustion when natural gas is the energy source. Sometimes there is spatter as well, but those particles are so large that they are not removed by ventilation. Residential kitchen hoods depend more on thermal buoyancy than mechanical exhaust to capture cooking effluent and by-products of combustion.

2.1 EXHAUST SYSTEMS

Hoods and Other Ventilation Equipment

Wall-mounted, conventional range hoods ventilate most residential kitchens. Overall, they do the best job at the lowest installed cost. There are unlimited style-based variations of the conventional range hood shape. Deep canopy hoods are somewhat more effective because of their capture volume. Other styles have less volume, or a more flat bottom, and may be somewhat less effective at capturing effluent. To the extent that residential range hoods are often mounted between cabinets, with portions of the cabinets extending below the sides of the hood, performance may be improved because the cabinet sides help contain and channel the exhaust flow into the hood.

An increasingly popular development in residential kitchen ventilation is using a ventilating microwave oven in place of the typical residential range hood. Microwave ovens used for this purpose typically include small mesh filters mounted on the bottom of the oven and an internal exhaust fan. Means are usually provided to direct the exhaust flow in two directions: back into the kitchen or upward to an exhaust duct leading outdoors. The latter is more expensive but highly preferred; otherwise, if directed back to the kitchen, walls, ceiling, and cabinet surfaces are likely to become coated with grease from condensed grease vapor, and grease residue can damage paint

and varnish. Additionally, typical microwave oven ventilators do not include vertical surfaces that provide a reservoir volume to contain the convective plume during transient effects, such as removing the lid from a cooking vessel. Consequently, microwave oven ventilators often provide lower exhaust capture and containment performance than standard range hoods.

Downdraft range-top ventilators have also become more popular. Functionally, these are an exception, because they capture contaminants by producing velocities over the cooking surface greater than those of the convective plume. With enough velocity, their operation can be satisfactory; however, velocity may be limited to prevent adverse effects such as gas flame disturbance and cooking process cooling. Additionally, this method is more effective for exhaust from cooking near the range surface, and it is usually much less effective for capturing the convective plume from taller cooking vessels, because the convective plume is too far above the ventilator intake to be affected by it.

Ironically, many high-end kitchens have less efficient ventilation than standard range hoods. Inefficient methods include

- Mounting range tops in cooking islands with no exhaust hood or other means of ventilation
- Mounting ovens in cabinets, separate from rangetops, without any way to remove heat and effluents from the oven
- Using low-profile exhaust devices with insufficient overhang over the appliance and no reservoir to contain convective plume during dynamic effects
- Having duct runs, particularly in larger homes, with very high static pressure losses, so that the actual exhaust flow rate is much lower than the nominal exhaust fan rating

Whole-kitchen exhaust fans were more common in the past, but they are still used. Mounted in the kitchen wall or ceiling, they ventilate the entire kitchen volume rather than capturing contaminants at the source. For kitchen exhaust fans not above the cooking surface, and without a capturing hood, 15 air changes per hour (ach) is recommended; for ceiling-mounted fans, this is usually sufficient, but for wall-mounted fans, it may be marginal.

Residential exhaust hoods are often furnished with multiple-speed fans, so that users can match exhaust fan speeds (and noise) with the cooking process and resultant convective plume. Carrying this concept further, there are high-end residential exhaust hood manufacturers that provide an automatic two-speed control that increases fan speed when higher convective plume temperature is sensed.

Continuous low-level, whole-building ventilation is increasingly used to ensure good indoor air quality in modern, tightly built houses with less infiltration. ASHRAE *Standard* 62.2 requires kitchen ventilation in most residences. Some whole-building ventilation systems can intermittently increase airflow to achieve the needed reduction in cooking effluent. In that case, there must be provision to avoid introducing and accumulating grease and other cooking effluent that may cause undesirable growth of microorganisms.

Differences Between Commercial and Residential Equipment

Safety requirements covering residential cooking area fans are contained in UL *Standard* 507. These fans and accessories are intended for use in conjunction with residential gas and electric cooking appliances only, and are investigated to determine the effects of increased air temperature and grease on electrical components. The filters provided as a part of the fan are also checked for flammability and smoke propagation. Products include hood fans intended to mount directly over (but not directly on) ranges, separate hoods provided with lights or other wiring and intended for use over ranges in conjunction with a remote blower, downdraft fans, and oven ventilators for use over wall-insert ovens. Fans intended for mounting directly on cooking equipment are investigated in

conjunction with the cooking appliances, and are typically listed as part of the accessory to the cooking appliance. Fans installed in close proximity to a stove, range, or oven where fumes, grease-laden air, or the like may be present and intended to discharge air away from the cooking area should be installed to discharge air to the exterior of the building and not into concealed walls or ceiling spaces or into the attic. Ductless fans intended for use in cooking areas are not required to discharge air to the building exterior.

Fire-actuated dampers are never part of the hood and are almost never used. Grease filters in residential hoods are much simpler, and grease collection channels are rarely used because inadequate maintenance could allow grease to pool, creating a fire and health hazard.

Conventional residential wall hoods usually have standard dimensions that match the standard 3 in. modular grid of residential cabinets. Heights of 6, 9, 12, and 24 in. are common, as are depths from 17 to 22 in. Width is usually the same as the cooking surface, with 30 in. width nearly standard in the United States. Current U.S. Housing and Urban Development (HUD) Manufactured Home Construction and Safety Standards call for 3 in. overhang per side.

Hood mounting height is usually 18, 24, or 30 in., and sometimes even higher with a sacrifice in collection efficiency. A lower-mounted hood captures more effectively because there is less opportunity for lateral air currents to disrupt the convective plume. Studies show 18 in. is the minimum height for cooking surface access. Some codes require a minimum of 30 in. from the cooking surface to combustible cabinets. In that case, the bottom of a 6 in. hood can be 24 in. above the cooking surface.

A minimum airflow rate (exhaust capacity) of 40 cfm per linear foot of hood width has long been recommended by the Home Ventilating Institute (HVI 2004), and confirmed by field tests. Additional capacity, with speed control, is desirable for handling unusually vigorous cooking and cooking mistakes, because airflow can be briefly increased to clear the air, and speed can be reduced to a quieter level for normal cooking.

Exhaust Duct Systems

Residential hoods offer little opportunity for custom design of an exhaust system. The range hood has a built-in duct connector and the duct should be the same size, whether round or rectangular. A hood includes either an axial or a centrifugal fan. The centrifugal fan can develop higher pressure, but the axial fan is usually adequate for low-volume hoods. The great majority of residential hoods in the United States have HVI-certified airflow performance. In all cases, it is highly preferable to vent the exhaust hood outdoors through a roof cap, rather than venting back into the home, whether into the kitchen or elsewhere.

Replacement (Makeup) Air

The exhaust rate of residential hoods is generally low enough and natural infiltration sufficient to avoid the need for replacement air systems. Although this may cause slight negative pressurization of the residence, it is brief and is usually less than that caused by other equipment. Still, backdrafts through the flue of a combustion appliance should be avoided and residences with gas furnace and water heater should have the flue checked for adequate flow. NFPA *Standard* 54 provides a method of testing flues for adequate performance. Sealed-combustion furnaces and water heaters are of less concern.

Sometimes commercial-style cooking equipment approved for residential use is installed in residences. For the higher ventilation requirements, see earlier sections of this chapter, especially the section on Replacement (Makeup) Air Systems.

Energy Conservation

The energy cost of residential hoods is quite low because of the few annual running hours and the low rate of exhaust. For example,

it typically costs less than \$10 per heating season in Chicago to run a hood and heat replacement air, based on running at 150 cfm for an hour a day and using gas heat.

Fire Protection for Residential Hoods

Residential hoods must be installed with metal (preferably steel) duct, positioned to prevent grease pooling. Residential hood exhaust ducts are almost never cleaned, and there is no evidence that this causes fires.

There have been some attempts to make fire extinguishers available in residential hoods, but none has met with broad acceptance. However, grease fires on the residential cooking surface continue to occur, almost always the result of unattended cooking. There is no industry-accepted performance standard or consistency of design in residential fire-extinguishing equipment.

Maintenance

All listed hoods and kitchen exhaust fans are designed for cleaning, which should be done at intervals consistent with the cooking practices of the user. Although cleaning is sometimes thought to be for fire prevention, the health benefits of removing nutrients available for the growth of organisms can be more important.

3. RESEARCH

Research Overview

ASHRAE Technical Committee TC 5.10, Kitchen Ventilation, has been active in research related to kitchen ventilation as shown in Table 12. This research has tended to focus on answering questions related to field-related issues, such as how to measure exhaust airflow rates for hood and replacement air systems (RP-623 and RP-1376) and how much grease is produced by cooking appliances (RP-745 and RP-1375). Some of the research focused on design aspects of kitchen ventilation systems, from optimizing exhaust hood performance (RP-1202 and RP-1480), to evaluating the grease removal efficiency of filtering devices (RP-851 and RP-1151) and reducing the velocity of airflow in the exhaust ductwork (RP-1033). Other projects evaluated relationships between appliances and ventilation systems and the HVAC system in the space (RP-1362). Although historically projects have focused on mechanical systems in the space, one recent project (RP-1469) evaluated the effect of the kitchen environment on thermal comfort in the space.

Benefits to the HVAC Industry

Many of the research projects that TC 5.10 sponsored have affected energy use and sustainability in the food service industry. RP-1033 data that showed that grease deposition on the walls of duct actually decreased when the duct velocity was lowered from 1500 fpm to 500 fpm. These data allowed both NFPA *Standard* 96 and the International Mechanical Code (ICC 2009) to allow lower duct velocities. These changes allow demand-controlled ventilation systems (in which airflow is lowered during noncooking periods of the day) to be used across the United States to achieve significant energy savings.

The two projects related to hood performance (RP-1202 and RP-1480) not only evaluated how wall canopy and island hoods perform with various appliances, but also evaluated methods of reducing the exhaust airflows required for the hoods to capture the cooking effluent more efficiently. These include items such as optimizing the appliance position underneath the hoods, installing side panels, and designing hoods to use larger overhangs if possible. If exhaust air is reduced, this also generally reduces how much conditioned air needs to be brought back into the space to replace the air that is exhausted, leading to large energy savings in restaurants. RP-1362 measured the heat gain from appliances underneath hoods, and these data can be

Table 12 Summary of TC 5.10 Research Projects

Year(s)	ASHRAE Project	Title
1993 to 1994	RP-623	A Field Test Method for Determining Exhaust Rates in Grease Hoods for Commercial Kitchens (Gordon and Parvin 1994)
1996 to 1997	RP-851	Determining the Efficiency of Grease-Removal Devices in Commercial Kitchen Applications (Schrock 1998)
1998 to 1999	RP-745	Identification and Characterization of Effluents from Various Cooking Appliances and Processes as Related to Optimum Design of Kitchen Ventilation Systems (Gerstler et al. 1998)
2000 to 2001	RP-1033	Effects of Air Velocity on Grease Deposition in Exhaust Ductwork (Kuehn 2000)
2001 to 2003	RP-1151	Development of a Draft Method of Test for Determining Grease Removal Efficiencies (Welch 2004)
2003 to 2005	RP-1202	Effect of Appliance Diversity and Position on Commercial Kitchen Hood Performance (Swierczyna et al. 2006)
2007 to 2008	RP-1375	Characterization of Effluents from Additional Cooking Appliances (Kuehn 2008)
2008 to 2009	RP-1362	Revised Heat Gain and Capture and Containment Exhaust Rates from Typical Commercial Cooking Appliances (Swierczyna 2008)
2008 to 2010	RP-1376	Method of Test to Evaluate Field Performance of Commercial Kitchen Ventilation Systems (Kuehn 2010)
2008 to 2009	RP-1480	Island Hood Energy Consumption and Energy Reduction Strategies (Swierczyna et al. 2010)
2010 to 2013	RP-1469	Thermal Comfort in Commercial Kitchens (Stoops 2013)
2013 to present	RP-1631	Countertop Commercial Appliance Emissions (Zhang [ongoing])

used to more accurately size the HVAC equipment needed to condition the kitchen space. A current project (RP-1631) related to exhaust hoods is attempting to answer the question of whether a Type I hood is needed or a Type II hood is sufficient smaller commercial countertop based on their grease and heat emissions.

Earlier projects related to grease emissions (RP-851, RP-745, and RP-1151) were used to help develop ASTM *Standard* F2519. Data from these research projects, along with *Standard* F2519 and data from RP-1375, revolutionized the kitchen ventilation industry with regard to how mechanical filters actually perform in the field. *Standard* F2519 provides a framework for making more efficient filters that help reduce the amount of grease built up in ductwork, on exhaust fans, and on the roof of buildings.

RP-623 and RP-1376 both examined how to accurately measure the exhaust and replacement air in food service establishments. By being able to more accurately measure the airflows, restaurants can be properly balanced to the design conditions so that excess energy is not consumed.

CHAPTER 34

GEOTHERMAL ENERGY

<p><i>RESOURCES</i> 34.1</p> <p><i>Fluids</i> 34.2</p> <p><i>Present Use</i> 34.3</p> <p><i>Renewability</i> 34.3</p> <p><i>DIRECT-USE SYSTEMS DESIGN</i>..... 34.3</p> <p><i>Cost Factors</i> 34.3</p> <p><i>Materials and Equipment</i>..... 34.5</p> <p><i>Residential and Commercial Building Applications</i> 34.8</p>	<p><i>Industrial Applications</i> 34.10</p> <p><i>GROUND-SOURCE HEAT PUMPS</i>..... 34.10</p> <p><i>Terminology</i>..... 34.10</p> <p><i>Ground-Coupled Heat Pump System</i></p> <p style="padding-left: 20px;"><i>Design</i>..... 34.13</p> <p><i>Groundwater Heat Pumps</i> 34.32</p> <p><i>Water Wells</i>..... 34.33</p> <p><i>Surface Water Heat Pumps</i>..... 34.38</p>
---	--

THE use of geothermal resources can be subdivided into three general categories: high-temperature (>300°F) electric power production, intermediate- and low-temperature (<300°F) direct-use applications, and ground-source heat pump applications (generally <90°F). This chapter covers only direct use (including wells, equipment, and applications) and ground-source heat pumps. Design aspects of the building heat pump loop may be found in Chapter 9 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*.

1. RESOURCES

Geothermal energy is the thermal energy in the earth's crust: thermal energy in rock and fluid (water, steam, or water containing large amounts of dissolved solids) that fills the pores and fractures in the rock, sand, and gravel. Calculations show that the earth, originating from a completely molten state, would have cooled and become completely solid many thousands of years ago without an energy input beyond that of the sun. It is believed that the ultimate source of geothermal energy is radioactive decay within the earth (Bullard 1973).

Through plate motion and vulcanism, some of this energy is concentrated at high temperature near the surface of the earth. Energy is also transferred from deeper parts of the crust to the earth's surface by conduction and by convection in regions where geological conditions and the presence of water allow.

Because of variation in volcanic activity, radioactive decay, rock conductivities, and fluid circulation, different regions have different heat flows (through the crust to the surface), as well as different temperatures at a particular depth. The normal increase of temperature with depth (i.e., the normal geothermal gradient) is about 13.7°F per 1000 ft of depth, with gradients of 5 to 27°F per 1000 ft being common. Areas that have higher temperature gradients and/or higher-than-average heat flow rates constitute the most interesting and viable economic resources. However, areas with normal gradients may be valuable resources if certain geological features are present.

Geothermal resources of the United States are categorized into the following types:

Igneous point resources are associated with magma bodies, which result from volcanic activity. These bodies heat the surrounding and overlying rock by conduction and convection, as allowed by the rock permeability and fluid content in the rock pores.

Hydrothermal convection systems are hot fluids near the earth's surface that result from deep circulation of water in areas of high regional heat flow. A widely used resource, these fluids rise from natural convection between hotter, deeper formations and cooler formations near the surface. The passageway that provides for this deep

convection must consist of adequately permeable fractures and faults.

Geopressed resources, present widely in the Gulf Coast of the United States, consist of regional occurrences of confined hot water in deep sedimentary strata, where pressures of greater than 10,000 psi are common. This resource also contains methane, which is dissolved in the geothermal fluid.

Radiogenic heat sources exist in various regions as granitic plutonic rocks that are relatively rich in uranium and thorium. These plutons have a higher heat flow than the surrounding rock; if the plutons are blanketed by sediments of low thermal conductivity, an elevated temperature at the base of the sedimentary section can result. This resource has been identified in the eastern United States.

Deep regional aquifers of commercial value can occur in deep sedimentary basins, even in areas of only normal temperature gradient. For deep aquifers to be of commercial value, (1) basins must be deep enough to provide usable temperature levels at the prevailing gradient, and (2) permeability in the aquifer must be adequate for flow.

Thermal energy in geothermal resources exists primarily in the rocks and only secondarily in the fluids that fill the pores and fractures. Thermal energy is usually extracted by bringing to the surface the hot water or steam that occurs naturally in the open spaces in the rock. Where rock permeability is low, the energy extraction rate is low. In permeable aquifers, fluid produced may be injected back into the aquifer at some distance from the production well to pass through the aquifer again and recover some of the energy in the rock. Figure 1 indicates geothermal resource areas in the United States.

Temperature

The temperature of fluids produced in the earth's crust and used for their thermal energy content varies from below 40°F to 680°F. As indicated in Figure 1, local gradients also vary with geologic conditions. The lower value represents fluids used as the low-temperature energy source for heat pumps, and the higher temperature represents an approximate value for the HGP-A well at Hilo, Hawaii.

The following classification by temperature is used in the geothermal industry:

High temperature	$t > 300^{\circ}\text{F}$
Intermediate temperature	$195^{\circ}\text{F} < t < 300^{\circ}\text{F}$
Low temperature	$t < 195^{\circ}\text{F}$

Electric generation is generally not economical for resources with temperatures below about 300°F, which is the reason for the division between high- and intermediate-temperature. However, binary (organic Rankine cycle) power plants, with the proper set of circumstances, have demonstrated that it is possible to generate electricity economically above 230°F. In 1988, there were 86 binary plants worldwide, generating a total of 126.3 MW (Di Pippo 1988).

The preparation of this chapter is assigned to TC 6.8, Geothermal Energy Utilization.

Fig. 1 U.S. Hydrothermal Resource Areas
(Lienau et al. 1995)

Geothermal resources at lower temperatures are more common. The frequency by reservoir temperature of identified convective systems above 194°F is shown in Figure 2.

1.1 FLUIDS

Geothermal energy is extracted from the earth through naturally occurring fluids in rock pores and fractures. Fluids produced are steam, hot water, or a two-phase mixture of both. These may contain various amounts of impurities, notably dissolved gases and dissolved solids.

Geothermal resources that produce essentially dry steam are **vapor-dominated**. Although these are valuable resources, they are rare. Hot-water (**fluid-dominated**) resources are much more common and can be produced either as hot water or as a two-phase mixture of steam and hot water, depending on the pressure maintained on the production well. If pressure in the production casing or in the formation around the casing is reduced below the saturation pressure at that temperature, some of the fluid will flash, and a two-phase fluid will result. If pressure is maintained above the saturation pressure, the fluid remains single-phase. In fluid-dominated resources, both dissolved gases and dissolved solids are significant.

Geothermal fluid chemistry varies over a wide range. In the Imperial valley of California, some high-temperature geothermal fluids may contain up to 300,000 ppm of **total dissolved solids (TDS)**. Fluids of this character are extremely difficult to accommodate in systems design and materials selection. In fact, most low-temperature fluids contain less than 3000 ppm and many meet drinking water standards. Despite this, even geothermal fluids of a few hundred ppm TDS can cause substantial problems with standard construction materials.

(Muffler 1979)

1.2 PRESENT USE

Discoveries of concentrated radiogenic heat sources and deep regional aquifers in areas of near-normal temperature gradient indicate that 37 states in the United States have economically exploitable direct-use geothermal resources (Interagency Geothermal Coordinating Council 1980). The Geysers, in northern California, is the largest single geothermal development in the world. The U.S. Department of Energy created a database of geothermal system data (including ground resource data) for practitioners to share data about installations (NGDS 2014).

The total electricity generated by geothermal development in the world was 7974 MW in 2000 (Lund et al. 2001). Direct application of geothermal energy for space heating and cooling, water heating, agricultural growth-related heating, and industrial processing represented about 51.6×10^9 Btu/h worldwide in 2000. In the United States in 2000, direct-use installed capacity amounted to 12.9×10^9 Btu/h, providing 19.3×10^{12} Btu/yr.

The major uses of geothermal energy in the United States are for heating greenhouse and aquaculture facilities. The principal industrial use is for food processing.

1.3 RENEWABILITY

Geothermal energy is a renewable resource (see the section on Nonrenewable and Renewable Energy Sources in Chapter 34 of the 2013 *ASHRAE Handbook—Fundamentals* for discussion). Quantification of the source may be required for renewable portfolio standards, utility programs, etc.; to do this, measure or calculate the electric or thermal energy that is either generated from, or avoided by, use of the geothermal resource.

Geothermal energy ultimately comes from a variety of sources, including earth heat and solar energy. Direct-use and higher-temperature geothermal resources may be considered renewable, because the heat removed is replaced by natural processes: heat is generated deep in the earth and transferred to more shallow depths. The geothermal resource must be carefully managed however, and can eventually be depleted if used at too high of a rate.

Geothermal heat pumps (GHPs) also use these sources (albeit in a more complex, indirect fashion) for building heating, cooling, and domestic hot water. Because this method of using geothermal energy does require electricity input, quantification of the renewable portion of GHP operation is to be based on the amount of electric and thermal energy that is avoided by use of GHPs. Attempts at quantifying this avoidance have been made (European Union 2013), but more work is needed before a more specific methodology can be published here.

2. DIRECT-USE SYSTEMS DESIGN

A major goal in designing direct-use systems is capturing the most possible heat from each gallon of fluid pumped. System owning and operating costs are composed primarily of well pumping and well capitalization components; maximizing system Δt (i.e., minimizing flow requirements) minimizes well capital cost and pump operating cost. In many cases, system design can benefit from connecting loads in series according to temperature requirements. Direct-use system design is covered in detail in Anderson and Lund (1980) and Rafferty (1989a).

Direct-use systems can be divided into four subsystems: (1) production, including the producing wellbore and associated wellhead equipment; (2) transmission and distribution to transport geothermal energy from the resource site to the user site and then distribute it to the individual user loads; (3) user system; and (4) disposal, which can be either surface disposal or injection back into a formation.

Fig. 3 Geothermal Direct-Use System with Wellhead Heat Exchanger and Injection Disposal

In a typical direct-use system, geothermal fluid is produced from the production borehole by a lineshaft multistage centrifugal pump. When the geothermal fluid reaches the surface, it is delivered to the application site through the transmission and distribution system.

In the system in Figure 3, geothermal fluid is separated from the heating system by a heat exchanger. This secondary loop is especially desirable when the geothermal fluid is particularly corrosive and/or causes scaling. The geothermal fluid is pumped directly back into the ground without loss to the surrounding surface.

2.1 COST FACTORS

The following characteristics influence the cost of energy delivered from geothermal resources:

- Well depth
- Distance between resource location and application site
- Well flow rate
- Resource temperature
- Temperature drop
- Load factor
- Composition of fluid
- Ease of disposal

Many of these characteristics have a major influence because the cost of geothermal systems is primarily front-end capital cost; annual operating cost is relatively low.

Well Depth

The cost of the wells is usually one of the larger items in the overall cost of a geothermal system, and increases with resource depth. Compared to many geothermal areas worldwide, well depth requirements in the western United States are relatively shallow; most larger geothermal systems there operate with production wells of less than 2000 ft, and many at less than 1000 ft.

Distance Between Resource Location and Application Site

Direct use of geothermal energy must occur near the resource. The reason is primarily economic; although geothermal (or secondary) fluid could be transmitted over moderately long distances (greater than 60 miles) without great temperature loss, such transmission is generally not economically feasible. Most existing geothermal projects have transmission distances of less than 1 mile.

Well Flow Rate

Energy output from a production well varies directly with the fluid flow rate. The energy cost at the wellhead varies inversely with the well flow rate. A typical good resource has a production rate of 400 to 800 gpm per production well; however, geothermal direct-use wells have been designed to produce up to 2000 gpm.

Resource Temperature

The available temperature is fixed by the prevailing resource. The temperature can restrict applications. It often requires a reevaluation of accepted application temperatures, which were developed for uses served by conventional fuels for which the application temperature could be selected at any value in a relatively broad range. Most existing direct-use projects use fluids in the 130 to 230°F range.

Temperature Drop

Because well flow is limited, power output from a geothermal well is directly proportional to the temperature drop of the geothermal fluid connected to the system. Consequently, a larger temperature drop reduces operating (pumping) and capital (well and production pump) costs.

Cascading geothermal fluid to uses with lower temperature requirements can help achieve a large temperature difference (Δt). Most geothermal systems are designed for a Δt between 30 and 50°F, although one system was designed for a Δt of 100°F with a 190°F resource temperature.

Load Factor

Defined as the ratio of the average load to the design capacity of the system, the load factor effectively reflects the fraction of time that the initial investment in the system is working. Again, because geothermal cost is primarily initial rather than operating cost, this factor significantly affects a geothermal system's viability. As the load factor increases, so does the economy of using geothermal energy. The two main ways of increasing the load factor are (1) to select applications where it is naturally high, and (2) to use peaking equipment so that the geothermal design load is not the application peak load, but rather a reduced load that occurs over a longer period.

Composition of Fluid

The quality of the produced fluid is site specific and may vary from less than 1000 ppm TDS to heavily brined. Fluid quality influences two aspects of the design: (1) material selection to avoid corrosion and scaling effects, and (2) disposal or ultimate end use of the fluid.

Ease of Disposal

The costs associated with disposal, particularly when injection is involved, can substantially affect development costs. Historically, most geothermal effluent was disposed of on the surface, including discharge to irrigation, rivers, and lakes. This method of disposal is considerably less expensive than constructing injection wells.

Geothermal fluids sometimes contain chemical constituents that make surface disposal problematic. Some of these constituents are listed in Table 1.

Most new, large geothermal systems use injection for disposal to minimize environmental concerns and ensure long-term resource reliability. If injection is chosen, the depth at which the fluid can be injected affects well cost substantially. Many jurisdictions require the fluid be returned to the same or similar aquifers; thus, it may be necessary to bore the injection well to the same depth as the production well. Direct-use injection wells are considered Class V wells under the U.S. Environmental Protection Agency's Underground

Table 1 Selected Chemical Species Affecting Fluid Disposal

Species	Reason for Control
Hydrogen sulfide (H ₂ S)	Odor
Boron (B ³⁺)	Damage to agricultural crops
Fluoride (F ⁻)	Level limited in drinking water sources
Radioactive species	Levels limited in air, water, and soil

Source: Lunis (1989).

Injection Control (UIC) program. Water wells, along with terminology relating to the technology, are discussed in the section on Groundwater Heat Pumps.

Direct-Use Water Quality Testing

Low-temperature geothermal fluids commonly contain seven key chemical species that can significantly corrode standard materials of construction (Ellis 1989). These include

- Oxygen (generally from aeration)
- Hydrogen ion (pH)
- Chloride ion
- Sulfide species
- Carbon dioxide species
- Ammonia species
- Sulfate ion

The principal effects of these species are summarized in Table 2. Except as noted, the described effects are for carbon steel. Kindle

Table 2 Principal Effects of Key Corrosive Species

Species	Principal Effects
Oxygen	<ul style="list-style-type: none"> • Extremely corrosive to carbon and low-alloy steels; 30 ppb shown to cause fourfold increase in carbon steel corrosion rate. • Concentrations above 50 ppb cause serious pitting. • In conjunction with chloride and high temperature, <100 ppb dissolved oxygen can cause chloride-stress corrosion cracking (chloride-SCC) of some austenitic stainless steels.
Hydrogen ion (pH)	<ul style="list-style-type: none"> • Primary cathodic reaction of steel corrosion in air-free brine is hydrogen ion reduction. Corrosion rate decreases sharply above pH 8. • Low pH (5) promotes sulfide stress cracking (SSC) of high-strength low-alloy (HSLA) steels and some other alloys coupled to steel. • Acid attack on cements.
Carbon dioxide species (dissolved carbon dioxide, bicarbonate ion, carbonate ion)	<ul style="list-style-type: none"> • Dissolved carbon dioxide lowers pH, increasing carbon and HSLA steel corrosion. • Dissolved carbon dioxide provides alternative proton reduction pathway, further exacerbating carbon and HSLA steel corrosion. • May exacerbate SSC. • Strong link between total alkalinity and corrosion of steel in low-temperature geothermal wells.
Hydrogen sulfide species (hydrogen sulfide, bisulfide ion, sulfide ion)	<ul style="list-style-type: none"> • Potent cathodic poison, promoting SSC of HSLA steels and some other alloys coupled to steel. • Highly corrosive to alloys containing both copper and nickel or silver in any proportions.
Ammonia species (ammonia, ammonium ion)	<ul style="list-style-type: none"> • Causes stress corrosion cracking (SCC) of some copper-based alloys.
Chloride ion	<ul style="list-style-type: none"> • Strong promoter of localized corrosion of carbon, HSLA, and stainless steel, as well as of other alloys. • Chloride-dependent threshold temperature for pitting and SCC. Different for each alloy. • Little if any effect on SSC. • Steel passivates at high temperature in 6070 ppm chloride solution (pH = 5) with carbon dioxide. 133,500 ppm chloride destroys passivity above 300°F.
Sulfate ion	<ul style="list-style-type: none"> • Primary effect is corrosion of cements.

Source: Ellis (1989).

Note: Except as indicated, described effects are for carbon steel.

and Woodruff (1981) present recommended procedures for complete chemical analysis of geothermal well water.

Two of these species are not reliably detected by standard water chemistry tests and deserve special mention. Dissolved oxygen does not occur naturally in low-temperature (120 to 220°F) geothermal fluids that contain traces of hydrogen sulfide. However, because of slow-reaction kinetics, oxygen from air inleakage may persist for some minutes. Once the geothermal fluid is produced, it is extremely difficult to prevent contamination, especially if pumps used to move the fluid are not downhole-submersible or lineshaft turbine pumps. Even if fluid systems are maintained at positive pressure, air inleakage at pump seals is likely, particularly with the low level of maintenance in many installations.

Hydrogen sulfide is ubiquitous in extremely low concentrations in geothermal fluids above 120°F. This corrosive species also occurs naturally in many cooler groundwaters. For strongly affected alloys, such as cupronickel, hydrogen sulfide concentrations in the low parts per billion (10^9) range may have a serious detrimental effect, especially if oxygen is also present. At these levels, the characteristic rotten egg odor of hydrogen sulfide may be absent, so field testing may be required for detection. Hydrogen sulfide levels down to 50 ppb can be detected using a simple field kit; however, absence of hydrogen sulfide at this low level may not preclude damage by this species.

Two other key species that should be measured in the field are pH and carbon dioxide concentrations. This is necessary because most geothermal fluids release carbon dioxide rapidly, causing a rise in pH.

Production of suspended solids (sand) from a well should be addressed during well construction with gravel pack, screen, or both. Proper selection of the screen/gravel pack is based on sieve analysis of cutting samples from drilling. Surface separation is less desirable because it requires sand to pass first through the pump, reducing its useful life.

Biological fouling is largely a phenomenon of low-temperature (<90°F) wells. The most prominent organisms are various strains (*Galionella*, *Crenothrix*) of what are commonly referred to as iron bacteria. These organisms typically inhabit water with a pH range of 6.0 to 8.0, dissolved oxygen content of less than 5 ppm, ferrous iron content of less than 0.2 ppm, and a temperature of 46 to 61°F (Hackett and Lehr 1985). Iron bacteria can be identified microscopically. The most common treatment for iron bacteria infestation is chlorination, surging, and flushing; success depends on maintaining proper pH (less than 8.5), dosage, free residual chlorine content (200 to 500 ppm), contact time (24 h minimum), and agitation or surging. Precleaning (wire brushing) of the screen and redevelopment of the well after treatment are key to effectiveness. Hackett and Lehr (1985) provide additional detail on treatment.

2.2 MATERIALS AND EQUIPMENT

For system parts exposed to the fluid, materials selection is an important part of the design process. Chemical treatment of the geothermal fluid is not an effective strategy in most cases, because of economics and environmental (disposal) considerations. Corrosion and scaling in direct-use systems are generally addressed by isolating the fluid from the majority of the system using a plate heat exchanger.

Performance of Materials

Carbon Steel. The Ryznar index has traditionally been used to estimate the corrosivity and scaling tendencies of potable water supplies. However, one study found no significant correlation (at the 95% confidence level) between carbon steel corrosion and the Ryznar index (Ellis and Smith 1983). Therefore, the Ryznar and other indices based on calcium carbonate saturation should not be

used to predict corrosion in geothermal systems, though they remain valid for scaling prediction.

In Class Va geothermal fluids [as described by Ellis (1989); <5000 ppm total key species (TKS), total alkalinity 207 to 1329 ppm as CaCO_3 , pH 6.7 to 7.6], corrosion rates of about 5 to 20 mil/yr can be expected, often with severe pitting.

In Class Vb geothermal fluids [as described by Ellis (1989); <5000 ppm TKS, total alkalinity <210 ppm as CaCO_3 , pH 7.8 to 9.85], carbon steel piping has given good service in a number of systems, as long as system design rigorously excluded oxygen. However, introduction of 30 ppb oxygen under turbulent flow conditions causes a fourfold increase in uniform corrosion. Saturation with air often increases the corrosion rate by at least 15 times. Oxygen contamination at the 50 ppb level often causes severe pitting. Chronic oxygen contamination causes rapid failure.

External surfaces of buried steel pipe must be protected from contact with groundwater. Groundwater is aerated and has caused pipe failures by external corrosion. Required external protection can be obtained by coatings, pipe-wrap, or preinsulated piping, provided the selected material resists the system operating temperature and thermal stress.

At temperatures above 135°F, galvanizing (zinc coating) does not reliably protect steel from either geothermal fluid or groundwater. Hydrogen blistering can be prevented by using void-free (killed) steels.

Low-alloy steels (steels containing not more than 4% alloying elements) have corrosion resistance similar, in most respects, to carbon steels. As with carbon steels, sulfide promotes entry of atomic hydrogen into the metal lattice. If the steel exceeds a hardness of Rockwell C22, sulfide stress cracking may occur.

Copper and Copper Alloys. Copper-tubed fan-coil units and heat exchangers have consistently poor performance because of traces of sulfide species found in geothermal fluids in the United States. Copper tubing rapidly becomes fouled with cuprous sulfide films more than 1 mm thick. Serious crevice corrosion occurs at cracks in the film, and uniform corrosion rates of 2 to 6 mil/yr appear typical, based on failure analyses.

Experience in Iceland also indicates that copper is unsatisfactory for heat exchange service and that most brasses (Cu-Zn) and bronzes (Cu-Sn) are even less suitable. Cupronickel often performs more poorly than copper in low-temperature geothermal service because of trace sulfide.

Much less information is available regarding copper and copper alloys in non-heat-transfer service. Copper pipe shows corrosion behavior similar to copper heat exchange tubes under conditions of moderate turbulence (Reynolds numbers of 40,000 to 70,000). An internal inspection of yellow brass valves showed no significant corrosion. However, silicon bronze CA 875 (12-16Cr, 3-5Si, <0.05Pb, <0.05P), an alloy normally resistant to dealloying, failed in less than three years when used as a pump impeller. Leaded red brass (CA 836 or 838) and leaded red bronze (SAE 67) appear viable as pump internal parts. Based on a few tests at Class Va sites, aluminum bronzes have shown potential for corrosion in heavy-walled components (Ellis 1989).

Solder is yet another problem area for copper equipment. Lead-tin solder (50Pb, 50Sn) was observed to fail by dealloying after a few years' exposure. Silver solder (1Ag, 7P, Cu) was completely removed from joints in under two years. If the designer elects to accept this risk, solders containing at least 70% tin should be used.

Stainless Steel. Unlike copper and cupronickel, stainless steels are not affected by traces of hydrogen sulfide. Their most likely application is heat exchange surfaces. For economic reasons, most heat exchangers are probably of the plate-and-frame type, most of which are fabricated with one of two standard alloys, Type 304 and Type 316 stainless steel. Some pump and valve trim also are fabricated from these or other stainless steels.

Fig. 4 Chloride Concentration Required to Produce Localized Corrosion of Stainless Steel as Function of Temperature
(Efrid and Moeller 1978)

These alloys are subject to pitting and crevice corrosion above a threshold chloride level, which depends on the chromium and molybdenum content of the alloy and on the temperature of the geothermal fluid. Above this temperature, the passivation film, which gives the stainless steel its corrosion resistance, is ruptured, and local pitting and crevice corrosion occur. Figure 4 shows the relationship between temperature, chloride level, and occurrence of localized corrosion of Type 304 and Type 316 stainless steel. This figure indicates, for example, that localized corrosion of Type 304 may occur in 80°F geothermal fluid if the chloride level exceeds approximately 210 ppm; Type 316 is resistant at that temperature until the chloride level reaches approximately 510 ppm. Because of its 2 to 3% molybdenum content, Type 316 is always more resistant to chlorides than is Type 304.

Aluminum. Aluminum alloys are not acceptable in most cases because of catastrophic pitting.

Titanium. This material has extremely good corrosion resistance and could be used for heat exchanger plates in any low-temperature geothermal fluid, regardless of dissolved oxygen content. Great care is required if acid cleaning is to be performed. The vendor's instructions must be followed. The titanium should not be scratched with iron or steel tools; this can cause pitting.

Chlorinated Polyvinyl Chloride (CPVC) and Fiber-Reinforced Plastic (FRP). These materials are easily fabricated and are not adversely affected by oxygen intrusion. External protection against groundwater is not required. The mechanical properties of these materials at higher temperatures may vary greatly from those at ambient temperature, and the materials' mechanical limits should not be exceeded. The usual mode of failure is creep rupture: strength decays with time. Manufacturer's directions for joining should be followed to avoid premature failure of joints.

Elastomeric Seals. Tests on O-ring materials in a low-temperature system in Texas indicated that a fluoroelastomer is the best material for piping of this nature; Buna-N is also acceptable (Ellis 1989). Neoprene, which developed extreme compression set, was a failure. Natural rubber and Buna-S should also be avoided. Ethylene-propylene terpolymer (EPDM) has been used successfully in gasket, O-ring, and valve seats in many systems. EPDM materials have swollen in some systems using oil-lubricated turbine pumps.

Pumps

Production well pumps are among the most critical components in a geothermal system and have been the source of much system

downtime. Therefore, proper selection and design of the production well pump is extremely important. Well pumps are available for larger systems in two general configurations: lineshaft and submersible. The lineshaft type is most often used for direct-use systems (Rafferty 1989b).

Lineshaft Pumps. Lineshaft pumps are similar to those typically used in irrigation applications. An aboveground driver, typically an electric motor, rotates a vertical shaft extending down the well to the pump. The shaft rotates pump impellers in the pump bowl assembly, which is positioned at such a depth in the wellbore that adequate net positive suction head pressure (NPSH) is available when the unit is operating. Two designs for the shaft/bearing portion of the pump are available: open and enclosed.

In the **open lineshaft pump**, the shaft bearings are supported in "spiders," which are anchored to the pump column pipe at 5 to 10 ft intervals. The shaft and bearings are lubricated by the fluid flowing up the pump column. In geothermal applications, bearing materials for open lineshaft designs are typically elastomer compounds. The shaft material is typically stainless steel. Experience with this design in geothermal applications has been mixed. It appears that the open lineshaft design is most successful in applications with high (<50 ft) static water levels or flowing artesian conditions. Open lineshaft pumps are generally less expensive than enclosed lineshaft pumps for the same application.

In an **enclosed lineshaft pump**, an enclosing tube protects the shaft and bearings from exposure to the pumped fluid. A lubricating fluid is admitted to the enclosed tube at the wellhead. It flows down the tube, lubricates the bearings, and exits where the column attaches to the bowl assembly. The bowl shaft and bearings are lubricated by the pumped fluid. Oil-lubricated, enclosed lineshaft pumps have the longest service life in low-temperature, direct-use applications.

These pumps typically include carbon or stainless steel shafts and bronze bearings in the lineshaft assembly, and stainless steel shafts and leaded red bronze bearings in the bowl assembly. Keyed-type impeller connections (to the pump shaft) are superior to collet-type connections (Rafferty 1989b).

Because of the lineshaft bearings, lineshaft pump reliability decreases as pump-setting depth increases. Nichols (1978) indicates that, below about 800 ft, reliability is questionable, even under good pumping conditions.

Submersible Pumps. The electrical submersible pump consists of three primary components located downhole: the pump, the drive motor, and the motor protector. The pump is a vertical multistage centrifugal type. The motor is usually a three-phase induction type that is filled with oil for cooling and lubrication; it is cooled by heat transfer to the pumped fluid moving up the well. The motor protector is located between the pump and the motor and isolates the motor from the well fluid while allowing pressure equalization between the pump intake and the motor cavity.

The electrical submersible pump has several advantages over lineshaft pumps, particularly for wells requiring greater pump bowl setting depths. The deeper the well, the greater the economic advantage of the submersible pump. Moreover, it is more versatile, adapting more easily to different depths.

Submersible pumps have not demonstrated acceptable lifetimes in most geothermal applications. Although they are commonly used in high-temperature, downhole applications in the oil and gas industry, the acceptable overhaul interval in that industry is much shorter than in a geothermal application. In addition, most submersibles operate at 3600 rpm, resulting in greater susceptibility to erosion in aquifers that produce moderate amounts of sand. They have, however, been applied in geothermal projects where an existing well of relatively small diameter must be used. At 3600 rpm, they provide greater flow capacity for a given bowl size than an equivalent 1750 rpm lineshaft pump.

Standard cold-water submersible motors can be used at temperatures up to approximately 120°F with adequate precautions. These

consist primarily of ensuring adequate water velocity past the motor (minimum 3 ft/s), which may require the use of a sleeve, and a small degree of motor oversizing (Franklin Electric 2001).

Well Pump Control. Well pumps serving variable loads are often controlled using variable-speed drives (VSDs). Submersible pumps can also be controlled using VSDs, but special precautions are required. Drive-rated motors are not commonly available for these applications, so external electronic protection should be used to prevent premature motor failure. In addition, the motor manufacturer must be aware that the motor will be applied in a variable-speed application. Finally, because of the large static head in many well pump applications, controls should be configured to prevent the pump from operating at no-flow conditions.

Heat Exchangers

Geothermal fluids can be isolated with large central heat exchangers, as in the case of a district heating system, or with exchangers at individual buildings or loads. In both cases, the principle is to isolate the geothermal fluid from complicated systems or those that cannot readily be designed to be compatible with the geothermal fluid. The main types of heat exchangers used in transferring energy from the geothermal fluid are plate and downhole.

Plate Heat Exchangers. For all but the very smallest applications, plate-and-frame heat exchangers are the most commonly used design. Available in corrosion-resistant materials, easily cleanable, and able to accommodate increased loads by adding plates, these exchangers are well suited to geothermal applications. Their high performance is also an asset in many system designs. Because geothermal resource temperatures are often less than those used in conventional hot-water heating system design, minimizing temperature loss at the heat exchanger is frequently a design issue. Approach temperatures of 5°F and less are common.

Materials for plate heat exchangers in direct-use applications normally include Buna-N or EPDM gaskets and 316 or titanium plates. Plate selection is often a function of temperature and chloride content of the water. For applications characterized by chloride contents of >50 ppm at 200°F, titanium would be used. At lower temperatures, much higher chloride exposure can be tolerated (see Figure 4).

Downhole Heat Exchangers. The downhole heat exchanger (DHE) is an arrangement of pipes or tubes suspended in a wellbore (Culver and Reistad 1978). A secondary fluid circulates from the load through the exchanger and back to the load in a closed loop. The primary advantage of a DHE is that only heat is extracted from the earth, which eliminates the need to dispose of spent fluids. Other advantages are the elimination of (1) well pumps with their initial operating and maintenance costs, (2) the potential for depletion of groundwater, and (3) environmental and institutional restrictions on surface disposal. One disadvantage of a DHE is the limited amount of heat that can be extracted from or rejected to the well. The amount of heat extracted depends on the hydraulic conductivity of the aquifer and well design. Because of the limitations of natural convection, only about 10% of the heat output of the well is available from a DHE in comparison to pumping and using surface heat exchange (Reistad et al. 1979). With wells of approximately 200°F and depths of 500 ft, output under favorable conditions is sufficient to serve the needs of up to five homes.

The DHE in low- to moderate-temperature geothermal wells is installed in a casing, as shown in Figure 5.

Downhole heat exchangers with higher outputs rely on water circulation within the well, whereas lower-output DHEs rely on earth conduction. Circulation in the well can be accomplished by two methods: (1) undersized casing and (2) convection tube. Both methods rely on the difference in density between the water surrounding the DHE and that in the aquifer.

Circulation provides the following advantages:

Fig. 5 Typical Connection of Downhole Heat Exchanger for Space and Domestic Hot-Water Heating

(Reistad et al. 1979)

- Water circulates around the DHE at velocities that, in optimum conditions, can approach those in the shell of a shell-and-tube exchanger.
- Hot water moving up the annulus heats the upper rocks and the well becomes nearly isothermal.
- Some of the cool water, being denser than the water in the aquifer, sinks into the aquifer and is replaced by hotter water, which flows up the annulus.

Figure 5 shows well construction in competent formation (i.e., where the wellbore will stand open without a casing). An undersized casing with perforations at the lowest producing zone (usually near the bottom) and just below the static water level is installed. A packer near the top of the competent formation allows installation of an annular seal between it and the surface. When the DHE is installed and heat extracted, thermosiphoning causes cooler water inside the casing to move to the bottom, and hotter water moves up the annulus outside the casing.

Because most DHEs are used for space heating (an intermittent operation), heated rocks in the upper portion of the well store heat for the next cycle.

Where the well will not stand open without casing, a convection tube can be used. This is a pipe one-half the diameter of the casing either hung with its lower end above the well bottom and its upper end below the surface or set on the bottom with perforations at the bottom and below the static water level. If a U-bend DHE is used, it can be either inside or outside the convection tube. DHEs operate best in aquifers with a high hydraulic conductivity and that provide water movement for heat and mass transfer.

Valves

In large (>2.5 in.) pipe sizes, resilient-lined butterfly valves are preferred for geothermal applications. The lining material protects the valve body from exposure to the geothermal fluid. The rotary rather than reciprocating motion of the stem makes the valve less susceptible to leakage and build-up of scale deposits. For many direct-use applications, these valves are composed of Buna-N or EPDM seats, stainless steel shafts, and bronze or stainless steel disks. Where oil-lubricated well pumps are used, a seat material of

oil-resistant material is recommended. Gate valves have been used in some larger geothermal systems but have been subject to stem leakage and seizure. After several years of use, they are no longer capable of 100% shutoff.

Piping

Piping in geothermal systems can be divided into two broad groups: pipes used inside buildings and those used outside, typically buried. Indoor piping carrying geothermal water is usually limited to the mechanical room. Carbon steel with grooved end joining is the most common material.

For buried piping, many existing systems use some form of non-metallic piping, particularly asbestos cement (which is no longer available) and glass fiber. With the cost of glass fiber for larger sizes (>6 in.) sometimes prohibitive, ductile iron is frequently used. Available in sizes >2 in., ductile iron offers several positive characteristics: low cost, familiarity to installation crews, and wide availability. It requires no allowances for thermal expansion if push-on fittings are used.

Most larger-diameter buried piping is preinsulated. The basic ductile iron pipe is surrounded by a layer of insulation (typically polyurethane), which is protected by an outer jacket of PVC or high-density polyethylene (HDPE).

Standard ductile iron used for municipal water systems is sometimes modified for geothermal use. The seal coat used to protect the cement lining of the pipe is not suitable for the temperature of most geothermal applications; in applications where the geothermal water is especially soft or low in pH, the cement lining should be omitted, as well. Special high-temperature gaskets (usually EPDM) are used in geothermal applications. Few problems have been encountered in using ferrous piping with low-temperature geothermal fluids unless high chloride concentration, low (<7.0) pH, or oxygen is present in the fluid. Most cases of corrosion failure have resulted from external attack by soil moisture in buried applications. For more information on piping systems for these applications, refer to Chapter 12 in the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* and to ASHRAE (2013a, 2013b).

2.3 RESIDENTIAL AND COMMERCIAL BUILDING APPLICATIONS

The primary applications for direct use of geothermal energy in the residential and commercial area are space and domestic water heating. Space cooling using the absorption process is possible but rarely applied.

Space Heating

Figure 6 illustrates a system that uses geothermal fluid at 170°F (Austin 1978). The geothermal fluid is used in two main equipment components for heating the buildings: (1) a plate heat exchanger that supplies energy to a closed heating loop previously heated by a natural gas boiler (the boiler remains as a standby unit) and (2) a water-to-air coil used for preheating ventilation air. In this system, proper control is crucial for economical operation.

The average temperature of discharged fluid is 120 to 130°F. Geothermal fluid is used directly in the preheat coils in the buildings, which would probably not be the case if the system were designed today (Lienau 1979).

Figure 7 shows a geothermal district heating system that has a unique feature: its design is based on a peak load Δt of 100°F using a 190°F resource. It is of closed-loop design with central heat exchangers. The production well has an artesian shut-in pressure of 25 psi, so the system operates with no production pump for most of the year. During colder weather, a surface centrifugal pump located at the wellhead boosts the pressure.

Geothermal flow from the production well is initially controlled by a throttling valve on the supply line to the main heat exchanger, which responds to a temperature signal from the supply water on the closed-loop side of the heat exchanger. When the throttling valve reaches the full-open position, the production booster pump is enabled. The pump is controlled through a variable-speed drive that responds to the same supply-water signal as the throttling valve. The booster pump is designed for a peak flow rate of 300 gpm of 190°F water.

A few district heating systems have also been installed using an open distribution system. In this design, central heat exchangers (as in Figure 7) are eliminated and the geothermal water is delivered to individual building heat exchangers. When more than a few buildings are connected to the system, using central heat exchangers is normally more cost-effective.

Terminal equipment used in geothermal systems is the same as that used in nongeothermal heating systems. However, certain types of equipment are better suited to geothermal design than others.

In many cases, buildings heated by low-temperature geothermal sources operate at lower supply water temperatures than conventional hydronic designs. Because many geothermal sources are designed to take advantage of a large Δt , proper selection of equipment for low flow and low temperature is important.

Finned-coil, forced-air systems generally function best in this low-temperature/high- Δt situation. One or two additional rows of coil depth compensate for the lower supply water temperature. Although an increased Δt affects coil circuiting, it improves controllability. This type of system should be able to use a supply water temperature as low as 110°F.

Radiant floor panels are well suited to very low water temperatures, particularly in industrial applications with little or no floor covering. In industrial settings, with a bare floor and a relatively low space-temperature requirement, the average water temperature could be as low as 95°F. For a higher space temperature and/or thick floor coverings, a higher water temperature may be required.

Baseboard convectors and similar equipment are the least capable of operating at low supply-water temperature. At 150°F average water temperatures, derating factors for this design load may be affected. This type of equipment can be operated at low temperatures from the geothermal source to provide base-load heating, with peak load supplied by a conventional boiler. Ensure the boiler does not supply a higher fraction of the load than intended by the designer.

Domestic Water Heating

Domestic water heating in a district space-heating system is beneficial because it increases the overall size of the energy load,

Fig. 6 Heating System Schematic

Fig. 7 Closed Geothermal District Heating System
(Rafferty 1989a)

energy demand density, and load factor. For those resources that cannot heat water to the required temperature, preheating is usually possible. Whenever possible, the domestic hot-water load should be placed in series with the space-heating load to reduce system flow rates and increase Δt .

Space Cooling

Geothermal energy has seldom been used for cooling, although emphasis on solar energy and waste heat has created interest in cooling with thermal energy. The absorption cycle is most often used, and lithium bromide/water absorption machines are available in a wide range of capacities. Temperature and flow requirements for absorption chillers run counter to the general design philosophy for geothermal systems: they require high supply water temperatures and a small Δt on the hot-water side. Figure 8 illustrates the effect of reduced supply water temperature on machine performance. The machine is rated at a 240°F input temperature, so derating factors must be applied if the machine is operated below this temperature. For example, operation at a 200°F supply water temperature results in a 50% decrease in capacity, which seriously affects the economics of absorption cooling at a low resource temperature.

Coefficient of performance (COP) is less seriously affected by reduced supply water temperature. The nominal COP of a single-stage machine at 240°F is 0.65 to 0.70; that is, for each ton of cooling output, a heat input of 12,000 Btu/h divided by 0.65, or 18,460 Btu/h, is required.

Most absorption equipment is designed for steam input (an isothermal process) to the generator section. When this equipment is operated from a hot-water source, a relatively small Δt must be used. This creates a mismatch between building flow requirements for space heating and cooling. For example, assume a 200,000 ft²

Fig. 8 Typical Lithium Bromide Absorption Chiller Performance Versus Temperature
(Christen 1977)

building is to use a geothermal resource for heating and cooling. At 25 Btu/h·ft² and a design Δt of 40°F, the flow requirement for heating is 250 gpm. At 30 Btu/h·ft², a Δt of 15°F, and a COP of 0.65, the flow requirement for cooling is 1230 gpm.

Some small-capacity (3 to 25 ton) absorption equipment has been optimized for low-temperature operation in conjunction with solar heat. Although this equipment could be applied to geothermal

resources, the prospects are questionable. Small absorption equipment generally competes with packaged direct-expansion units in this range; absorption equipment requires a great deal more mechanical auxiliary equipment for a given capacity. The cost of the chilled-water piping, pump, and coil; cooling-water piping, pump, and tower; and hot-water piping raises the capital cost of the absorption equipment substantially. Only in large sizes (>10 tons) and in areas with high electric rates and high cooling requirements (>2000 full-load hours) would this type of equipment offer an attractive investment to the owner (Rafferty 1989a).

2.4 INDUSTRIAL APPLICATIONS

Design philosophy for the use of geothermal energy in industrial applications, including agricultural facilities, is similar to that for space conditioning. However, these applications have the potential for much more economical use of the geothermal resource, primarily because they (1) operate year-round, which gives them greater load factors than possible with space-conditioning applications; (2) do not require extensive (and expensive) distribution to dispersed energy consumers, as is common in district heating; and (3) often require various temperatures and, consequently, may be able to make greater use of a particular resource than space conditioning, which is restricted to a specific temperature. In the United States, the primary non-space-heating applications of direct-use geothermal resources are dehydration (primarily vegetables), gold mining, and aquaculture.

3. GROUND-SOURCE HEAT PUMPS

Ground-source heat pumps were originally developed in the residential arena and are now widely applied in the commercial sector. Many of the installation recommendations and design guides appropriate to residential design must be amended for large buildings. Kavanaugh and Rafferty (1997) provide a more complete overview of design of ground-source heat pump systems. Kavanaugh (1991) and OSU (1988a, 1988b) provide a more detailed treatment of the design and installation of ground-source heat pumps, but their focus is primarily residential and light commercial applications. Comprehensive coverage of commercial and institutional design and construction of ground-source heat pump systems is provided in *CSA Standard C448*.

3.1 TERMINOLOGY

The term **ground-source heat pump (GSHP)** is applied to a variety of systems that use the ground, groundwater, or surface water as a heat source and sink. The general terms include **ground-coupled (GCHP)**, **groundwater (GWHP)**, and **surface-water (SWHP) heat pumps**. Many parallel terms exist [e.g., **geothermal heat pumps (GHP)**, **geo-exchange**, and **ground-source (GS) systems**] and are used to meet a variety of marketing or institutional needs (Kavanaugh 1992). See Chapter 9 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for a discussion of the merits of various other nongeothermal heat sources/sinks.

This chapter focuses primarily on the ground heat exchanger portion of GSHP systems, although the heat pump units used in these systems are unique to GSHP technology as well. GSHP systems typically use extended-range water-source heat pump units, in most cases of water-to-air configuration. Extended-range units are specifically designed for operation at entering water temperatures between 23°F in heating mode and 104°F in cooling mode. Units not meeting the extended-range criteria are not suitable for use in GSHP systems (except for some groundwater heat pump systems). Some applications can include a free-cooling mode when water-loop temperatures fall near or below 55°F. This includes groundwater loops, deep-surface-water loops, and interior core zones of ground-coupled loops when perimeter zones require heating. This is

typically accomplished by inserting a water coil in the return air stream before the refrigerant coil.

Ground-Coupled Heat Pump Systems

The GCHP is a subset of the GSHP and is often called a closed-loop heat pump. A GCHP system consists of a reversible vapor compression cycle that is linked to a closed ground heat exchanger (also called a ground loop) buried in soil (Figure 9). The most widely used unit is a water-to-air heat pump, which circulates a water or a water/antifreeze solution through a liquid-to-refrigerant heat exchanger and a buried thermoplastic piping network. Heat pump units often include desuperheater heat exchangers (shown on the left in Figure 9). These devices use hot refrigerant at the compressor outlet to heat water. A second type of GCHP is the direct-expansion (DX) GCHP, which uses a buried copper piping network through which refrigerant is circulated.

The GCHP is further subdivided according to ground heat exchanger design: vertical and horizontal. **Vertical GCHPs** (Figure 10) generally consist of two small-diameter, high-density polyethylene (HDPE) tubes placed in a vertical borehole that is subsequently filled with a solid medium. The tubes are thermally fused at the bottom of the bore to a close return U-bend. Vertical tubes range from 0.75 to 1.5 in. nominal diameter. Bore depths normally range from 50 to 400 ft depending on local drilling conditions and available equipment, but can go to 600 ft or more if procedures for deep boreholes are followed (see the section on Pump and Piping System Options). Boreholes are typically 4 to 6 in. in diameter.

To reduce thermal interference between individual bores, a minimum borehole separation distance of 20 ft is recommended when loops are placed in a grid pattern. This distance may be reduced when bores are placed in a single row, the annual ground load is balanced (i.e., energy released in the ground is approximately equal to the energy extracted on an annual basis), or water movement or evaporation and subsequent recharge mitigates the effect of heat build-up in the loop field.

Advantages of the vertical GCHP are that it (1) requires relatively small plots of ground, (2) is in contact with soil that varies very little in temperature and thermal properties, (3) requires the smallest amount of pipe and pumping energy, and (4) can yield the most efficient GCHP system performance. Disadvantages are (1) typically higher cost because of expensive equipment needed to

Fig. 9 Vertical Closed-Loop Ground-Coupled Heat Pump System
(Kavanaugh 1985)

drill the borehole and (2) the limited availability of contractors to perform such work.

Hybrid systems are a variation of ground-coupled systems in which a smaller ground heat exchanger is used, augmented in cooling mode by a fluid cooler or a cooling tower. This approach can have merit in large cooling-dominated applications. The ground heat exchanger is sized to meet the heating requirements. The downsized loop is used in conjunction with the fluid cooler or cooling tower with an isolation heat exchanger to meet the heat rejection load. Using the cooler reduces the capital cost of the ground heat exchanger in such applications, but somewhat increases maintenance requirements. For heavily heating-dominant applications, a downsized loop also can be augmented with an auxiliary heat source such as electric resistance, solar collectors, or fossil fuel.

Horizontal GCHPs (Figure 11) can be divided into several sub-groups, including single-pipe, multiple-pipe, spiral, and horizontally bored. Single-pipe horizontal GCHPs were initially placed in narrow trenches at least 4 ft deep. These designs require the greatest amount of ground area. Multiple pipes (usually two, four, or six), placed in a single trench, can reduce the amount of required ground area. Trench length is reduced with multiple-pipe GCHPs, but total pipe length must be increased to overcome thermal interference from adjacent pipes. The spiral coil is reported to further reduce required ground area. These horizontal ground heat exchangers are made by stretching small-diameter polyethylene tubing from the tight coil in which it is shipped into an extended coil that can be placed vertically in a narrow trench or laid flat at the bottom of a wide trench. Recommended trench lengths are much shorter than those of single-pipe horizontal GCHPs, but pipe lengths must be much longer to achieve equivalent thermal performance. When horizontally bored loops are grouted and placed in the deep earth, as shown in the bottom of Figure 11, design lengths are near those for vertical systems, because annual temperature and moisture content variations approach deep-earth values.

Advantages of horizontal GCHPs are that (1) they are typically less expensive than vertical GCHPs because relatively low-cost installation equipment is widely available, (2) many residential

applications have adequate ground area, and (3) trained equipment operators are more widely available. Disadvantages include, in addition to a larger ground area requirement, (1) greater adverse variations in performance because ground temperatures and thermal properties fluctuate with season, rainfall, and burial depth; (2) slightly higher pumping-energy requirements; and (3) lower system efficiencies. OSU (1988a, 1988b), Remund and Carda (2014), and Svec (1990) cover the design and installation of horizontal GCHPs.

Groundwater Heat Pump Systems

The second subset of GSHPs is groundwater heat pumps (Figure 12). Until the development of GCHPs, they were the most widely used type of GSHP. In the commercial sector, GWHPs can be an attractive alternative because large quantities of water can be delivered from and returned to relatively inexpensive wells that require very little ground area. Whereas the cost per unit capacity of the ground heat exchanger is relatively constant for GCHPs, the cost per unit capacity of a well water system is much lower for a large GWHP system. A single pair of high-volume wells can serve an entire building. Properly designed groundwater loops with correctly developed water wells require no more maintenance than conventional air and water central HVAC. When groundwater is injected back into the aquifer by a second well, net water use is zero.

One widely used design places a central water-to-water heat exchanger between the groundwater and a closed water loop, which is connected to water-to-air heat pumps in the building. A second possibility is to circulate groundwater through a heat recovery chiller (isolated with a heat exchanger), and to heat and cool the building with a distributed hydronic loop.

Fig. 10 Vertical Ground-Coupled Heat Pump Piping

Note: If frost line is greater than 3 ft below grade, average depth of coils should be a minimum of 2 ft below frost line and upper pipe should be a minimum of 1 ft below frost line.

Fig. 11 Trenched Horizontal (top) and Horizontally Bored (bottom) Ground-Coupled Heat Pump Piping

Fig. 12 Unitary Groundwater Heat Pump System

Both types and other variations may be suited for direct preconditioning in much of the United States. Groundwater below 60°F can be circulated directly through hydronic coils in series or in parallel with heat pumps. The cool groundwater can displace a large amount of energy that would otherwise have to be generated by mechanical refrigeration.

Advantages of GWHPs under suitable conditions are (1) they cost less than GCHP equipment, (2) the space required for the water well is very compact, (3) water well contractors are widely available, and (4) the technology has been used for decades in some of the largest commercial systems.

Disadvantages are that (1) local environmental regulations may be restrictive, (2) water availability may be limited, (3) fouling precautions may be necessary if groundwater is used directly in the heat pumps and water quality is poor, and (4) pumping energy may be high if the system is poorly designed or draws from a deep aquifer.

Surface Water Heat Pump Systems

Surface water heat pumps are included as a subset of GSHPs because of the similarities in applications and installation methods. SWHPs can be either closed-loop systems similar to GCHPs or open-loop systems similar to GWHPs. However, the thermal characteristics of surface water bodies are quite different than those of the ground or groundwater. Some unique applications are possible, though special precautions may be warranted.

Closed-loop SWHPs (Figures 13 and 34) consist of water-to-air or water-to-water heat pumps connected to a piping network (also called a surface water loop) placed in a lake, river, or other open body of water. A pump circulates water or a water/antifreeze solution through the heat pump water-to-refrigerant heat exchanger and the submerged piping loop, which transfers heat to or from the body of water. The recommended piping material is thermally fused HDPE tubing with ultraviolet (UV) radiation protection.

Advantages of closed-loop SWHPs are (1) relatively low cost (compared to GCHPs) because of reduced excavation costs, (2) low pumping-energy requirements, (3) low maintenance requirements, and (4) low operating cost. Disadvantages are (1) the possibility of coil damage in public lakes and (2) wide variation in

Fig. 13 Lake Loop Piping

water temperature with outdoor conditions if lakes are small and/or shallow. Such variation in water temperature would cause undesirable variations in efficiency and capacity, though not as severe as with air-source heat pumps.

Open-loop SWHPs can use surface water bodies the way cooling towers are used, but without the need for fan energy or frequent maintenance. In warm climates, lakes can also serve as heat sources during winter heating mode, but in colder climates where water temperatures drop below 45°F, closed-loop systems are the only viable option for heating.

Lake water can be pumped directly to water-to-air or water-to-water heat pumps through an intermediate heat exchanger that is connected to the units with a closed piping loop. Direct systems tend to be smaller, having only a few heat pumps. In deep lakes (40 ft or more), there is often enough thermal stratification throughout the year that direct cooling or precooling is possible. Water can be pumped from the bottom of deep lakes through a coil in the return air duct. Total cooling is possible if water is 50°F or below. Precooling is possible with warmer water, which can then be circulated through the heat pump units. Large-scale cooling-only systems have been deployed successfully in some locations, including Cornell University and the city of Toronto [Cornell University 2006; Enwave (no date)].

Site Characterization

Site characteristics influence the type of GSHP system most suitable for a particular location. Site characterization is the evaluation of a site's geology and hydrogeology with respect to its effect on GSHP system design. Important issues include presence or absence of water, depth to water, water (or soil/rock) temperature, groundwater quality, depth to rock, rock type, and the nature and thickness of unconsolidated materials overlying the rock. Information about the nature of water resources at the site helps to determine whether an open-loop system may be possible. Depth to water affects pumping energy for an open-loop system and possibly the type of rig used for drilling closed-loop boreholes. Groundwater temperature in most locations is the same as the undisturbed ground temperature. These temperatures are key inputs to the design of GSHP systems. The types of soil and rock allow a preliminary evaluation of the range of thermal conductivity/diffusivity that might be expected. The thickness and nature of the unconsolidated (soil, gravel, sand, clay, etc.) materials overlying the rock influence whether casing is required in the upper portion of boreholes for closed-loop systems, a factor which increases drilling cost.

After the GSHP system type has been decided, specific details about the subsurface materials' (rock/soil) thermal conductivity and diffusivity, water well static and pumping levels, drawdown, etc., are necessary to design the system. Ways to obtain these more detailed data are discussed in other parts of this chapter.

There are many sources for gathering site characterization information, such as geologic and hydrologic maps, state geology and water regulatory agencies, the U.S. Geological Survey (USGS 2000), and any information that may be available from geotechnical studies of the site. Among the best sources of information are completion reports for nearby water wells. These reports are filed by the driller upon completion of a water well and provide a great deal of information of interest for both open- and closed-loop designs. The most thorough versions of well completion reports (level of detail varies by state) cover all of the issues of interest listed at the beginning of this section. Information about access to and interpretation of these reports and other sources of information for site characterization is included in Rafferty (2000a) and Sachs (2002).

Once the type of system has been selected, more site-specific tests (ground thermal properties test for GCHP or well flow test for GWHP) can be used to determine the parameters necessary for system design. In many areas, ground heat exchangers are regulated by the state or other jurisdictions and under the jurisdiction of a state water rights authority, department of natural resources or environmental quality, or possibly a federal agency such as the U.S. Army Corps of Engineers. The regulation scope may include any type of ground-coupled system. The engineer or designer should be aware of and versed in regulatory issues affecting the project site. More recently, the U.S. Department of Homeland Security has required that certain activities, especially those close to drinking water sources, be excluded or stringently regulated. For security reasons, resource protection zones may not be found in public records archives. The simplest solution may be to contact the permitting authority.

Commissioning GSHP Systems

The design phase of GSHP commissioning requires a thorough site survey and characterization, accurate load modeling, and ensuring that the design chosen (and its documentation) meets the design intent.

The construction phase is dominated by observation of installation and verification of prefunctional checks and tests. It also involves planning, training development, and other activities to help future building operators understand the HVAC system.

The acceptance phase starts with functional tests and verification of all test results. It continues with full documentation: completing the commission report to include records of design changes and all as-built plans and documents, and completing the operations and maintenance manual and system manual. Finally, after system testing and balancing is complete, the owner's operating staff are trained. The acceptance phase ends when "substantial completion" is reached. The warranty period begins from this date.

Table 3 provides information on tasks and participants involved in the GSHP commissioning process. Additional details on this topic, along with preventive maintenance and troubleshooting information, are included in Caneta Research (2001).

3.2 GROUND-COUPLED HEAT PUMP SYSTEM DESIGN

Ground-coupled heat pumps use a thermoplastic heat exchanger to transfer heat to/from the ground. This section discusses how to design components of such a system, including options for different configurations.

Table 3 Example of GSHP Commissioning Process for Mechanical Design

System	Function	Performed By	Witnessed By

Vertical Design

This section provides an overview of a suggested design procedure for vertical, ground-coupled systems; related information and equations are discussed in more detail in Kavanaugh and Rafferty (1997). Several public software programs are available for performing the repetitive computations necessary for system optimization. Shonder et al. (1999, 2000) tested the accuracy of these programs, and agreement was attained with several programs in subsequent evaluations.

A more recent publication (Kavanaugh 2008) updates the design recommendations for GCHP systems as follows:

1. Calculate peak zone cooling and heating loads, and estimate off-peak loads.
2. Estimate annual heat rejection into and absorption from the ground heat exchanger to account for potential ground temperature change (see Tables 7 and 8).
3. Select preliminary loop operating temperatures and flow rate to begin optimization of first cost and efficiency (selecting temperatures near normal ground temperature results in high efficiencies but larger and more costly ground heat exchangers).
4. Correct heat pump performance at rated conditions to actual design conditions (see Table 14).
5. Select heat pumps to meet cooling and heating loads, and locate units to ensure accessibility for maintenance and to minimize duct cost and fan power and noise.
6. Arrange heat pump into ground heat exchanger circuits to minimize system cost, pump energy and electrical demand (see Figures 20 to 22).
7. Conduct site survey to determine ground thermal properties and drilling conditions (see following recommendations).
8. Determine and evaluate possible loop field arrangements that are likely to be optimum for the building and site (bore depth,

separation distance, completion methods, annulus grout/fill, and header arrangements); include subheader circuits (typically 5 to 15 U-tubes on each) with isolation valves to allow air and debris flushing of sections of loop field through a set of full-port purge valves.

9. Determine optimum ground heat exchanger dimensions with Equations (4) and (5) or software; one or more alternatives (depth, number of bores, grout/fill material, etc.) that provide equivalent performance may yield more competitive bids.
10. Iterate to determine optimum operating temperatures, flows, loop field arrangement, depth, bores, grout/fill materials, etc.
11. Lay out interior piping and compute head loss through critical path.
12. Select pumps and control method, determine system efficiency, and consider modifying water distribution system if pump demand exceeds 8% of the system total demand or air distribution system if fan demand exceeds 12% of the system total.

Deliverables from this process that are necessary to adequately describe a GCHP installation include, as a minimum,

- Heat pump specifications at rated conditions
- Pump(s) specifications, expansion tank size, and air separator
- Fluid specifications: system volume, inhibitors, antifreeze concentration (if required), water quality, etc.
- Design operating conditions: entering and leaving ground heat exchanger temperatures, return air temperatures (including wet bulb in cooling), airflow rates, and liquid flow rates
- Pipe header details with ground heat exchanger layout, including pipe diameters, spacing, and clearance from building and utilities
- Bore depth and approximate bore diameter
- Piping material specifications, and visual inspection and pressure testing requirements
- Grout/fill specifications: thermal conductivity and acceptable placement methods to eliminate voids
- Purge provisions and flow requirements to ensure removal of air and debris without reinjecting air when switching to adjacent sub-header circuits
- Instructions on connecting to building loop(s) and coordinating building and ground heat exchanger flushing
- If applicable, a drilling report from the thermal properties test borehole that includes the type of equipment used (rig, bit, etc.), drilling fluid (air, foam, drilling mud), depth of hole, description of drilled soil or rock, time needed to drill the borehole, any special conditions encountered.
- Sequence of operation for controls

Thermal Property Testing. In the design of vertical GCHPs, accurate knowledge of soil/rock formation thermal properties is critical. These properties can be estimated in the field by installing a loop of approximately the same size and depth as the heat exchangers planned for the site. The test loop location should be chosen with care, and designed to be used for the eventual full borefield, especially if geothermal is a likely final system choice (this may require the test loop to meet all local ground heat exchanger standards). Heat is added in a water loop at a constant rate, and data are collected as shown in Figure 14. Inverse methods are applied to find thermal conductivity, diffusivity, and temperature of the formation. These methods are based on the either the line source (Gehlin 1998; Mogensen 1983; Witte et al. 2002), the cylindrical heat source (Ingersoll and Zobel 1954), or a numerical algorithm (Austin et al. 2000; Shonder and Beck 1999; Spitler et al. 1999). More than one of these methods should be applied, when possible, to enhance reported accuracy. Recommended test specifications are as follows (Kavanaugh 2000, 2001):

- Thermal property tests should be performed for 36 to 48 h.
- Heat rate should be 15 to 25 W/ft of bore, which are the expected peak loads on the U-tubes for an actual heat pump system.

Fig. 14 Thermal Properties Test Apparatus

- Standard deviation of input power should be less than $\pm 1.5\%$ of the average value and peaks less than $\pm 10\%$ of average, or resulting temperature variation should be less than $\pm 0.5^\circ\text{F}$ from a straight trend line of a log (time) versus average loop temperature.
- Accuracy of temperature measurement and recording devices should be $\pm 0.5^\circ\text{F}$.
- Combined accuracy of the power transducer and recording device should be $\pm 2\%$ of the reading.
- Flow rates should be sufficient to provide a differential loop temperature of 6 to 12°F . This is the temperature differential for an actual heat pump system.
- A waiting period of five days is suggested for low-conductivity soils ($k < 1.0 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}$) after the ground heat exchanger has been installed and grouted (or filled) before the thermal conductivity test is initiated. A delay of three days is recommended for higher-conductivity formations ($k > 1.0 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}$).
- The initial ground temperature measurement should be made at the end of the waiting period by directly inserting a probe inside a liquid-filled ground heat exchanger at three locations, representing the average, or by temperature measurement as liquid exits the loop during the period immediately after start-up.
- Data collection should be at least once every 10 min.
- All aboveground piping should be insulated with a minimum of 0.5 in. closed-cell insulation or equivalent. Test rigs should be enclosed in a sealed cabinet that is insulated with a minimum of 1.0 in. fiberglass insulation or equivalent.
- If retesting a bore is necessary, loop temperature should be allowed to return to within 0.5°F of the pretest initial ground temperature. This typically requires a 10 to 12 day delay in mid- to high-conductivity formations and 14 days in low-conductivity formations if a complete 48 h test has been conducted. Waiting periods can be proportionally reduced if tests were shorter.

Ground Heat Exchanger Sizing. This is perhaps the most critical step in design of a vertical GCHP. Ground-loop design methods must proceed with limited information; a major missing component is long-term, field-monitored data, which are needed to further validate the design method to address effects of water movement and long-term heat storage more fully. The conservative designer can assume no benefit from water movement; designers who assume maximum benefit must ignore annual imbalances in heat rejection and absorption.

Two design methods are presented in the following section. Both methods have been implemented in design software tools,

and are based on the assumption that heat transfer in the ground is governed by conduction only. The first method is based on the solution of the equation for heat transfer from a cylinder buried in the earth. This equation was developed and evaluated by Carlsaw and Jaeger (1947) and was suggested by Ingersoll and Zobel (1954) as an appropriate method of sizing ground heat exchangers. Kavanaugh (1985) adjusted the method to account for the U-bend arrangement and hourly heat rate variations. Alternative design methods are described by Eskilson (1987), Morrison (1997), Philippe et al. (2010), Spitler (2000), and Spitler et al. (2000). A second method, attributed to Eskilson, is presented after this first method.

Vertical Ground Heat Exchanger Sizing. The method of Ingersoll and Zobel (1954), based on the following steady-state heat transfer equation, can be used to size vertical ground heat exchangers:

$$q = \frac{L(t_g - t_w)}{R_{ov}} \quad (1)$$

where

- q = heat transfer rate, Btu/h
- L = required bore length, ft
- t_g = ground temperature, °F
- t_w = liquid temperature, °F
- R_{ov} = overall resistance of ground and bore, ft·h·°F/Btu

The heat rate delivered to the ground in the cooling mode by the condenser includes the heat of the heat pump and auxiliary equipment. Thus, q_{cond} can be calculated to be

$$q_{cond}/q_{lc} = \frac{EER + 3.412}{EER} \quad (2)$$

where

- q_{cond} = heat pump condenser heat rejection rate to ground, Btu/h
- q_{lc} = building design cooling block load, Btu/h
- q_{lh} = building design heating block load, Btu/h

However, the heat of the heat pump and auxiliary equipment in the heating mode is delivered to the building. Thus the heat removed from the ground by the evaporator is

$$q_{evap}/q_{lh} = \frac{COP - 1}{COP} \quad (3)$$

where q_{evap} is the heat pump evaporator heat extraction rate from ground, and q_{lh} is the building design heating block load, both of which are in Btu/h.

The equation is rearranged to solve for the required bore length L . The steady-state equation is modified to represent the variable heat rate of a ground heat exchanger by using a series of constant-heat-rate “pulses.” Thermal resistance of the ground per unit length is calculated as a function of time corresponding to the time span over which a particular heat pulse occurs. The term R_b is also included to account for thermal resistance of the borehole, which includes the thermal resistance of the pipe wall and interfaces between the pipe and fluid and the pipe and the ground. The resulting equation takes the following form for required length to satisfy cooling loads:

$$L_c = \frac{q_a R_{ga} + (q_{lc} - 3.41 W_c)(R_b + PLF_m R_{gm} + R_{gd} F_{sc})}{t_g - \frac{t_{wi} + t_{wo}}{2} - t_p} \quad (4)$$

The required length for heating is

$$L_h = \frac{q_a R_{ga} + (q_{lh} - 3.41 W_h)(R_b + PLF_m R_{gm} + R_{gd} F_{sc})}{t_g - \frac{t_{wi} + t_{wo}}{2} - t_p} \quad (5)$$

where

- F_{sc} = short-circuit heat loss factor
- L_c = required bore length for cooling, ft
- L_h = required bore length for heating, ft
- PLF_m = part-load factor during design month
- q_a = net annual average heat transfer to ground, Btu/h
- R_{ga} = effective thermal resistance of ground (annual pulse), ft·h·°F/Btu
- R_{gst} = effective thermal resistance of ground (peak short term) 1 to 6 hours recommended, ft·h·°F/Btu
- R_{gd} = effective thermal resistance of ground (peak daily pulse: 1 h minimum, 4 to 6 h recommended), ft·h·°F/Btu
- R_{gm} = effective thermal resistance of ground (monthly pulse), ft·h·°F/Btu
- R_b = thermal resistance of bore, ft·h·°F/Btu
- t_g = undisturbed ground temperature, °F
- t_p = temperature penalty for interference of adjacent bores, °F
- t_{wi} = liquid temperature at heat pump inlet, °F
- t_{wo} = liquid temperature at heat pump outlet, °F
- W_c = system power input at design cooling load, W
- W_h = system power input at design heating load, W

Note: Heat transfer rate, building loads, and temperature penalties are positive for heating and negative for cooling.

Equations (4) and (5) consider three different pulses of heat to account for long-term heat imbalances, average monthly heat rates during the design month, and maximum heat rates for a short-term period during a design day. This period could be as short as 1 h, but a 4 to 6 h block is recommended.

The required total bore length is the larger of the two lengths L_c and L_h calculated with Equations (4) and (5). If L_c is larger than L_h , an oversized coil could be beneficial during the heating season. A second option is to install the smaller heating length along with a cooling tower to compensate for the undersized coil (see the section on Hybrid System Design). If L_h is larger, the designer should install this length, and during cooling mode the efficiency benefits of an oversized ground coil could be used to compensate for the higher first cost.

Thermal resistance of the ground is calculated from ground properties, pipe dimensions, and operating periods of the representative heat rate pulses. Table 4 lists typical thermal properties for soils and fills for the annular region of the boreholes. Type of fill material depends on thermal, regulatory, and economic considerations. Historically, a relatively low-thermal-conductivity bentonite grout common in the water well industry had been used. More recently, thermally enhanced materials have been developed to supplement or replace conventional grouts. In some cases, drill cuttings or a manufactured sand/gravel mix have been placed instead. Note that placing such fill material from the surface may cause the borehole to bridge, leaving voids or ungrouted sections of the borehole, so using a tremie pipe to inject fill from the bottom upward is recommended. Additionally, using any pumped grout in a formation with large voids, karst, or caverns can also result in voids through grout settling or flowing out of the borehole. Nutter et al. (2001) contains a detailed evaluation of potential fills and grouts for vertical boreholes. Also, Jenkins (2009), Sachs (2002), and Skouby (2011) have additional recommendations regarding grout and grout placement.

Table 5 summarizes potential completion methods for various geological conditions. “Two-fill” refers to the practice of placing a low-permeability material in the upper portion of the hole and/or in intervals where it is required to separate individual aquifers, and a more thermally advantageous material in the remaining intervals.

The thermal resistance of the ground heat exchanger vertical bore considers the effects of pipe resistance R_p and bore annulus grout resistance R_{grt}

$$R_b = R_p + R_{grt} \quad (6)$$

Pipe resistance includes the convective film resistance of the fluid and the conductive resistance of the pipe walls. Contact resistances are negligible compared to the high resistance of plastic pipe walls and annular grouts. For a single U-tube (two tubes) the pipe resistance is

$$R_p = (R_{film} + R_{tube})/2 = [1/(\pi d_o h_{conv}) + \ln(d_o/d_i)/2\pi k_p]/2 \quad (7)$$

where h_{conv} is the convection coefficient inside the pipes and k_p is pipe thermal conductivity.

A correlation for the grout's thermal resistance has been developed using shape factor correlations (Remund 1999):

$$R_{grt} = \left[\beta_0 \left(\frac{d_b}{d_o} \right)^{\beta_1} \times k_{grt} \right]^{-1} \quad (8)$$

where k_{grt} is grout thermal conductivity. Coefficients β_0 and β_1 in Equation (8) have been developed for three locations of the tubes, as shown in Figure 15: centered in the bore and in contact each other (A), centered and spaced evenly in the bore (B), and centered and in contact with the bore wall (C). However, the most likely location of the U-tubes is BC, and coefficients for this location are unavailable. A similar but slightly more detailed solution has been developed by Hellström (1991) and applied to a few design and simulation tools (Liu 2008; Philippe et. al. 2010).

Because locations of U-tubes cannot be determined even when spacers are installed, exact computation of bore resistance values is somewhat uncertain. It is possible to apply the results from thermal property tests to calculate the bore resistance if the U-tube dimensions, grout conductivity and borehole diameter are known (Kavanaugh 2010). Thermal property tests were conducted at 15 installations where these values were known and the bore resistance was calculated. The field calculated bore resistances best matched the values computed with Equations (6) to (8) using

- Location C at 4 (27%) of the sites
- An average of location B and location C at 5 (33%) of the sites
- Location B at 5 (33%) of the sites, and
- Location A at 1 (7%) site

Table 6 provides the bore resistances computed using Equations (6) to (8) for three different grout conductivities, three different fluid

flow regimes (laminar, transition, and fully turbulent), three different U-tubes sizes, and three different bore diameters for location B, and location C. The resistance is also computed a double U-tube in a bore. These values were calculated with a value of k_p equal to 0.24 Btu/h·ft·°F. Designers can choose to use the values of location B (conservative), BC (average), C (risky), or Double.

The most difficult parameters to evaluate in Equations (4) and (5) are the equivalent thermal resistances of the ground. The solutions of Carslaw and Jaeger (1947) require that the time of operation, bore diameter, and thermal diffusivity of the ground be related in the dimensionless Fourier number (Fo):

Table 4 Thermal Properties of Selected Soils, Rocks, and Bore Grouts/Fills

	Dry Density,* lb/ft ³	Conductivity,* Btu/h·ft·°F	Diffusivity, ft ² /day
Soils			
Heavy clay, 15% water	120	0.8 to 1.1	0.45 to 0.65
5% water	120	0.6 to 0.8	0.5 to 0.65
Light clay, 15% water	80	0.4 to 0.6	0.35 to 0.5
5% water	80	0.3 to 0.5	0.35 to 0.6
Heavy sand, 15% water	120	1.6 to 2.2	0.9 to 1.2
5% water	120	1.2 to 1.9	1.0 to 1.5
Light sand, 15% water	80	0.6 to 1.2	0.5 to 1.0
5% water	80	0.5 to 1.1	0.6 to 1.3
Rocks			
Granite	165	1.3 to 2.1	0.9 to 1.4
Limestone	150 to 175	1.4 to 2.2	0.9 to 1.4
Sandstone		1.2 to 2.0	0.7 to 1.2
Shale, wet	160 to 170	0.8 to 1.4	0.7 to 0.9
dry		0.6 to 1.2	0.6 to 0.8
Grouts/Backfills			
		Liquid* Density, lb/ft³	Conductivity,* Btu/h·ft·°F
Bentonite (20 to 30% solids)		9.32 to 9.81	0.42 to 0.43
20% bentonite/80% SiO ₂ sand		11.27 to 13.51	0.57 to 0.95
15% bentonite/85% SiO ₂ sand		14.07 to 14.39	1.0 to 1.1
10% bentonite/90% SiO ₂ sand		14.39 to 14.93	1.0 to 1.2
Low-density bentonite/graphite (plus additives)*		10.0 to 12.0	0.79 to 1.60
Neat cement (not recommended)		10.40 to 14.80	0.88 to 1.60
30% concrete/70% SiO ₂ sand (plus plasticizer)		13.80 to 16.00	0.40 to 0.45

*Intermediate densities and thermal conductivities can be obtained by mixing silica sand and graphite in different proportions. Contact the grout manufacturer for additional information on the thermal properties and density of the various grout silica sand/graphite mixtures.

Table 5 Summary of Potential Completion Methods for Different Geological Regime Types

Geological Regime Type	Grout			Backfill with Cutting	Two-Fill with	
	0.4 < k ≤ 0.8 Btu/h·ft·°F	0.8 < k ≤ 1.2 Btu/h·ft·°F	k > 1.2 Btu/h·ft·°F		Cuttings Below Aquifers	Other* Below Aquifers

$$Fo = \frac{4\alpha_g \tau}{d_b^2} \tag{9}$$

where

- α_g = thermal diffusivity of the ground, ft²/day
- τ = time of operation, days
- d_b = bore diameter, ft

The method may be modified to permit calculation of equivalent thermal resistances for varying heat pulses. A system can be modeled by three heat pulses: a 10 year (3650 day) pulse of q_a , a 1 month (30 day) pulse of q_m , and a 4 h (0.167 day) pulse of q_{st} . Three times are defined as

- $\tau_1 = 3650$ days
- $\tau_2 = 3650 + 30 = 3680$ days
- $\tau_f = 3650 + 30 + 0.167 = 3680.167$ days

The Fourier number is then computed with the following values:

$$Fo_f = 4\alpha\tau_f/d_b^2$$

$$Fo_1 = 4\alpha(\tau_f - \tau_1)/d_b^2$$

$$Fo_2 = 4\alpha(\tau_f - \tau_2)/d_b^2$$

An intermediate step in computing the ground's thermal resistance using the methods of Ingersoll and Zobel (1954) is to identify a G-factor, which is then determined from Figure 16 for each Fourier value. [The algorithm proposed by Cooper (1976) provides an alternative to the use of Figure 15.]

$$R_{ga} = (G_f - G_1)/k_g \tag{10}$$

$$R_{gm} = (G_1 - G_2)/k_g \tag{11}$$

$$R_{gst} = G_2/k_g \tag{12}$$

Correlations for the values of R_{ga} , R_{gm} , and R_{gst} were presented by Philippe et al. (2010) for a wide range of conditions.

Ranges of the ground thermal conductivity k_g are given in Table 6. State geological surveys are a good source of soil and rock data.

Fig. 15 Coefficients for Equation (8)

However, geotechnical site surveys are highly recommended to determine load soil, rock types, and drilling conditions.

Performance degrades somewhat because of short-circuiting heat losses between the upward- and downward-flowing legs of a conventional U-bend loop. This degradation can be accounted for by introducing the short-circuit heat loss factor [F_{sc} in Equations (4) and (5)] in the following table. Normally U-tubes are piped in parallel to the supply and return headers. Occasionally, when bore depths are shallow, two or three loops can be piped in series. In these cases, short-circuit heat loss is reduced; thus, the values for F_{sc} are smaller than that for a single bore piped in parallel.

Bores per Loop	F_{sc}	
	2 gpm/ton	3 gpm/ton
1	1.06	1.04
2	1.03	1.02
3	1.02	1.01

Fig. 16 Fourier/G-Factor Graph for Ground Thermal Resistance
(Kavanaugh and Rafferty 1997)

The remaining terms in Equations (4) and (5) are temperatures. The local deep-ground temperature t_g can best be obtained from local water well logs and geological surveys. A second, less accurate source is a temperature contour map, similar to Figure 17, prepared by state geological surveys. A third source, which can yield ground temperatures within 4°F, is a map with contours, such as Figure 18. Comparison of Figures 17 and 18 indicates the complex variations that would not be accounted for without detailed contour maps.

Selecting the temperature t_{wi} of water entering the unit is critical in the design process. Choosing a value close to ground temperature results in higher system efficiency, but makes the required ground coil length very long and thus unreasonably expensive. Choosing a value far from t_g allows selection of a small, inexpensive ground coil, but the system's heat pumps will have both greatly reduced capacity and increased electric demand. Selecting t_{wi} to be 20 to 30°F higher than t_g in cooling and 10 to 20°F lower than t_g in heating is a good compromise between first cost and efficiency in many regions of the United States.

A final temperature to consider is the temperature penalty t_p resulting from thermal interferences from adjacent bores. The designer must select a reasonable separation distance to minimize required land area without causing large increases in the required bore length (L_c, L_h). Table 7 presents the temperature penalty for a 10 by 10 vertical grid of bores for various operating conditions after 10 years of operation in a nonporous soil where cooling effects from moisture evaporation or water movement do not mitigate temperature change (Kavanaugh 2003; Kavanaugh and Rafferty 1997). Correction factors are included to find the temperature penalty for four other grid patterns. Note that the higher the number of internal bores, the larger the correction factor.

Fig. 17 Water and Ground Temperatures in Alabama at 50 to 100 ft Depth
(Chandler 1987)

In the table, adjustments are made to the number of equivalent full-load hours (EFLHs) in cooling and heating that correspond to values consistent with the local ground temperature. To mitigate long-term heat build-up for small separation distances, the required heat exchanger length is extended to maintain good system efficiencies. Larger separation distances result in shorter required lengths and smaller temperature changes, because there is greater thermal capacity available and greater area to diffuse heat to the far field.

The table applies only to a limited number of specific cases and is not intended for application to actual designs. It is intended to demonstrate trends for various ground temperatures, hours of operation in heating and cooling, and bore separation distances. Note that values of t_p in the table are significantly different from those obtained using the approach presented by Bernier et al. (2008).

Smaller bore lengths per ton of peak block load result in larger temperature changes; the relationship between bore length and temperature change is inverse and linear.

Table 7 applies only to a limited number of specific cases and is not intended for application to actual designs. It is intended to demonstrate trends for various ground temperatures, hours of operation in heating and cooling, and bore separation distances. Note that values of t_p in the table are significantly different from those obtained using the approach presented by Bernier et al. (2008). Values represent worst-case scenarios, and the temperature change is usually mitigated by groundwater recharge (vertical flow), groundwater movement (horizontal flow), and evaporation (and condensation) of water in the soil.

Groundwater movement strongly affects the long-term temperature change in a densely packed bore field (Chiasson et al. 2000a). A related factor is the evaporative cooling effect experienced with heat addition to the ground. Although thermal conductivity is

Table 7 Long-Term Temperature Penalty for Worst-Case Nonporous Formations for 10 × 10 grid and 100 ton Load

EFLH _c , h/yr	EFLH _h , h/yr	EER, Btu/W·h	COP	T _g , °F	Bore		T _p , °F

1500	0	Not recommended without fluid cooler or cooling tower assist					

Note:
 $k_g = 1.4 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$, $k_{grout} = 0.85 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$, rated EER/COP = 20.0/4.2 (GLHP).

Correction Factors for Other Grid Patterns:

1 × 10 grid	2 × 10 grid	5 × 5 grid	20 × 20 grid
C _f = 0.36	C _f = 0.45	C _f = 0.75	C _f = 1.14

somewhat reduced with lower moisture content (see Table 5), the net effect is beneficial in porous soils when water movement recharges the ground to original moisture levels. A similar effect may be experienced in cold climates when soil moisture freezes and the heat of solidification mitigates excessive temperature decline. Because these effects have not been thoroughly studied, the design engineer must establish a range of design lengths between one based on minimal groundwater movement, as in very tight clay soils with poor percolation rates, and a second based on the higher rates characteristic of porous aquifers.

Kavanaugh and Kavanaugh (2012) examined ground heat exchanger performance in 40 commercial buildings with vertical ground heat exchangers and between 5 and 25 years of operation. They calculated maximum approach temperature (difference between average loop temperatures t_{wi} and t_{wo} and initial ground temperature t_g) for all of the buildings; higher approach temperatures as years of operation increased would indicate an increase in ground temperature and raise concern about the expected life of ground heat exchangers with imbalanced cooling loads compared to heating loads.

In fact, the data suggested that older GSHP systems had lower approach temperatures. Results were not adjusted for many important factors such as vertical bore length, ground thermal properties, and vertical bore separation distance. Newer systems tended to have slightly shorter ground heat exchangers, but this was offset somewhat by the older systems' tendency to have smaller vertical bore separation distances and lower conductivity grout and fill. Of the loops with the largest approach, three of the newer systems had vertical bore lengths less than 120 ft/ton. Two systems with long loops but large approach temperatures had low thermal conductivity grout (0.38 Btu/h·ft·°F), 15 ft bore separation, and indoor air temperatures below 70°F.

The study's data set is small, and significant long-term temperature change cannot be excluded at this point. Although much more

Fig. 18 Approximate Groundwater Temperature (°C) in the Continental United States

field study is desirable, the absence of any significant trend of increased ground temperature (noted by elevation of maximum approach temperature) with increased years of GSHP operation suggests that long-term ground temperature change is not prevalent in properly designed GSHPs.

Results from this project cannot be applied to long-term temperature decline in which the amount of heat removed from the ground in heating far exceeds the heat rejected in cooling. In cold climates the heat capacity available at the freeze point of water is significant but the impact on grout thermal and physical properties also needs further field study.

The long-term temperature change table and a commonly used software for GCHP system design both use EFLH calculations. To the extent that annual loads are proportional to peak loads, the equivalent full-load hours method provides a simple estimate of

annual loads from peak loads. The EFLHs in Table 8 provide a quick means to estimate annual loads needed to size ground heat exchangers at the initial feasibility study phase of a project. Because EFLHs vary with changes in both annual loads and peak loads, not all building parameters effects are included in EFLHs. For instance, building operating hours change annual loads by increasing the amount of time that internal gains are at elevated levels, but they do not change the peak load. Occupancy hours can add load without increasing the installed capacity, thereby changing the EFLHs. Furthermore, changes in other parameters, such as internal gains, do not necessarily scale with system capacity in the same proportion as annual load, again leading to changing EFLHs. Potential users of EFLHs must understand these sources of variability to use them effectively (Carlson 2001).

Notes: 1. The ranges in values are from internal gains at 0.6 and 2.5 W/ft².

2. Operating with large temperature setbacks during unoccupied periods (effectively turning off the system) reduces heating EFLHs by 20% and cooling EFLHs by 5%.

Equations relating EFLH to Heating and Cooling Degree Days allowing calculation of EFLH for locations other than those listed here can be found in Carlson (2001).

Example 1. Size a vertical ground-coupled heat pump system for a six-zone classroom addition in Atlanta, GA. The addition has a peak cooling (block) load q_{lc} of 247,000 Btu/h and a peak heating (block) load q_{lh} of 160,000 Btu/h. The design monthly part-load factor PLF_m is 0.28.

Ground temperature $t_g = 65^\circ\text{F}$

Ground conductivity k_g and diffusivity $\alpha_g = 1.4 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}$, $1.0 \text{ ft}^2/\text{day}$

Bore fill conductivity $k_b = 1.0 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}$

Vertical U-tube = 1.0 in. nominal, DR11, HDPE, 5 in. borehole diameter

2×10 grid (20 vertical bores) with 20 ft separation

Heat pump inlet and outlet temperatures t_{wi} and $t_{wo} = 85$ and 95°F

Heat pump cooling and heating efficiency (EER, COP) = 14.9 Btu/Wh, 4.4

10 year (3650 day), 1 month (30 day), and 4 h (0.167 day) heat pulse analysis:

$EFLH_c = 760 \text{ h}$, $EFLH_h = 245 \text{ h}$ (Table 8, Average Atlanta values for school)

$$q_{cond} = q_{lc} \times \frac{EER + 3.412}{EER} = -247,000 \text{ Btu/h} \times \frac{14.9 + 3.412}{14.9} = -303,600 \text{ Btu/h}$$

$$q_{evap} = q_{lh} \times \frac{COP - 1}{COP} = 160,000 \text{ Btu/h} \times \frac{4.4 - 1}{4.4} = 123,600 \text{ Btu/h}$$

$$q_a = \frac{q_{cond} \times EFLH_c + q_{evap} \times EFLH_h}{8760 \text{ h}} = \frac{-303,600 \text{ Btu/h} \times 760 \text{ h} + 123,600 \text{ Btu/h} \times 245 \text{ h}}{8760 \text{ h}} = -22,900 \text{ Btu/h}$$

$$Fo_f = 4 \times 1.0 \text{ ft}^2/\text{day} \times 3680.167 \text{ days} \div (5 \text{ in.} \div 12 \text{ in./ft.})^2 = 84,800; \text{ from Figure 16, } G_f = 0.96$$

$$Fo_1 = 4 \times 1.0 \text{ ft}^2/\text{day} \times (3680.167 - 3650) \div (5 \text{ in.} \div 12 \text{ in./ft.})^2 = 695; \text{ from Figure 16, } G_1 = 0.58$$

$$Fo_2 = 4 \times 1.0 \text{ ft}^2/\text{day} \times (3680.167 - 3680) \div (5 \text{ in.} \div 12 \text{ in./ft.})^2 = 3.85; \text{ from Figure 16, } G_2 = 0.21$$

$$R_{ga} = (0.96 - 0.58) \div 1.4 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F} = 0.271 \text{ h}\cdot\text{ft}\cdot^\circ\text{F}/\text{Btu}$$

$$R_{gm} = (0.58 - 0.21) \div 1.4 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F} = 0.264 \text{ h}\cdot\text{ft}\cdot^\circ\text{F}/\text{Btu}$$

$$R_{gst} = 0.21 \div 1.4 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F} = 0.15 \text{ h}\cdot\text{ft}\cdot^\circ\text{F}/\text{Btu}$$

$R_b = 0.185 \text{ h}\cdot\text{ft}\cdot^\circ\text{F}/\text{Btu}$ (average of Locations B and C, $k_{grou} = 1.0 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}$, transition flow).

The required total bore length, assuming no long-term ground temperature change ($t_p = 0$) caused by moisture evaporation and subsequent groundwater recharge is

$$L_c = \frac{(-22,900 \times 0.271) - 303,600 \times (0.185 + 0.28 \times 0.264 + 1.04 \times 0.15)}{65^\circ\text{F} - \frac{85^\circ\text{F} + 95^\circ\text{F}}{2} - 0}$$

$$= 5290 \text{ ft} = 5290 \text{ ft} \div 20 \text{ bores} = 265 \text{ ft/bore}$$

For nonporous soils, a 2×10 grid on 20 ft bore centers with $EFLH_c = 1000 \text{ h}$ and $EFLH_h = 500 \text{ h}$ (i.e., the example building operates 515 h more in cooling than in heating), the temperature penalty from Table 7 is

$$t_p = C_f(2 \times 10 \text{ grid}) \times t_{pp}(10 \times 10 \text{ grid}) = 0.45 \times 3.8 = 1.7^\circ\text{F}$$

$$L_c = \frac{(-22,900 \times 0.271) - 303,600 \times (0.185 + 0.28 \times 0.264 + 1.04 \times 0.15)}{65^\circ\text{F} - \frac{85^\circ\text{F} + 95^\circ\text{F}}{2} - 1.7}$$

$$= 5169.8 \text{ ft} = 5169.8 \text{ ft} \div 20 \text{ bores} = 259 \text{ ft/bore}$$

Repeat the process using Equation (5) to find the bore length for heating L_h . The design bore length is the larger value of L_c and L_h .

Alternative Sizing Method. The preceding traditional design method has several advantages. For instance, the effective ground

Fig. 19 Typical g -Function Curves for 3×2 Bore Field

thermal resistances R_{ga} , R_{gm} , and R_{gst} and the temperature penalty t_p are assumed to be independent of borehole length. This implies that the design length can be determined by solving a relatively simple equation. In contrast, the following method, used in some software design tools, is more complex and involves an iterative process to evaluate the design length.

Thermal response factors, also known as **g -functions** (not to be confused with the G -factor) may be used as an alternative to calculate the ground thermal resistance required in Equations (4) and (5). The concept was first introduced by Eskilson (1987) and extended to short-time steps by Yavuzturk and Spitler (1999). The g -functions give a relation between the heat extracted (or rejected) from the ground per unit borehole length q_L and the borehole wall temperature T_b . The borehole wall temperature is given by

$$T_b = T_g - \frac{q_L}{2\pi k_g} \cdot g(t/t_s, r_b/H, B/H) \tag{13}$$

where g represents the g -function. As shown in Equation (13), which depend on three non-dimensional parameters: B/H , the ratio of the borehole spacing over the borehole length; r_b/H , the ratio of the borehole radius over the borehole length; and t/t_s , a nondimensional time where t_s is a characteristic time ($= H^2/9\alpha_g$). Typical g -functions curves are presented in Figure 19 for a 3×2 bore field.

The g -function curves are presented graphically in Figure 19 as a function of $\ln(t/t_s)$ for six bore field spacings (B/H) and for a value of $r_b/H = 0.0005$. The curve for $B/H = \infty$ corresponds to the g -function of a single borehole. One of the major advantages of these nondimensional curves is that they apply to any 3×2 bore field.

Eskilson (1987) provides g -function curves for a number of bore field geometries. Design software tools that use the g -function concept have a relatively large data set of g -function curves to choose from. Eskilson (1987) calculated g -functions using two-dimensional transient finite-difference equations on a radial-axial coordinate system for a single borehole in homogeneous ground. The temperature fields from a single borehole were superimposed in space to obtain the response from a borehole field with a certain configuration.

Example 2. Boreholes in a 3×2 bore field have the following characteristics: $r_b = 2 \text{ in.}$, $H = 328 \text{ ft}$, and $B = 16.4 \text{ ft}$. The undisturbed ground temperature is 59°F , the thermal conductivity is $0.87 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}$, and the thermal diffusivity is $1.04 \text{ ft}^2/\text{day}$. What is the resulting borehole wall

temperature after 10 years of heat extraction at an average rate of 5.2 Btu/h per foot of bore?

Evaluation of the three non-dimensional parameters lead to: $r_b/H = 0.0005$, $B/H = 0.05$, $t_s = 31.5$ years and $\ln(t/t_s) = -1.15$. According to Figure 19, the resulting g -function is 12.3. Using Equation (13), the borehole wall temperature is then equal to 47.3°F.

The g -functions can be used to determine the design length of a bore field. One possible approach is to use Equations (4) and (5) but with two modifications. First, when g -functions are used, thermal interference among boreholes is implicitly accounted for and t_p can be eliminated. Second, the values of R_{ga} , R_{gm} , and R_{gst} are now based on g -functions. Hence, Equations (10) to (12) take the following forms:

$$R_{ga} = \frac{g(t_f) - g(t_f - t_1)}{2\pi k_g} \quad (14)$$

$$R_{gm} = \frac{g(t_f - t_1) - g(t_f - t_2)}{2\pi k_g} \quad (15)$$

$$R_{gst} = \frac{g(t_f - t_2)}{2\pi k_g} \quad (16)$$

where $g(t_s - t_s)$ is the g -function evaluated at $\ln[(t_x - t_s)/t_s]$ for a given bore field and B/H ratio. Note that determining L (i.e., $n_b \times H$, where n_b is the number of boreholes) is an iterative process because R_{ga} , R_{gm} , and R_{gst} depend on H , which is unknown beforehand. Thus, software tools are often required to accomplish this task. Because g -functions account for 3D heat transfer in the borefield, they are considered to be more accurate than the G -factors, which derive from a radial-only heat transfer model.

Example 3. A building has a cooling block load of 15 tons with a corresponding value of $q_{cond} = -225,200$ Btu/h. The annual ground imbalance $q_a = -10,236$ Btu/h, $PLF_m = 0.30$, and $F_{SC} = 1.0$. The 3×2 bore field has the following characteristics: $r_b = 2$ in., $B = 16.4$ ft, and $R_b = 0.173$ h·ft·°F/Btu. The undisturbed ground temperature is 50°F, the thermal conductivity is 1.93 Btu/h·ft·°F, and the thermal diffusivity is 1.04 ft²/day $\times 10^{-6}$. Calculate the equivalent thermal resistances R_{ga} , R_{gm} , and R_{gst} for three consecutive heat pulses of 10 years, 1 month, and 6 hours and the total required length if the maximum mean fluid temperature in the borehole is to be kept below 95°F.

From the problem statement, $t_f = 3680.25$ days, $t_2 = 3680$ days, and $t_1 = 3650$ days. After iterations, this leads to $g(t_f) = 12.34$, $g(t_f - t_1) = 3.99$, and $g(t_f - t_2) = 1.55$; and $R_{ga} = 0.689$ h·ft·°F/Btu, $R_{gm} = 0.201$ h·ft·°F/Btu, and $R_{gst} = 0.128$ h·ft·°F/Btu; and

$$L_c = \frac{-10,236 \times 0.689 - 225,200(0.173 + 0.3 \times 0.201 + 0.128)}{50 - 95} = 1965 \text{ ft}$$

Thus, 321 ft per bore is required with a borehole spacing of 16.4 ft. This represents a length of 131 ft per ton.

Simulation of Ground Heat Exchangers

After the design length has been determined, it is often necessary to evaluate the outlet fluid temperature of a bore field as a function of time, generally on an hourly basis, and estimate the annual heat pump energy consumption. Energy simulation can be used to compute this temperature (they can also be used iteratively to assist in sizing the ground heat exchanger). Some energy simulation programs use the duct ground storage (DST) model introduced by Hellström (1989) to evaluate the outlet fluid temperature of a bore field as a function of time. Yavuzturk and Spitler (1999) describe the calculation method behind the DST model.

The DST model calculates the transient thermal process in densely packed borehole fields. The boreholes are assumed to be evenly distributed within a cylindrical storage region in the ground. Although the DST model was originally intended to simulate borehole thermal energy storage (BTES) systems, it has been used to simulate ground source heat pump systems.

Other energy simulation programs have a g -function-based routine to evaluate the outlet fluid temperature of a bore field as a function of time (Fisher et al. 2006; Liu 2008). The following analysis is intended to give only the salient features of an hourly simulation based on g -functions. As an example, assuming that $F_{SC} = 1$ and that the borehole length and the inlet fluid temperature are known, and that the heat transfer rates for three consecutive time intervals (0 to t_1 , t_1 to t_2 , and t_2 to t_3) are given by Q_1 , Q_2 , and Q_3 , then, using temporal superposition, the mean fluid temperature at the end of the third time interval is given by

$$T_m = T_g - \left[\frac{Q_1[g(t_3 - 0) - g(t_3 - t_1)] + Q_2[g(t_3 - t_1) - g(t_3 - t_2)] + Q_3 g(t_3 - t_2)}{2\pi k_g L} + \frac{Q_3 R_b}{L} \right] \quad (17)$$

with $T_m = (T_{wi} + T_{wo})/2$.

Based on the work of Yavuzturk and Spitler (1999), Equation (17) can be generalized for n time steps as follows:

$$T_m = T_g - \sum_{i=1}^n \frac{(Q_i - Q_{i-1})}{2\pi k_g L} g\left(\frac{t_n - t_{i-1}}{t_s}, \frac{r_b B}{H}, \frac{R_b}{L}\right) - \frac{Q_n R_b}{L} \quad (18)$$

Solving Equation (18) can be computationally intensive if the number of time steps is large, because there is no recurrence in the summation term. In other words, the calculations performed at time step $n - 1$ cannot be used at time step n , and the ground loop loading history must be updated at each time step. Load aggregation is typically used to reduce the number of terms in the summation without sacrificing accuracy. It is based on the fact that recent ground loads have a more significant effect on the current mean fluid temperature than distant ground loads. For example, in the case of hourly simulations, the determination of T_m at the end of a year would require a summation of 8760 hourly terms according to Equation (18). One possible alternative is to aggregate (i.e., average) the ground loads of the first 8000 hours, then aggregate the next 730 hours and keep intact the last 30 hours. The summation term would then be reduced to 32 terms. Other aggregation schemes have been proposed by Bernier et al. (2004), Liu (2005), and Yavuzturk and Spitler (1999).

Hybrid System Design

The design methods described previously size the ground loop for the larger of the heating or cooling loads, including a temperature penalty for the amount of imbalance (which can be large in severe climates). An alternative approach for imbalanced buildings is to partially balance the load on the ground, both at peak and annual scale, by adding a supplemental device to help meet the larger of the two peak loads. This is a hybrid geothermal (or **hybrid ground-coupled**) system. Hybrids can provide several benefits for buildings with a load imbalance. The biggest economic effect is in decreasing the ground heat exchanger size/cost. First-cost savings have been reported of 6 to 16% of total HVAC system cost, with little consequence reported on operating cost (Hackel and Pertzborn 2011; Singh and Foster 1998) because the HVAC systems operates for the vast majority of the year at a fraction of peak design. Table 7 shows that the more balanced loads resulting from hybrids also significantly affect long-term performance too.

In most U.S. commercial buildings, the cooling load is dominant both annually and at the peak because of high internal loads, ventilation heat recovery, and good building envelopes. Heat from compressors, pumps, and fans also plays a factor; in heating mode, this heat is delivered to the building, so less heat is required from the

Fig. 20 Hybrid System Configuration Options, (A) Series and (B) Parallel

ground. As a result, achieving annual thermal balance requires heat pumps in a geothermal system to operate in heating mode 1.6 to 1.8 h for every hour in cooling.

The ideal configuration of the ground heat exchanger and supplemental cooling device in a hybrid depends on many factors, such as climate, building peak load, and building annual loads. Carefully analyze which approach may work best for a specific building. One common configuration for cooling-dominated systems, a series hybrid, is shown in Figure 20A. This approach could also be taken with a closed-circuit cooling tower (i.e., fluid cooler) downstream of the ground heat exchanger (GHX). In general, it is most effective to place the lower-temperature heat sink downstream; an energy model can help determine which order most often results in this scenario throughout the year. As a rule of thumb, in drier climates with warmer ground (e.g., desert southwestern United States) the tower is almost always the lower-temperature sink, whereas in humid climates with moderate-temperature ground (e.g. southeastern United States), the ground is often the lower-temperature sink. The hybrid can also be configured in parallel, as shown in Figure 20B, which is especially desirable if the ground heat exchanger is small in comparison to the building peak cooling load (a series system in this example would require a more complex partial GHX bypass). In either case, there are two guidelines for design and operation of hybrid systems:

- A valve can be used to bypass the ground heat exchanger when the system is balanced; a dead band of 55 to 75°F can be used for this purpose. This valve can be three-way as shown, or two-way where appropriate.
- Cooling towers are optimal when they are oversized, use a variable-speed fan, and minimize fan speed across cells.

Control of a cooling-dominated hybrid depends on the configuration. If equipment is placed as shown in Figure 20A, the temperature downstream of the tower can be used to control the use and speed of the tower based on a high limit (some additional savings are possible if the tower is controlled by the Δt between entering fluid and ambient wet-bulb temperatures, though this method depends on a difficult measurement of wet bulb). If the tower is located upstream of the ground heat exchanger, the temperature exiting the tower and the ground heat exchanger should both be used in tower control (to ensure the ground is not being cooled). For parallel configurations (Figure 20B), one practical tower control sequence bases tower operation on a calculation of the average of fluid temperature entering the heat pumps over the previous week

(Xu 2007). Xu also suggests a strategy for controlling the parallel three-way valve.

A heating-dominated hybrid with a boiler instead of a cooling tower can use a series configuration, with the boiler downstream of the loop (because of the boiler’s high temperature output). The boiler is ideally controlled based on the temperature leaving the heat pumps.

Sizing hybrid components is a bit more complex than standard systems. For cooling dominated hybrids, Kavanaugh and Rafferty (1997) suggest that heat exchanger length for heating L_h be determined using Equation (5) with heating-mode loop temperatures t_{wi} and t_{wo} as low as possible to minimize L_c . A tower with an isolation heat exchanger is sized to meet the capacity difference between the required cooling length L_c from Equation (4) and the heating length L_h . Kavanaugh (1998) revised this method to include an additional iteration to size the ground heat exchanger only after estimating the annual heat rejection from the tower: $q_{tower}(\text{rated gpm}) = \text{gpm}_{system}(L_c - L_h)/L_c$, where L_c is calculated from Equation (5) but based on reduced EFLH_c to account for tower operation rejecting an estimated amount of the annual load. The strategy suggests eliminating long-term ground temperature change with additional tower operation.

A more detailed study (Hackel et al. 2009) included assumptions about typical installation and operating costs to demonstrate an optimized design strategy for cooling dominated hybrids. Based on lifecycle cost, this approach was roughly attractive whenever the peak heating load was less than 80% of the cooling load; savings increased logarithmically as the ratio decreased below 80%. A variety of cases were modeled, and the simplified best-fit regression for the hybrid ground heat exchanger length L_{hyb} in a cooling-dominated scenario was found to be proportional to heating load:

$$L_{hyb} = C_1 \times q_h / (t_g - t_{wo}) \quad (19)$$

where $C_1 = 254 \text{ ft} \cdot \text{h} \cdot \text{°F} / \text{kBtu}$, at $k = 1.4 \text{ Btu} / \text{ft} \cdot \text{h} \cdot \text{°F}$. For other ground conductivities, the change in ground heat exchanger size is approximately inversely proportional to the change in conductivity. In choosing t_{wo} , Hackel et al. also suggest in cooler climates it is often economical to include antifreeze in the system and allow the entering fluid temperature to drop to 35°F or lower. The supplemental cooling device (closed-circuit tower) should then be sized to meet the fraction of the cooling load that this smaller hybridized ground heat exchanger cannot. The study suggests that the tower should even be oversized slightly and its fan put on variable-speed control, to achieve optimal performance. Furthermore, tower sizing

Table 9 Guidelines for Pump Power for GSHP Ground Heat Exchangers

Installed Pump Power		Grade	Head at 3 gpm/ton, ft of water
hp _{pump} /100 tons			
< 5		A	< 46
5 to 7.5		B	46 to 69
7.5 to 10		C	69 to 92
10 to 15		D	92 to 138
> 15		F	> 138

Source: Kavanaugh and Rafferty (1997).

should be completed using the local peak wet-bulb and design entering fluid temperature for the hybrid.

This basic strategy of sizing hybrids was found to be valid for a wide range of economic scenarios. This economically justifies the general concept laid out in Kavanaugh (1998); however, results showed that it is generally not economically optimal to balance the load on the ground, and some increase in ground temperature can be accepted. Preliminary research showed that running the tower at night or in winter before there is significant cooling load (precooling the ground) to balance the ground load is not always necessary, and if done without care (i.e., in-depth energy analysis) could possibly lead to increased energy consumption.

Regardless of the calculation method used, detailed building load calculation is critical when sizing and configuring a hybrid, to determine the impacts of heating and cooling loads across time scales from peak to annual. Further refinement of hybrid sizing (and control) can be done through energy simulation software, including some of the design software mentioned earlier, as well as a tool created as a result of ASHRAE research project RP-1384 (Hackel et al. 2009). Building energy simulation can estimate loads at every hour of the year, establishing better understanding of annual ground loads as well as the load sharing between ground heat exchanger and supplemental device.

Heating-Dominated Hybrids. These hybrids are needed in only very cold climates. In heating-dominated buildings in such climates (i.e., with approximately twice as much annual heating load as cooling load), however, a heating-dominated hybrid could decrease the size of the ground heat exchanger. Optimally, the ground heat exchanger is sized to meet the cooling load and a supplemental device meets the remaining heating load through a supplemental heat coil on the ground-coupled fluid loop. Coil energy could be supplied by gas boiler, solar panels, electric resistance, or another source. Several things need to be considered if using this approach:

- The potentially high temperatures of the heating coil are not covered by typical ground heat exchanger warranties.
- Controls must be maintained correctly. Place boiler in series, downstream of ground heat exchanger, with control of boiler and ground heat exchanger coordinated so that heat is never rejected to the ground while the boiler operates (very little of such heat would be recovered).
- The heat pumps operate whenever heating is needed, even though a high-temperature coil is also operating, reducing efficiency.

An alternative strategy for heating dominated buildings that poses some advantages is to simply remove some loads in the building from the ground-coupled loop and serve them by boilers, solar panels, or some other source which provides high enough temperatures to heat without added heat pump energy. Baseboard, unit heaters, and preheat coils can be good applications for this approach. This may alleviate some of the complications with boiler hybrids discussed previously.

Pump and Piping System Options

Loop design can have a substantial effect on both pumping power requirements and system installed cost. A GSHP survey (Caneta Research 1995) reported that installed pumping power varied from 0.04 to 0.21 hp/ton of heat pump power. This represents 4 to 21% of the total demand of typical GSHP systems and up to 50% of the total energy for some pump control schemes. Table 9 gives a recommended set of guidelines for minimizing the power of closed-loop GSHPs and maximizing system efficiency.

Good Table 9 grades can be obtained by minimizing extensive piping arrangements with long interior and exterior piping runs, high-head-loss fittings, valves, and control devices. Designers must compare the costs and advantages of large central piping loops and larger pumps with those of multiple smaller loops and smaller pumps. Pumping rates greater than 3.0 gpm/ton in closed-loop systems result in marginal equipment capacity gains in modern water-to-air heat pumps, and typically decrease overall system efficiency.

Kavanaugh et al. (2002) found the total cost of vertical GCHP ground-loop systems (including headers) ranged from \$6.00 to \$25.60 per foot of vertical bore. The cost of headers is a significant portion of the total and in many cases exceeded the cost of the vertical bore. The savings in vertical loop costs because of central systems' load diversity often is not warranted because of the increased cost of large-diameter piping networks connecting equipment inside the building and below-grade circuits connecting exterior ground heat exchangers.

In low-rise buildings with large footprints, such as a school, multiple unitary loop systems (Figure 21) are an effective option to offset the high cost of central interior piping and ground-loop header costs. Although the total length of vertical bore for unitary systems is greater than for central loop systems, the high cost of interior piping, exterior headers, and valve vaults often offsets the bore cost savings. Additionally, pump demand is substantially reduced in the unitary system because of the short header runs, so low-wattage on/off circulator pumps are suggested.

A compromise in applications with significant load diversity is to group ground heat exchangers into multiple smaller subcentral loops in different areas of the building (Figure 22). Subcentral loops can be served by on/off circulator pumps located on each heat pump if a check valve is installed on each heat pump to prevent reverse water circulation through idle units.

Figure 23 is an example of a central loop that can effectively reduce the cost of the required vertical bore in buildings with higher load diversities. The central ground heat exchanger consists of several subheader sets, each having 6 to 20 vertical U-tube heat exchangers. The subheaders are gathered into a valve manifold located either near the center of the loop field in a below-grade vault or in the building equipment room. Each subheader set has isolation valves for independent purging of air and debris. Interior piping is similar to conventional water-source heat pump systems in which interior piping is routed to individual water-to-air heat pumps in each zone and/or heat pump water heaters and water-to-water heat pumps.

Variable-speed drives (VSDs) are recommended for central loop systems because they offer substantial energy savings compared to primary/secondary pump schemes in GSHP applications. However, in buildings with primary occupancy of less than 60 h per week, measures should be incorporated to turn off the main VSD pump and provide some alternative means of pumping water to critical building zones during low-occupancy or unoccupied periods.

Table 10 is a summary of Tables 9 and 10 from Chapter 32 of the 2007 *ASHRAE Handbook—HVAC Applications*, which compared a central GCHP loop and a set of eight subcentral loops for a 40,000 ft², four-story office with a 100 ton cooling load. The total cost of the single central loop was higher (\$2114 per ton, versus

\$1956 per ton). Although the vertical portion of the subcentral loop cost slightly more (\$1343 per ton, versus \$1327 per ton), the total system cost was projected to be lower because of the lower header cost.

Table 10 also compares a central loop with multiple unitary loops for a 57,000 ft² elementary school. The projected 17% reduction in total cost (\$2099 per ton versus \$2530 per ton) of the unitary system is more significant compared to the reduction in the four-story office because of the building's layout. The single-story, large-footprint

design increases the cost of a central loop because of the long interior piping runs, even though the vertical portion of the central loop system is smaller. The unitary loop system benefits because the large footprint provides ample space for loops to be located near heat pump units.

GSHP Piping Materials. It is an industry standard that the buried ground-loop piping materials be fusion welded. For this reason, the current International Ground Source Heat Pump Association

Fig. 21 Unitary GCHP Loops with On/Off Circulator Pumps

Table 10 GCHP Piping Cost Comparison for Two Sample Buildings

	Four-Story Office Building, 40,000 ft ²		Elementary School, 57,000 ft ²	
	Central Loop	Sub-Central Loops (Eight)	Central Loop	Unitary Loops
Vertical loop cost per ft	\$6.63	\$6.63	\$6.63	\$6.63
Header and vertical loop cost per ft	\$10.57	\$9.67	\$12.91	\$10.71
Vertical loop cost per ton	\$1327	\$1343	\$1300	\$1430
Header and vertical loop cost per ton	\$2114	\$1956	\$2530	\$2099

(IGSHPA) design and installation standards lists only high-density polyethylene (HDPE), and most recently an exception for cross-linked polyethylene (PEX-a) as approved materials for buried pipe. (IGSHPA 2011). In most cases, this pipe is buried without insulation.

Distribution systems in a building need to be carefully chosen and not solely driven by cost or ease of installation. As with any system, piping materials must be compatible with system design temperatures and with the fluids conveyed. Closed-loop systems typically use potable water and may also include an antifreeze solution and/or water treatment chemicals. With newer refrigerants, care is needed to ensure the piping materials are compatible with the oils used in the refrigeration system and that equipment seals are compatible with the heat transfer fluids conveyed; for instance, polyolester (POE) oil used with R-410A is not compatible with PVC pipe. Consult chemical resistance charts provided by materials manufacturers.

Whether designing a new system or retrofitting an existing one, it is the design engineer’s responsibility to size and select the proper piping materials for each application and to select only those materials allowed by code (ICC 2012). In large building systems, the aboveground piping specifications commonly include steel, iron, copper or PVC. Where the hydronic mains are 4 in. or larger, it is often more cost effective to specify steel pipe. Specifying steel pipe may require some type of water treatment to inhibit general corrosion and dielectric isolation when connected to geothermal heat pumps.

Water Quality, Heat Transfer Fluids, and Water Treatment.

When engineers introduce dissimilar metals into closed-loop hydronic piping systems, improperly address water treatment requirements for their designs, or are not properly informed of the local groundwater regulations, water quality problems may result. Poor water quality contributes to a decline in mechanical system

performance, increased maintenance, and can reduce the useful lifetime of mechanical system components.

The standard working fluid in small residential closed-loop piping systems is either potable water or, in colder regions, an antifreeze solution. Where required, the antifreeze solution is introduced after the ground loop is properly pressure tested, flushed, and purged of debris and air. There has been little problem with or concern about water quality in these GSHP systems, because piping materials have historically been HDPE, copper, or stainless steel hose kits for final connection at the heat pumps.

Quality of potable water can vary, depending upon the source, and rules on its use vary from state to state. The chemistry of this water is one of the contributors to corrosion and water quality problems in closed-loop piping systems, so engineers need to be precise with hydronic piping and water treatment system specifications. Chapter 49 offers some guidance on understanding the consequences of water quality on both open- and closed-loop hydronic systems.

The type of chemical used for water treatment in closed-loop systems is based on several criteria, including the materials being protected, the quality of the water in the piping system, local regulations, and cost. These systems are typically specified to include a rigorous process for cleaning the distribution piping, flushing the piping systems of air and debris, and then adjusting the water quality of the final local water to meet the long-term performance requirements of the building systems. Chemicals used to adjust water quality for these systems are often not acceptable for use when the circulating fluid is also connected to a ground loop. This is not a problem unless there is a pipe failure or problem with the ground loop, but a potential leak is a concern of the regulatory agencies that protect groundwater in each state.

Flush and Purge. To ensure that a geothermal heat pump system provides trouble-free operation, all ground-loop systems must be properly flushed and purged prior to connection to the building piping system (IGSHPA 2011). The current standard of care is defined by IGSHPA as providing a minimum velocity of 2 ft/s through each piping system, and flushing and purging each supply and return circuit in the forward and reverse directions for long enough to remove all debris and air from the system.

Recommendations for Good GSHP Piping System Design.

- Before beginning design, consult the local regulatory agency for guidance on requirements related to the ground-loop portion. In many locations, this may be the Departments of Health or Environmental Services. Drilling for a vertical closed-loop system may not be allowed. Local groundwater conditions may limit the

use of certain working fluids due to the sensitive nature of the resource and the concern for contamination.

- Conform to applicable codes on adding nonpotable chemicals to building mechanical piping systems and for any discharge to public sewage systems. Good piping designs minimize the need for chemical treatment and any potential impact to the environment.
- Note that corrosion occurs at some level in all hydronic systems. The best GSHP distribution system from a corrosion standpoint is one that includes only HDPE. Breaking down the system into the subcentral or individual loops may accommodate the use of only HDPE in large buildings.
- Review pressure ratings of all piping materials specified for the system design temperatures.
- Minimize the number of fittings, valves, and specialties where practical. Fittings, valves, specialties, and pumps perform best when stainless steel or bronze fitted.
- Even in a closed-loop piping system, it is possible for air to be introduced by expansion and contraction of the pipe and occasional addition of make-up water. For suspended gases, air separators installed upstream of the pumps with an expansion tank can provide deaeration. For dissolved gases, particularly oxygen, the problem can only be addressed with chemical treatment.
- It is very important that all ground-loop and building systems are properly flushed and purged of debris. Not only can debris clog equipment, but biological material contributes to a drop in water pH as it decays.
- Take a water sample of the local potable water supply if it is planned to be the hydronic system's working fluid. If dissimilar metals are used and/or the local water quality is poor, a water-treatment specialist can help select a water treatment regimen for the system. Alert the owner to the requirement for periodic monitoring of water quality.
- If a chemical pot feeder is added into the system as a place to introduce the chemicals for the hydronic system, include an integral filter. The filter will help to maintain water quality and remove residual debris that may break loose after the system has been properly flushed and purged.
- If propylene glycol is to be used as an antifreeze, note that concentrations less than 20% may promote bacterial growth. Check this percentage with the supplier (NGWA 2010).

Pressure Considerations In Deeper Vertical Boreholes. Vertical systems have been designed and installed to depths greater than 400 ft with mixed results. More field data are needed to extend this range without prominent warning. Pay special attention to the effect of both the internal and external fluid(s) differential pressure on the HDPE pipe, regardless of the specified U-bend type or insertion depth.

In most cases, the only design compensation for increased hydrostatic pressure on the U-bend assembly at these depths was to specify heavier-walled HDPE pipe [e.g., DR-9 (Dimension Ratio)]. Below 350 ft, in a borehole full of fluid, pipe collapse is more probable than burst due to the fact that thermal grout is denser than water. This results in an imbalance of the hydrostatic head in the annulus of the borehole versus the hydrostatic pressure exerted by the fluid inside of the pipe.

Internal working pressure (IWP) and external pressure resistance (EPR) of HDPE material decreases with time of exposure and elevated temperature. The 10 h IWP and EPR for HDPE 3406/3408 and 4710 at 73.4°F for DR-11 and DR-9 are shown in Table 11. The designer should check the manufacturer's material specifications for all buried piping. Should the lower pipe DR (thicker wall) be selected, the EPR pressure increases at the expense of an increase in friction loss at any given flow. HDPE material selection, DR selection, grout selection, and the short term use of additional pressure (air

Table 11 HDPE Internal and External Working Pressures

HDPE at 73.4°F	Internal Working Pressure		External Pressure Resistance	
	kPa (ft of water)		psig (ft of water)	
	DR-11	DR-9	DR-11	DR-9
3406/3408	160 (368)	200 (461)	60 (138)	119 (274)
4710	200 (461)	250 (576)	62 (142)	121 (280)

or fluid) on the U-bend assembly may be remedies to deal with excessive differential pressure on the U-bend assembly.

Recent developments in clay-based thermally enhanced grout include the addition of graphite along with, or in place of, silica sand. Graphite-based-grout can have a thermal conductivity of up to 1.60 Btu/h·ft·°F. In addition, graphite-based grout has a significantly lower density and viscosity than clay/silica sand mixtures at a given thermal conductivity (Table 4). Graphite-based products are more expensive than clay/silica sand thermally enhanced product, but economics, geology, and site conditions may warrant the additional expense. Contact the grout manufacturer for additional information. In the long term, the annular fluid in a properly grouted borehole is designed to gel using a clay-based grout, or harden (set) using a cementitious grout, thus mitigating part of the differential pressure. In general, the maximum working time for most grouts is 30 to 45 min, depending on factors such as makeup water temperature and chemistry, borehole temperature, etc. After this amount of time, the grout begins to gel or set and become unworkable. Note that grouting is not required in some jurisdictions and not addressed in others; this has given rise to substituting a manufactured fill material, which may be acceptable in some cases.

In deeper boreholes it is especially important for the designer to be aware of conditions that may lead to pipe failure and design accordingly. Equation (19) may be used to calculate differential pressure between the internal and external pressures on the HDPE U-bend assembly at any depth:

$$P_d = 0.052 \times (D_2 - D_1) \times \text{Depth} \tag{20}$$

where

- P_d = pressure differential, psi
- D_1 = density of internal fluid, lb/gal (ppg)
- D_2 = density of the external fluid, ppg

Depth = net vertical feet

0.052 = pressure gradient for a fluid with a density of 1 ppg 1 ft high.

The following is a design example for a deeper borehole pipe design. A borehole is designed to be 500 ft deep. The thermal conductivity test indicates that the average deep earth temperature is 73°F. The selected U-bend assembly is HDPE 3408, DR-11. The clay-based thermal grout selected weighs 15.1 ppg at a thermal conductivity of 1.2 Btu/h·ft·°F. The manufacturer's data sheet indicates that the grout will gel within 30 to 45 min of mixing and placement. The U-bend assembly is full of water (8.34 ppg). Using Equation (19), the differential pressure is $0.052 \text{ lb}_f/\text{in}^2 \times (15.1 \text{ ppg} - 8.34 \text{ ppg}) \times 500 \text{ ft}$, or 175.8 psi on the exterior of the pipe at 500 ft. *Note:* The 10 h EPR for 3408 DR-11 at 73°F is 60 psi. Safety and best practice dictate that a design change may be warranted. The design would need to include direction to either stage pressure on the U-bend assembly to offset the hydrostatic head of the grout, or use a lower-density grout (see Table 4 for more information on grout options).

Effect of GSHP Equipment Selection on Heat Exchanger Design

The ground heat exchanger must absorb the heat of compression and heat from auxiliary equipment (e.g., fans, pumps) in cooling mode. In heating mode, heat from auxiliary equipment reduces the amount of heat required from the ground. Therefore, the cooling- and

heating-mode power values W_c and W_h in Equations (4) and (5) must include the auxiliary input.

Rated values published in compliance with ANSI/ARI/ASHRAE/ISO Standard 13256-1 do not include the auxiliary power required to circulate air and water through the distribution systems. Furthermore, the auxiliary power required to distribute chilled air (and water) can have a substantial negative effect on the equipment's cooling capacity.

Table 12 summarizes the air and water temperatures used to generate the rated performance of water-to-air heat pumps.

Table 13 summarizes the conditions for ANSI/ARI/ASHRAE/ISO Standard 13256-2, the rating standard for water-tower heat pumps.

Actual heat pump performance can be substantially different from rated conditions. Designers must convert rated performance to design conditions by accounting for the effect of auxiliary power input and for design ELTs and EWTs. When water-to-water heat pumps or chillers are used in this application, corrections should include power for the pump(s) of the source/sink loop and the chilled-/hot-water loop, and power for fans in the air distribution system. Table 14 demonstrates the difference between rated GSHP efficiency and actual system efficiencies for various options when the effect of auxiliary components is considered. Note that using a high-static-pressure air handler for air distribution significantly reduces cooling efficiency. In heating, 120°F hot water also lowers heating COP compared to direct condensation and hydronic systems (e.g., in-floor heating) that use lower-temperature water.

Horizontal and Small Vertical System Design

The buried pipe of a closed-loop GSHP may theoretically produce a change in temperature in the ground up to 16 ft away. For all practical purposes, however, the ground temperature is essentially unchanged beyond about 3 ft from the pipe loop. For that reason, the pipe can be buried relatively near the ground surface and still benefit from the moderating temperatures that the earth provides. Because the ground temperature may fluctuate as much as ±10°F at a depth of 6 ft, an antifreeze solution must be used in most heating-dominated regions. The critical design aspect of horizontal applications is to have enough buried pipe loop in the available land area to serve the equipment. The design guidelines for residential horizontal loop installations can be found in OSU (1988b).

A horizontal loop design has several advantages over a vertical loop design for a closed-loop ground source system:

- Ground-loop installation is usually less expensive than for vertical well designs because the capital cost of a backhoe or trencher is only a fraction of the cost of most drilling rigs.
- Most ground-source contractors must have a backhoe for construction of the header pits and trenches to the building, so they can perform the entire job without the need to schedule a special contractor.
- Large drilling rigs may not be able to get to all locations because of their size and weight.
- There is usually little potential for aquifer contamination because the trench is shallow.
- There is minimal residual temperature effect from unbalanced annual loads on the ground heat exchanger because heat transfer to or from the ground heat exchanger is small compared to the normal heat transfer occurring at the ground surface.

Table 12 Rating Conditions for Water-to-Air Heat Pumps for Total Cooling (TC, Btu/h), Energy Efficiency Ratio (EER, Btu/W·h), Heating Capacity (HC, Btu/h) and Coefficient of Performance (COP, W/W)

10 ton WWHP, 4000 cfm/4 in. of water AHU	3.8	100°F HW	3.36	1.07	1.07	+14.4 (12.0%)	3.1
10 ton WWHP, in-floor heat	3.8	100°F HW	0	1.07	1.07	+3.7 (3.1%)	3.7

Note: If frost line is greater than 3 ft below grade, average depth of coils should be a minimum of 2 ft below frost line and upper pipe should be a minimum of 1 ft below frost line.

Fig. 24 Horizontal Ground Heat Exchanger Configurations

Some limitations on selecting a horizontal loop design include the following:

- The minimum land area needed for most nonspiral horizontal loop designs for an average house is about 0.5 acre. Horizontal systems are not feasible for most urban houses, which are commonly built on smaller lots.
- The larger length of pipe buried relatively near the surface is more susceptible to being cut during excavations for other utilities.
- Soil moisture content must be properly accounted for in computing the required ground heat exchanger length, especially in sandy soils or on hilltops that may dry out in summer.
- Rocks and other obstructions near the surface may make excavation with a backhoe or trencher impractical.
- Multiple pipes are often placed in a single trench to reduce the land area needed for horizontal loop applications. Some common multiple-pipe arrangements are shown in Figure 24. When pipes are placed at two depths, the bottom row is placed first, and then the trench is partially backfilled before the upper row is put in place. Rarely are more than two layers of pipe used in a single trench because of the extra time needed for the partial backfilling. Higher pipe densities in the trench provide diminishing returns because thermal interference between multiple pipes reduces the heat transfer effectiveness of each pipe. The most common multiple-pipe applications are the two-pipe arrangement used with chain trenchers and the four- or six-pipe arrangements placed in trenches made with a wide backhoe bucket.

An overlapping spiral configuration, shown in Figure 25, has also been used with some success. However, it requires special attention during backfilling to ensure that soil fills all the pockets formed by the overlapping pipe. Large quantities of water must be added to compact the soil around the overlapping pipes. The backfilling must be performed in stages to guarantee complete filling around the pipes and good soil contact. The high pipe density (up to 10 ft of pipe per linear foot of trench) may cause problems in prolonged extreme weather conditions, either from soil drying during cooling or from freezing during heating. This spiral design has been used in vertical trenches cut with a chain trencher as well as in laying the coil flat on the bottom of a large pit excavated with a bulldozer. Installations using the horizontal spiral coil on the bottom of a pit have generally performed better than those with spiral coils that were stood upright in a vertical trench.

The extra time needed to backfill and the extra pipe length required make spiral configurations nearly as expensive to install as straight pipe configurations. However, the reduced land area needed for the more compact design may allow use on smaller residential lots that are too small for conventional horizontal-pipe ground-loop designs. The spiral pipe configuration laid flat in a horizontal pit arrangement is used commonly in the northern Midwest of the

Fig. 25 General Layout of Spiral Earth Coil

United States, where sandy soil causes vertical trenches to collapse. A large open pit is excavated by a bulldozer, and then the overlapping pipes laid flat on the bottom of the pit. The bulldozer is also used to cover the pipe, being careful to not run over them with the bulldozer tread.

Although most horizontal closed-loop systems are installed with either a chain trencher or a backhoe, horizontal boring machines are also now available for this application. Developed for buried utility applications such as electric or potable water service, these devices simply bore through the ground parallel to the ground surface. A detector at the surface can show the exact point where the boring head is located underground so that the bore does not penetrate other known utilities or cross over into a neighbor's lot.

Most horizontal loop installations place the pipe loops in a parallel rather than a single (series) loop to reduce pumping power (Figure 26). Parallel loops may require slightly more pipe, but may use smaller pipe and thus have smaller internal volumes, requiring less antifreeze (if needed). Also, smaller pipe is typically much less expensive for a given length, so total pipe cost should be less for parallel loops. An added benefit is that parallel loops can be flushed out with a smaller purge pump than is required for a larger single-pipe loop. A disadvantage of parallel loops is the potential for unequal flow in the loops and thus nonuniform heat exchange efficiency.

The time required to install a horizontal loop is not much different from that for a vertical system. For the arrangements described, a two-person crew can typically install the ground heat exchanger for an average house in a single day.

Soil characteristics are an important concern for any ground heat exchanger design. With horizontal loops, the soil type can be more easily determined because the excavated soil can be inspected and tested. EPRI (1990) lists criteria and simple test procedures that can be used to classify soil and rock for horizontal ground-loop design.

Fig. 26 Parallel and Series Ground Heat Exchanger Configurations

Although soil type and moisture content are important considerations in sizing the ground heat exchanger, some design guidelines have been developed based on extensive analysis of monitored systems in mostly southern climates (Kavanaugh and Calvert 1995). Table 15 gives recommended trench lengths for the various types of commonly used excavation methods. Heating-mode run times approaching 100% on a daily basis would be the norm at heating design conditions in heating-dominated climates. In contrast, daily run times of no more than 50% would be encountered at design cooling conditions in cooling-dominated climates. The combination of long run times and ice formation around the pipes makes performance of horizontal systems dependent on both the loop field design and how the system is matched to the building load. Though many thousands of these systems have been installed in heating climates, no comparable analysis has been performed to determine proper design guidelines. The loop length data in Table 15 for soil temperatures below 56°F are based on nominal heat pump capacity and use of supplemental resistance heat at design conditions. If installing such a system for the first time, contact several experienced contractors in the area to determine successful design lengths for the local climate and soil types.

Trench lengths in Table 15 are based on a minimum trench separation of 10 ft and minimum horizontal loop average burial depth of the greater of 5 ft or 2 ft below the frost line. Bore lengths are based on a vertical bore separation of 20 ft. Design ground heat exchanger temperatures are a maximum of 90°F return and 100°F entering in warm climates and a minimum of 28°F return and 22°F entering in cold climates.

Additional considerations for horizontal loop systems in colder climates arise from the potential for ice formation around the pipe loop. The loop should not pass within 2 ft of any buried water line (potable, sewer, or rainwater). If such proximity cannot be avoided, the GCHP loop can be insulated in that area. Horizontal loops should not be placed closer than 6 ft from a basement or crawl space wall when buried parallel to the wall. Heaving from ice formation

could cause structural damage if placed in close proximity to the wall.

Leaks in heat-fused plastic pipe are rare when attention is paid to pipe cleanliness and proper fusion techniques. Should a leak occur, it is usually best to try to isolate the leaking parallel loop and abandon it in place. The effort required to find the source of the leak usually far outweighs the cost of replacing the defective loop. Because the loss of as little as 0.25 gal of water from the system causes the system to lose pressure and shut down, leaks cannot be located by looking for wet soil, as is commonly done with water lines.

Although leaks should be rare with properly thermally fused pipe, some states have adopted restrictions against the use of certain types of antifreeze mixtures in GCHP systems; check local water-quality regulations before selecting a mixture. Methanol has been used extensively because of its low cost and good physical properties when cold. Comprehensive studies by Heinonen and Tapscott (1996) and Heinonen et al. (1997) showed that propylene glycol is a good alternative when issues of flammability or environmental safety are important considerations. A more thorough discussion of antifreeze solutions is given in the Antifreeze Requirements section of this chapter.

Fluid Flow and Loop Circuiting. Residential systems, like commercial applications, sometimes have excessive pumping power. This trend may result from undersized piping, excessive amounts of viscous antifreeze solutions, or conservative pump sizing. Because a 3 ton heat pump with an energy efficiency ratio (EER) of 15 requires a total power (compressor and fan) of 2400 W, the addition of a second 1/6 hp pump (which draws 245 W) reduces system efficiency by 10%. Table 16 provides a guideline to ensure adequate liquid flow rate with the least possible number of pumps. It should be used in conjunction with Table 15 and applies to loops with 0 to 15% propylene glycol solutions (by volume; note that caution and additional treatment may be needed for solutions lower than 20%, because of risks of corrosion and biological growth below this level). This solution has the reputation of being the most difficult of the commonly used solutions to pump when cold. However, it is no more difficult to pump than ethyl alcohol, and pumping penalties can be mitigated by adding only the required amount of antifreeze. Shorter loops may require higher levels of antifreeze solutions. See the section on Antifreeze Requirements for more details. Any exposed piping above the frost line must be insulated with closed-cell insulation with ultraviolet (UV) protection (paint or wrap).

Example 4.

Design the vertical ground coupling grid and the pumping loop for a 4 ton (48,000 Btu/h) residential heat pump system. The home is located in Nashville, Tennessee, and the header pipes can be brought into the equipment room where the unit will be located. The driller can bore 4.5 in. holes to a depth of 175 ft in the light limestone and clay at the site. The owner wants the drilling site to be located 75 ft from the house. Thermally enhanced grout with thermal conductivity of 0.85 Btu/h·ft·°F is used to fill the annular region between the U-tubes and borehole walls.

Solution: The soil temperature is estimated to be 59°F in Nashville. Table 15 suggests bore lengths of 170 ft/ton for 3/4 in. U-bends, 160 ft/ton for 1 in., and 150 ft/ton for 1 1/4 in. (bores are deep, greater than 100 ft). However, 1 1/4 in. U-bends are very difficult to install in a 4.5 in. borehole, and are not considered. Therefore, either 680 ft (170 ft/ton × 4 tons) of 3/4 in. U-bend coupling or 640 ft (160 × 4 tons) of 1 in. coupling is required. The latter is used in this example. Also, Table 15 is based on a soil conductivity of 1.2 Btu/h·ft·°F, which is an approximate average between limestone and clay, and a bore fill (or grout) conductivity of 0.85 Btu/h·ft·°F. If the ground conductivity is higher (i.e., more limestone than clay), the loops should be reduced as noted in Table 15; if lower, the loops should be lengthened. Loop lengths also must be lengthened if the bore fill (or grout) conductivity is lower than 0.85 Btu/h·ft·°F, as noted in Table 15.

Table 15 Recommended Lengths of Trench or Bore per Ton for Residential GCHPs

Coil Type ^a		Pitch ^b Feet of Pipe per Foot Trench/Bore	Ground Temperature, °F

*Based on DR11 HDPE pipe.

Layout is dictated by drilling conditions. The total length of 640 ft requires four bores, because the driller can only drill to 175 ft. This can be accomplished with four 160 to 165 ft holes. Table 16 suggests between three and five parallel circuits for the grid. Three and five circuits do not divide evenly into the four U-bends. Therefore, four circuits (one per U-bend) should be used in an arrangement similar to Figure 27.

Central Plant Systems

Central plant GCHP systems use central water-to-water equipment (e.g., a water-cooled chiller) to move thermal energy between a source loop (the ground coupled heat exchanger), a chilled-water loop, and a hot-water loop. Here, the term *central plant* implies the mechanical equipment is in one centralized location; it does not

imply a campus is served, and single buildings are a common application. The central plant source loop is commonly a vertical closed-loop heat exchanger, but any combination of GCHP types may be used. The chilled- and hot-water loops may serve any HVAC distribution equipment (fan coils or radiant systems are efficient options) as long as design hot-water supply temperatures do not exceed heat pump temperature ranges (typically 130°F). Best practice in these applications is largely theoretical or anecdotal; research is needed on the efficacy of the various central plant GCHP applications and designers considering central plant GCHPs must be cautious.

Compared to traditional unitary (water-to-air) GCHP systems, central plant systems offer the potential advantages of (1) incorporating direct heat recovery from hot-water loads to chilled-water loads, (2) sometimes allowing waterside economizing, (3) centralizing equipment maintenance, and (4) expanding retrofit opportunities. However, when such plants are connected to conventional distribution such as variable air volume (VAV), the loss of zone level heating and cooling results in large fan and reheat energy penalties. Pumping power is often higher than equivalent unitary heat pump systems. Central plants also have significantly more complex design, controls, commissioning, operational training, and maintenance. Most existing tools and methods for sizing ground heat exchangers and evaluating energy performance do not accurately represent central plant GCHP operation.

As with unitary systems, central plant systems may take many forms. Figure 28 illustrates the basic building blocks of a central plant GCHP system. Any number of heat recovery chillers and heating or cooling heat pumps may be installed. Either or both of the load-side loops may be connected to the source loop to achieve direct heat transfer (water economizing). The loops may be separated by control valves or heat exchangers (as shown in Figure 28), but loops should be linked only by control valves where fluid type and pressure are compatible.

Most central plant heat pump equipment is designed for use in one of three basic strategies:

- **Parallel water-to-water heat pumps:** dedicated heat pumps provide hot and/or chilled water in parallel. This type is often used in conjunction with unitary heat pumps or in simple applications where there is little opportunity for heat recovery or water economizing.

- **Packaged modular heat pumps:** multiple units are connected by control valves to any of the loops (source, hot water, or chilled water) such that each individual heat pump may serve for heating, cooling, or heat recovery.
- **Heat pump chiller:** one or more large heat recovery chillers, designed to operate with a large lift, operate to maintain both hot and chilled water at required temperatures. No dedicated cooling heat pump or heating heat pump is provided. The heat exchangers (or direct valve connections between loops) provide the means to achieve heat rejection or heat absorption with the ground heat exchanger.

To provide stable temperature control and part load operation, central plant GCHP systems can benefit from additional thermal capacitance (buffer tanks) on the load side loops. Any loop flow control

methodology may be used; however, variable flow should be used to minimize pumping energy penalties where equipment allows. Consider using water as the working fluid wherever possible, because of the energy and capital cost associated with antifreeze solutions.

Central plant designers have the option to connect hybrid heating and cooling equipment to the load side of the heat pumps instead of the source/ground side, which adds redundancy and reduces pump and compressor energy at the expense of increased controls complexity. Hybrid air-cooled chillers may serve the chilled-water loop directly, whereas evaporative cooling equipment is best placed on the source loop in series or in parallel with the ground heat exchanger. Connecting a hybrid boiler to the hot-water loop reduces thermal stress for boilers designed to operate at higher temperatures and provides direct emergency heat; connecting a hybrid boiler to the source loop reduces control interconnection/complexity and reduces heat pump faults caused by low entering water temperatures.

Fig. 27 Residential Design Example

3.3 GROUNDWATER HEAT PUMPS

A groundwater heat pump system (GWHP) removes groundwater from a well and delivers it to a heat pump (or an intermediate heat exchanger) where heat is absorbed from or rejected to the water. Both unitary and central plant designs are used. In the unitary type, a large number of small water-to-air heat pumps are distributed throughout the building. The central plant design uses one or a small number of large-capacity chillers supplying hot and chilled water to a two- or four-pipe distribution system. The unitary approach is more common and tends to be more energy-efficient.

Direct systems (in which groundwater is pumped directly to the heat pump without an intermediate heat exchanger) are not recommended except on the very smallest installations. Although some systems of this design have been successful, many have had serious difficulty even with groundwater of apparently benign chemistry. Thus, prudent design for commercial/industrial-scale projects isolates groundwater from the building system with a heat

Fig. 28 Central Plant GCHP System

exchanger. The increased capital cost of installing the heat exchanger is only a small percentage of the total cost and, in view of these systems' greatly reduced maintenance requirements, is quickly recovered.

Past GWHP systems sometimes used surface disposal (to rivers, lakes, drainage ditches, etc.) of the groundwater. Injection, in general, should be the standard disposal method because it eliminates the potential for negative effects on the aquifer water level over time and preserves the positive environmental character associated with GSHP systems.

Regardless of the type of equipment installed in the building, the specific components for handling groundwater are similar. Primary items include (1) wells (supply and injection), (2) well pump and controls, and (3) groundwater heat exchanger. Some specifics of these items are discussed in the Direct-Use Systems Design section of this chapter. In addition to those comments, the following considerations apply specifically to unitary GWHP systems using a groundwater isolation heat exchanger.

Design Strategy

An open-loop system design must balance well pumping power with heat pump performance. As groundwater flow increases through a system, more favorable average temperatures are produced for the heat pumps. Higher groundwater flow rates, to a point, increase system EER or COP: increased well pump power is outweighed by decreased heat pump power requirements (because of the more favorable temperatures). At some point, additional increases in groundwater flow result in a greater increase in well pump power than the resulting decrease in heat pump power. The key strategy in open-loop system design is identifying the point of maximum system performance with respect to heat pump and well pump power requirements. Once this optimum relationship has been established for the design condition, the method of controlling the well pump determines the extent to which the relationship is preserved at off-peak conditions. This optimization process involves evaluating the performance of the heat pumps and well pump(s) over a range of groundwater flows. Key data necessary to make this calculation include well performance (flow and drawdown at various groundwater flows) and heat pump performance versus entering water temperatures at different flow rates. Well information is generally derived from well pump test results. Heat pump performance data are available from the manufacturer.

GWHP systems employ the same type of extended-range unitary heat pumps as GCHP systems. Building loop pumping guidelines (see Table 9) in the GCHP portion of this chapter also apply to GWHP systems. In large commercial applications, the head loss associated with the isolation heat exchanger in a GWHP system is typically lower than that of an equivalently sized ground heat exchanger in a GCHP system. A guideline for building loop head loss in a GWHP system can be described as follows:

$$\text{Building loop head loss (ft of water)} = 28 + 0.1d$$

where *d* = pipeline distance ft from plate heat exchanger outlet to most distant heat pump unit inlet.

This calculation assumes a maximum head loss of 4 ft/100 ft fittings at 25% of total head loss and a heat pump unit head loss of 12 ft. Because of more extensive fittings, retrofits can sometimes exceed this value.

For moderate-efficiency heat pumps (EER of 14.2), efficient loop pump design (7.5 hp/100 tons), and a heat exchanger approach of 3°F, Figure 29 provides curves for two different groundwater temperatures (GWT = 50 and 65°F) and two well pump situations (SWL 75 ft/specific capacity 10 gpm/ft and SWL 300 ft/specific capacity 3 gpm/ft). The curves are plotted for constant well pump head, a situation which does not occur in practice. In reality, well pump head rises with flow but at a rate typically less than that in friction head applications.

Although the four curves show a clear optimum flow, sometimes operating at a lower groundwater flow reduces well/pump capital cost and the problem of fluid disposal. These considerations are highly project specific, but do afford the designer some latitude in flow selection. Generally, an optimum design results in a groundwater flow rate that is less than the building loop flow rate.

The exception to this occurs in the case of groundwater temperatures of less than 47°F and greater than 72°F. In these situations the groundwater flow requirement is influenced more by avoiding excessive heat pump EWT in the cooling mode (groundwater temperatures above 72°F) and heat pump LWTs that could result in freezing conditions in the heating mode (groundwater temperatures less than 47°F). In the case of low water temperatures, some designers have found it advantageous to use antifreeze in the building loop to slightly broaden the allowable loop temperature range.

Table 17 provides design data for a specific example system.

3.4 WATER WELLS

This section includes information on water wells that is generally common to both direct-use and groundwater heat pump (GWHP) systems.

Table 17 Example GWHP System* Design Data

Heat Pump EWT, °F	Heat Pump LWT, °F	Heat Pump EER	Ground-water LWT, °F	Ground-water Flow, gpm	Well Pump Head, ft	Well Pump kW	Loop Pump kW	System EER

Fig. 29 Optimum Groundwater Flow for Maximum System EER

SWL is static water level in ft, and SC is specific capacity of well in gpm/ft. (Kavanaugh and Rafferty 1997)

Fig. 30 Water Well Terminology

An **aquifer** is a geologic unit that is capable of yielding groundwater to a well in sufficient quantities to be of practical use (UOP 1975). Aquifers can exist in areas where water is present in conjunction with pore spaces in the subsurface materials sufficient to allow the water to move laterally.

In many projects, construction of the well (or wells) is handled through a separate contract between the owner and the driller or a hydrology/hydrogeology consultant. As a result, the engineer is not responsible for its design. However, because design of the building system depends on performance of the wells, it is critical that the engineer be familiar with water well terminology and test data. The most important consideration with regard to the wells is that they be completed and tested (for flow volume and water quality) before final system design, in much the same way that ground thermal properties testing precedes GCHP system design.

Figure 30 illustrates some of the more important well terms. Several references (Anderson 1984; Campbell and Lehr 1973; EPA 1975; Roscoe Moss Company 1985) cover well drilling and well construction in detail.

Static water level (SWL) is the level that exists under static (nonpumping) conditions. In some cases, this level is much closer to the surface than that at which the driller encounters water during drilling. **Pumping water level (PWL)** is the level that exists under specific pumping conditions. Generally, this level is different for different pumping rates (higher pumping rates mean lower pumping levels). The difference between the SWL and the PWL is the **drawdown**. The **specific capacity** of a well is frequently quoted in gpm per foot of drawdown. For example, for a well with a static level of 50 ft that produces 150 gpm at a pumping level of 95 ft, drawdown = $95 - 50 = 45$ ft; specific capacity = $150/45 = 3.33$ gpm per foot.

Water entrance velocity (through the screen or perforated casing) can be an important design consideration. Velocity should be

limited to a maximum of 0.1 fps (0.05 ft/s for injection wells) to avoid incrustation of the entrance openings. The **pump bowl assembly** (impeller housings and impellers) is always placed sufficiently below the expected pumping level to prevent cavitation at the peak production rate. For the previous example, this pump should be placed at least 115 ft below the casing top (pump setting depth = 115 ft) to allow for adequate submergence at peak flow. Along with any expected annual aquifer water level fluctuations, the specific **NPSH pressure** required for a pump varies with each application and should be carefully considered in selecting the setting depth along with any expected annual aquifer water level fluctuations.

For the well pump, **total pump head** is composed of four primary components: lift, column friction, surface requirements, and injection head (pressure). **Lift** is the vertical distance that water must be pumped to reach the surface. In the example, lift is 95 ft. The additional 20 ft of submergence imposes no static pump head (pressure).

Column friction, the friction loss in the pump column between the bowl assembly and the surface, is calculated from pump manufacturer data in a similar manner to other pipe friction calculations (see Chapter 22 of the 2013 *ASHRAE Handbook—Fundamentals*). **Surface pressure requirements** account for friction losses through piping, heat exchangers, and controls, and in many applications are between 25 and 35 ft. **Injection pressure requirements** are a function of well design, aquifer conditions, and water quality. In theory, an injection well penetrating the same aquifer as the production well experiences a water level rise (assuming equal flows) that mirrors the drawdown in the production well. Using the earlier example, an injection well with a 50 ft static level would experience a water level rise of 45 ft, resulting in a surface injection pressure of $45 - 50 = -5$ ft (i.e., a water level that remains 5 ft below the ground surface). Thus, no additional pump head is required for injection in the example.

In practice, injection pressure requirements usually exceed the theoretical value. With good (nonscaling) water quality, careful drilling, and little sand production, injection pressure should be near the theoretical value. For poor water quality, high sand production, or poor well construction, injection pressure may be 10 to 40% higher.

The well casing diameter depends on the diameter of the pump (bowl assembly) necessary to produce the required flow rate. Table 18 presents nominal casing sizes for a range of water flow rates.

In addition to the production well, most systems should include an injection well to dispose of the fluid after it has passed through the system. Injection stabilizes the aquifer from which the fluid is withdrawn by reducing or eliminating long-term drawdowns, and helps to ensure long-term productivity. Construction of injection wells differs from production wells primarily in the recommended screen velocity (0.05 ft/s, or 1/2 that of production wells) and well sealing design. Injection wells, particularly those likely to be subject to positive injection pressure, should be fully cased and sealed from the top of the injection zone to the surface.

It is commonly thought that wells, particularly injection wells, often fail, but failure is more often attributable to the designer than to the well itself. The most common factors in reduced water well (production and injection) performance are encrustation and biofouling of screens, formation plugging with fines, sand pumping, casing/screen collapse, and pump problems (Driscoll 1986). To a large extent, encrustation and biofouling can be reduced by minimizing drawdown through careful well design and the avoidance of excessive groundwater flows. Material selection appropriate for the water chemistry and avoidance of substandard casing and screen products can reduce or eliminate failures in these components. Sand production should be limited by screen, gravel pack, and development practices, or removed by strainers before injection. With such

good practices, maintenance intervals can be reduced to approximately 10 to 15 years in favorable conditions, and 5 to 8 years in unfavorable settings. One key to successful water well operations is effective monitoring: regular testing of well yield, drawdown, specific capacity, and sand production, coupled with periodic review of trends in these parameters.

Flow Testing

When possible, well testing should be completed before mechanical design. Only with actual flow test data and water chemical analysis information can accurate design proceed.

Flow testing can be divided into three different types of tests: rig, short-term, and long-term (Stiger et al. 1989). Rig tests are generally very short and are accomplished while the drilling rig is on site. The primary purpose of this test is to purge the well of remaining drilling fluids and cuttings and to get a preliminary indication of yield. The length of the test is generally governed by the time required for the water to run clean. The rate is determined by the available pumping equipment. Frequently, the well is “blown” or pumped with the drilling rig’s air compressor. As a result, limited information about the well’s production characteristics is available from a rig test. If the well is air lifted, it may not be useful to collect water samples for chemical analysis because certain chemical constituents may be oxidized by the compressed air.

Properly conducted, short-term, single-well tests lasting 4 to 24 h yield information about well flow rate, temperature, drawdown, and recovery. These tests are used most frequently for direct-use and GWHP applications. The test is generally run with a temporary electric submersible pump or lineshaft turbine pump driven by an internal combustion engine and are often performed by a well pump contractor.

A step test (Table 19), the most common type, involves at least three production rates, the largest being equal to the design flow rate for the system served. The three points are the minimum required to determine a productivity curve for the well that relates production to drawdown (Stiger et al. 1989). The key parameters monitored during these tests are well water level and water flow. Water level and pumping rate should be stabilized at each point before flow is increased. In many cases, water level is monitored with a bubbler or an electric sounder, and flow is measured using an orifice meter. More sophisticated instrumentation (e.g., pressure transducers for water level, magnetic flow meters, data loggers) can also be used. Short-term testing is generally used for small projects and provides information on yield, drawdown, and specific capacity.

Test results should reflect stable flows rates and individual flow “steps” are extended until water level readings stabilize. In many cases brief intervals of turbidity may occur at flow changes but extensive periods of turbidity indicate instability in the near well formation.

Long-term tests of up to 30 days provide information on the reservoir. Normally these tests involve monitoring nearby wells to evaluate interference effects. The data are useful in calculating transmissivity and storage coefficient, reservoir boundaries, and

Table 18 Nominal Well Surface Casing Sizes

12	16	14	900 to 1300	

recharge areas (Stiger et al. 1989) but are rarely used for direct-use and GWHP systems.

It is also important to collect background information before the test, and water level recovery data after pumping has ceased. Recovery data in particular can be used to evaluate skin effect, which is a type of well flow resistance caused by residual drilling fluids, insufficient screen or slotted liner area, or improper filter pack.

Groundwater Quality

The importance of groundwater quality depends on the system design. Systems using isolation heat exchangers commonly encounter no water quality issues (other than iron bacteria) that would prevent a GWHP system from operating under reasonable maintenance levels.

For systems that use groundwater directly in heat pump units (e.g., standing-column systems and small residential GWHP systems), several issues are of concern. The primary water quality problem in the United States is scaling, usually of calcium carbonate (lime). Because this type of scaling is partially temperature driven, the temperature of surfaces that groundwater contacts determines the extent to which scaling will occur. In these systems, peak temperatures in the refrigerant-to-water exchanger in cooling mode are likely to be over 160°F. For the same system using an isolation plate heat exchanger, the groundwater is unlikely to encounter temperatures over 90°F. Using the plate heat exchanger reduces the propensity for scaling and limits any scale that does occur to a single heat exchanger. Rafferty (2000b) provides information on water scaling potential on a state-by-state basis.

Although cupronickel, originally developed for seawater applications, is an excellent material in that role, it provides few benefits for most groundwater applications. It has been shown to perform more poorly than pure copper with hydrogen-sulfide-bearing waters.

Excessive iron, particularly ferrous iron, in the water can result in coating of heat transfer surfaces if the water is exposed to air (allowing the iron to oxidize to the ferric state, a form with much lower solubility in water). Periodically removing this iron from the plates of

Table 20 Water Chemistry Constituents

Quality	Comment
pH	Typical range: 6.5 to 9.0. Lower values typically associated with higher rates of general corrosion in ferrous and copper alloys; higher values associated with scaling.
TDS	Total dissolved solids: gross indicator of quantity of dissolved constituents. Higher levels associated with increased corrosion and/or scaling; used in calculation of scale index.
Fe	Iron: use care to prevent exposure to air; problems possible at >0.5 ppm.
Total M alkalinity	Ability of water to buffer acid; strongly linked to scale and used to calculate scaling index. Usually expressed as ppm CaCO ₃ .
Ca	Calcium ion: linked to scaling of water and used to calculate scaling index. Expressed in ppm Ca × 0.5 = ppm as CaCO ₃ .
CO ₃ /HCO ₃	Carbonate/bicarbonate: varies in concentration with pH.
Hardness	Linked to scaling and used to calculate of scale index; at >100 ppm, scaling can occur. Expressed in ppm/17.1 = hardness in gr/gal.
Cl	Chloride: accelerates corrosion of carbon and stainless steels; may be elevated in coastal areas.
Mn	Manganese: causes black scale; possible deposits at >0.2 ppm.
O ₂	Oxygen: dissolved gas; accelerates corrosion; promotes other reactions; test in field.
H ₂ S	Hydrogen sulphide: dissolved gas; rotten egg odor >0.5 ppm; attacks copper alloys; test in field.
CO ₂	Carbon dioxide: dissolved gas, often present at pH < 7.5, test in field. GW pressurization keeps CO ₂ in solution.
Stability index	
(Ryznar index)	Originally developed to predict corrosion but used in GWHP for scaling prediction; calculated from temperature, Ca, TDS, alkalinity, and hardness. Must use temperature reflective of application: 85°F for systems with plate heat exchanger, 150°F for nonisolated systems.
Saturation index	
(Langlier index)	Similar to stability index. Originally developed to predict corrosion but used in GWHP for scaling prediction; calculated from temperature, Ca, TDS, alkalinity, and hardness. Must use temperature reflective of application: 85°F for systems with plate heat exchanger, 150°F for nonisolated systems
BART	Bacteriological activity reaction test: broad indicator of various bacteria. Most common tests are for iron-reducing (IRB), slime-forming (SLYM), and sulfate-reducing (SRB) bacteria.

Source: Rafferty (2008).

a single heat exchanger is much less labor-intensive than removing it from tens or hundreds of individual heat pump heat exchangers. Table 20 summarizes the minimum parameters that should be evaluated for a GWHP application.

Particulate matter (e.g., sand) in the groundwater stream, although usually not a problem in the mechanical system, can effectively plug injection wells. Sand production should be addressed in construction of the production well (screen/gravel pack/development). If it must be dealt with on the surface, a screen or strainer is preferable to a centrifugal separator, which can be ineffective at start-up and shutdown and can experience variable flow (Kavanaugh and Rafferty 1997). Perforation size selection is critical to a strainer's effectiveness. Sizing should be based on 90 to 100% removal of the particulate material. Particle size information can be based on the sieve analysis results of drill cuttings (used to size the well screen) or of a sample taken during well flow testing. In applications with very fine sand, multiple strainers in parallel may be necessary to control pressure drop (Rafferty 2008).

Well Pumps

Submersible pumps have not performed well in higher-temperature, direct-use projects. However, the submersible pump

Table 21 Controller Range Values for Dual Set-Point Well Pump Control*

is a cost-effective option with normal groundwater temperatures, as encountered in heat pump applications. The low temperature eliminates the need to specify an industrial design for the motor/protector, thereby greatly reducing the first cost relative to direct use. Caution should still be used for wells that are expected to produce moderate amounts of sand. The high speed (nominal 3600 rpm) of most submersible pumps makes them susceptible to erosion damage.

Small groundwater systems have frequently been identified with excessive well pump energy consumption. The reasons for excessive pump energy consumption (high water flow rate, coupling to the domestic pressure tank, and low efficiency of small submersible pumps) are generally not present in large, commercial groundwater systems. In large systems, the groundwater flow per unit capacity is frequently less than half that of residential systems. Pressure at the wellhead is not the 30 to 50 psi typical of domestic systems, but is rather a function only of pressure losses through the groundwater loop. Finally, large well pumps have efficiencies of up to 83% compared to the 35 to 40% range for small submersible pumps.

In GWHP system design, the control method for the well pump determines the extent to which the optimum relationship between well pump power and heat pump power is preserved at off-peak conditions. There are several ways the pump can be controlled. Multiple pumps can be staged to meet system loads, either with multiple wells or with multiple pumps installed in a single well. A dual set-point control similar to that used in boiler/tower systems energizes the well pump above a given temperature in cooling mode and below a given temperature in heating mode. Between those temperatures, the building loop floats without the addition of groundwater. To control well pump cycling, it is necessary to establish a temperature range (difference between pump-on and pump-off temperatures) over which the pump operates in both the heating and cooling modes. The size of this range is primarily a function of the building loop water volume in terms of gallons per peak per ton of peak block system load (Rafferty 2000c). Table 21 summarizes these data. In the example in Table 17, the optimum system building loop return temperature (at peak system EER) is 80.6°F. If this system had a water volume of 8 gal/ton, from Table 21, a range of 8°F in cooling mode would be required. This range would result in a well pump start temperature of 80.6 + (8/2) = 84.6°F and a well pump stop temperature of 80.6 – (8/2) = 76.6°F. A similar calculation can be made for heating mode. From Table 21, for systems with very low thermal mass, the dual set-point method of control becomes impractical because of the very large temperature range required. For these applications, an alternative method of control (variable speed, staging, etc.) is required.

Well pumps may also be controlled using a variable-speed drive, which responds to building loop return temperature by varying groundwater flow to the exchanger to maintain the cooling or heating mode set point. Submersible-motor variable-speed applications are somewhat different than surface motor applications. Most manufacturers limit speed reduction to 50%, and other issues such as minimum water velocity for motor cooling, switching frequency, reactor requirement, and motor protection must be addressed. Additional information on VFD applications for submersible motors is available in Rafferty (2008).

Heat Exchangers

Design of a plate-and-frame heat exchanger is largely a trade-off between pressure drop, which influences pumping (operating cost), and overall heat transfer coefficient, which influences surface area (capital cost). In general, exchangers in GWHP systems can be economically selected for approach temperatures (between loop return and groundwater leaving temperatures) as low as 3°F. Most selections involve an approach of between 3 and 7°F and a pressure drop of less than 10 psi on the building loop side. Excessive fouling factors ($>0.0002 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$) should not be specified when selecting plate heat exchangers, which can be easily disassembled and cleaned.

Heat exchanger cost may be reduced for groundwater applications by using Type 304 stainless steel plates rather than the Type 316 or titanium plates common in direct-use projects. The low temperature and generally low chloride content of heat pump fluids frequently make the less expensive Type 304 material acceptable. Chloride content of the groundwater, particularly in coastal areas, should always be compared to values in Figure 4 to determine plate material acceptability. Exchanger performance should be checked at minimum system flow rates to ensure adequate heat transfer. In some cases, very low design pressure drop selections can encounter inadequate heat transfer at minimum flows.

Residential Groundwater Heat Pump Systems

Residential groundwater heat pump systems have the same design considerations as commercial groundwater heat pump systems, but differ on three main items: typically they (1) are integrated with a household domestic water system, (2) are single-zone systems, and (3) do not isolate the groundwater from the heat pump unit(s).

Groundwater heat pumps are a prudent choice in residential buildings on well water if the groundwater is of good quality. As such, the heat pump can be integrated into the domestic water system and considered another water-using appliance. Design care must be taken to ensure that the well and pressure tank have adequate capacity to handle the additional flow demand of the heat pump. Well pumps may be of the submersible or jet type, and the design groundwater flow rate should be chosen based on its temperature such that the system COP or EER is maximized. Flow control valves are recommended in the discharge line to ensure that the well is not over-pumped. Placement of a slow-closing motorized valve also on the discharge line ensures positive pressure on the heat pump water coil, and stops the flow of water when the heat pump is not operating (Figure 31).

The pressure tank provides water at pressure on demand without short-cycling the well pump. A prepressurized bladder tank is pre-

ferred, and it should be large enough that filling it with the well pump takes at least 1 min.

Residential groundwater heat pump systems are small enough that the additional cost of an isolation heat exchanger is typically not economically justified. Raw groundwater is generally used as the heat transfer fluid, but provisions must be made (such as hose bibs or boiler drains) to allow for flushing and descaling of the heat pump water/refrigerant coil if necessary.

After exiting the heat pump, groundwater should be returned to a point of discharge in accordance with best practices and/or local codes. Surface discharge to a pond or wetland, or infiltration in to a dry well may be more of an option in these smaller systems than with larger commercial systems due to the correspondingly lower flow rates.

Central Plant Systems

Central plant systems, in which a conventional or heat recovery central chiller is connected to a four-pipe system, are the oldest type of open-loop design, having first been installed in the late 1940s. Because of the cost and energy requirements of the central plant design, these systems typically do not result in the same level of energy efficiency as unitary GWHP systems.

For central plant groundwater systems, two heat exchangers are normally used: one in the chilled-water loop and one in the condenser water loop (Figure 32). The evaporator-loop exchanger provides a heat source for heating-dominated operation and the condenser-loop exchanger provides a heat sink for cooling-dominated operation.

Sizing the **condenser-loop exchanger** is based on providing sufficient capacity to reject the condenser load in the absence of any building heating requirement.

Sizing the **chilled-water-loop exchanger** must consider two loads. The primary criterion is the load required during heating-dominant operation. The exchanger must transfer sufficient heat (when combined with compressor heat) from the groundwater to the chilled-water loop to meet the building's space heating requirement. Depending on the relative groundwater and chilled-water temperatures and on the design temperature rise, exchangers may also provide some free cooling during cooling-dominant operation. If groundwater temperature is lower than that of chilled water returning to the exchanger, some chilled-water load can be met by the exchanger. This mode is most likely available in regions with groundwater temperatures below 60°F.

Central plant chiller controls must also allow for the unique operation with a groundwater source. Controls can be similar to those on a heat-recovery chiller with a tower, with one important difference.

Fig. 31 Motorized Valve Placement

Fig. 32 Central Plant Groundwater System

In a conventional heat-recovery chiller, waste heat is available only when there is a building chilled-water (or conditioning) load. In a groundwater system, a heat source (the groundwater) is available year round. To take advantage of this source during the heating season, the chiller must be loaded in response to the heating load instead of the chilled-water load. That is, the control must include a heating-dominant mode and a cooling-dominant mode. Two general designs are available for this:

- Chiller capacity remains controlled by chilled-water (supply or return) temperature, and groundwater flow through the chilled-water exchanger is varied in response to the heating load
- Chiller capacity is controlled by the heating-water (condenser) loop temperature, and groundwater flow through the chilled-water exchanger is controlled by chilled-water temperature

For buildings with a significant heating load, the former may be more attractive, whereas the latter may be appropriate for conventional buildings in moderate to warm climates.

Standing-Column Systems

In practice, standing-column wells (SCWs) are a trade-off between groundwater systems and ground-coupled systems. They do not require well flow testing of the sort necessary for groundwater systems, and conductive heat transfer can be based on existing closed-loop theory. Though standing-column systems have been applied mostly in the northeastern United States, approximately 60% of the country is underlain by near-surface (<150 ft) bedrock suitable for the systems.

A heating capacity of 350,000 to 420,000 Btu/h or cooling capacity of 30 to 35 tons can be expected from a 1500 ft deep standing-column well. Ideal spacing between SCWs is 50 to 75 ft (Orio et al. 2005). Typically, spacing between standing-column wells is greater than vertical closed-loop (GCHP) boreholes. These estimated capacities assume a 10% advective bleed flow, discussed later in this section. Closer spacing affects well field performance and can be evaluated with design software. Additional information on standing-column systems can be found in Spittle (2002).

The standing-column well combines supply and injection wells into one, and does not depend on the presence or flow of groundwater, beyond that of the typical bleed rate of 10 to 20% of total pumped flow. Standing-column wells are always augmented with a bleed circuit, to monitor the entering water temperature. Well water temperatures that are below or above design limits because of variations in rock conductivity, building anomalies, or non-standard weather patterns can be restabilized (i.e., brought back to far-field temperatures by overflowing smaller amounts of water on command). This advective flow is a powerful short-term method of warming and cooling well columns that are beyond design limits.

Standing-column wells (Figure 33) consist of a borehole cased in steel or other material until competent bedrock is reached. The casing must be driven 25 to 50 ft into and sealed in competent bedrock. Bedrock sealing requirements vary by state. The remaining depth of the well is then self-supporting through bedrock. For deep commercial SCWs, a tail pipe (porter shroud) is inserted to form a conduit to draw up water, and an annulus to return water downward. This tail pipe is perforated at the bottom to form a diffuser. Water is drawn into the diffuser and up the central riser pipe to the submersible pump. The well pump must be located below the water table in line with the central riser pipe. The tail pipe allows a shorter, reduced-power wire size as well as more accessible well pump service.

The U.S. Environmental Protection Agency (EPA) Underground Injection Control program considers standing-column reinjection well water a Class V water use, type 5A7, noncontact cooling water for geothermal heating and cooling. The EPA and equivalent state

Fig. 33 Commercial Standing-Column Well

agencies regard SCW reinjection as a beneficial use. Permitting or notice may be required, depending on average daily water flow rates. SCWs are serviced by qualified well contractors with minimal familiarization training.

3.5 SURFACE WATER HEAT PUMPS

Surface water bodies can be very good heat sources and sinks if properly used. In some cases, lakes can be the very best water supply for cooling. Various water circulation designs are possible; several of the more common are presented here.

In a **closed-loop system**, one or more water-to-water or water-to-air heat pumps are linked to one or more submerged coils or flat plate heat exchangers, referred to as **surface water heat exchangers (SWHEs)**. Heat is exchanged to (cooling mode) or from (heating mode) the lake by the fluid (usually a water/antifreeze mixture) circulating inside the SWHE. The heat pump transfers heat to or from the air in the building.

In an **open-loop system**, water is pumped from the lake through a heat exchanger and returned to the lake some distance from the point at which it was removed.

Thermal stratification of water often keeps large quantities of cold water undisturbed near the bottom of deep lakes. This water is cold enough to adequately cool buildings by simply being circulated through heat exchangers. A heat pump is not needed for cooling, and energy use is substantially reduced. Closed-loop coils may also be used in colder lakes. Heating can be provided by a separate source or with heat pumps in heating mode. As noted previously, precooling or supplemental total cooling are also allowed when water returning to the building is near or below 55°F.

Heat Transfer in Lakes

Heat is transferred to lakes by three primary modes: radiant energy from the sun, convective heat transfer from the surrounding air (when the air is warmer than the water), and conduction from the ground. Solar radiation, which can exceed 300 Btu/h per square foot of lake area, is the dominant heating mechanism, but it occurs primarily in the upper portion of the lake unless the lake is very clear. About 40% of solar radiation is absorbed at the surface (Pezent and Kavanaugh 1990). Approximately 93% of the remaining energy is absorbed at depths visible to the human eye.

Convection transfers heat to the lake when the lake surface is cooler than the air. Wind speed increases the rate at which heat is transferred to the lake, but maximum heat gain by convection is usually only 10 to 20% of maximum solar heat gain. Conduction gain from the ground is even less than convection gain (Pezent and Kavanaugh 1990).

Lakes are cooled primarily by evaporative heat transfer at the surface. Convective cooling or heating in warmer months contributes only a small percentage of the total because of the relatively small temperature difference between the air and lake surface. At night when the sky is clear, longwave radiation can account for significant amount of cooling. The relatively warm water surface radiates heat to the cooler sky. For example, on a clear night, a cooling rate of up to 50 Btu/h·ft² is possible from a lake 25°F warmer than the sky. The last mode of heat transfer, conduction to the ground, does not play a major role in lake cooling (Pezent and Kavanaugh 1990), though it does provide significant heating under winter conditions (Gu and Stefan 1990) when the surface of the lake is frozen.

To put these heat transfer rates in perspective, consider a 1 acre (43,560 ft²) lake used in connection with a 10 ton (120,000 Btu/h) heat pump. In cooling mode, the unit rejects approximately 150,000 Btu/h to the lake. This is 3.4 Btu/h·ft², or approximately 1% of the maximum heat gain from solar radiation in the summer. In winter, a 10 ton heat pump absorbs only about 90,000 Btu/h, or 2.1 Btu/h·ft², from the lake.

Thermal Patterns in Lakes

The maximum density of water occurs at 39.2°F, not at the freezing point of 32°F. This phenomenon, in combination with the normal modes of heat transfer to and from lakes, produces temperature profiles advantageous to efficient heat pump operation. In the winter, the coldest water is at the surface. It tends to remain at the surface and freeze. The bottom of a deep lake stays 5 to 10°F warmer than the surface. This condition is referred to as **winter stagnation**. The warmer water is a better heat source than the colder water at the surface.

As spring approaches, the surface water warms until the temperature approaches the maximum density point of 39.2°F. The winter stratification becomes unstable, and circulation loops begin to develop from top to bottom. This condition of spring overturn (Peirce 1964) causes the lake temperature to become fairly uniform.

Later in the spring, as water temperatures rise above 45°F, the circulation loops are in the upper portion of the lake. This pattern continues throughout the summer. The upper portion of the lake remains relatively warm, with evaporation cooling the lake and solar radiation warming it. The lower portion (hypolimnion) of the lake remains cold because most radiation is absorbed in the upper zone. Circulation loops do not penetrate to the lower zone, and conduction to the ground is quite small. The result is that, in deeper lakes with small or medium inflows, the upper zone is 70 to 90°F, the lower zone is 40 to 55°F, and the intermediate zone (thermocline) has a sharp change in temperature in a small change in depth. This condition is referred to as **summer stagnation**.

As fall begins, the water surface begins to cool by radiation and evaporation. With the approach of winter, the upper portion begins to cool toward the freezing point and the lower levels approach the maximum density temperature of 39.2°F. An ideal temperature-versus-depth chart is shown in Figure 34 for each of the four seasons (Peirce 1964).

Many lakes do exhibit near-ideal temperature profiles. However, (1) high inflow/outflow rates, (2) insufficient depth for stratification, (3) level fluctuation, (4) wind, and (5) lack of enough cold weather to establish sufficient amounts of cold water necessary for summer stratification can disrupt the profile. Therefore, a thermal survey of the lake should be conducted or existing surveys of similar lakes in similar geographic locations should be consulted (Hattemer and Kavanaugh 2005). When interpreting survey data, be aware that there are annual variations in temperature profiles that will not be reflected in measurements for a single year. Shallow ponds and lakes often destratify completely. This does not preclude their use for SWHP systems, but does reduce performance in cooling mode

Fig. 34 Idealized Diagram of Annual Cycle of Thermal Stratification in Lakes

and may require larger heat exchangers compared to lakes that remain stratified.

The thermal and environmental effects of heat rejection and absorption on larger lakes and streams have been studied (Hattemer et al. 2006; Spitler 2014). However, the effect of SWHPs on thermal stratification profiles is not well characterized, and there is a lack of experimental data. The relative importance of heat transfer modes is not well known, especially during heating mode. There are no publicly available design tools that consider the many heat and mass flow modes of lakes, streams, and oceans. The model of unstratified ponds developed by Chiasson et al. (2000b) has been implemented in publicly available energy calculation programs, but its lack of accounting for stratification, freezing on the coil, or freezing at the surface limits its usefulness for analysis of deeper lakes and operation in heating mode. The model developed by Spitler et al. (2012) accounts for stratification and for freezing both on the coil and at the surface, but makes several approximations such as neglecting inflows, outflows, and water level variations. Furthermore, validation of all such models is necessarily limited to a small number of lakes for which experimental data are available. Therefore, some caution in using such tools is warranted.

Closed-Loop Lake Water Heat Pump Systems

The closed-loop SWHPs shown in Figure 35 have several advantages over the open loop:

- Fouling is reduced because clean water (or water/antifreeze solution) circulates through the heat pump
- Pumping-power requirement is lower because there is no elevation head from the lake surface to the heat pumps
- It is the only type recommended with unitary heat pumps if a lake temperature below 40°F is possible: fluid outlet temperature is about 6°F below that of the inlet at a flow of 3 gpm per ton, and icing occurs on heat exchanger surfaces when the lake water temperature is in the 34 to 38°F range

Disadvantages of closed-loop systems include the following:

Fig. 35 SWHEs: (A) HDPE Coil Type and (B) Plate Type

- Heat pump performance decreases slightly because circulation fluid temperature drops 4 to 12°F below lake temperature
- Coils may be damaged in public lakes; thermally fused polyethylene loops are much more resistant to damage than copper, glued plastic (PVC), or tubing with band-clamped joints
- Fouling can occur on the outside of the lake coil, particularly in murky lakes or where coils are located on or near the lake bottom.

High-density polyethylene (HDPE 3408) is recommended for in-lake piping. All connections must be either thermally socket-fused or butt-fused. These plastic pipes should also have protection from UV radiation, especially when near the surface. Polyvinyl chloride (PVC) pipe and plastic pipe with band-clamped joints are not recommended.

Plate heat exchangers are also available, and manufacturers typically provide estimated capacities for specified conditions. However, use care in applying metal heat exchangers in cold climates. For an equal temperature difference between the reservoir and fluid inside the coil, the surface temperature of metal heat exchangers is closer to the freezing point of water. The higher thermal resistance of HDPE results in a larger required surface area and a much lower heat transfer per unit of surface area. Thus, the surface temperature of an adequately designed HDPE coil tends to be higher than that of a metal tube or plate and less likely to develop ice on the coil exterior. In certain circumstances, ice build-up may occur on the closed-loop SWHE nonetheless. Use proper methods for anchoring the SWHE to resist the upward buoyant force caused by ice build-up.

The piping networks of closed-loop systems resemble those used in ground-coupled heat pump systems. Both a large-diameter header between the heat pump and lake coil and several parallel loops of piping in the lake are required. Loops are spread out to limit thermal interference, hot spots, and cold pockets. Although this layout is preferred in terms of performance, installation is more time consuming. Many contractors simply unbind plastic pipe coils and submerge them in a loose bundle. Some compensation for thermal interference is obtained by making bundled coils longer than the spread coils. A diagram of this type of installation is shown in Figure 35A.

Copper coils have also been used successfully. Copper tubes have a very high thermal conductivity, so coils only one-fourth to one-third the length of plastic coils are required. However, copper pipe does not have the durability of HDPE 3408, and if fouling is possible, coils must be significantly longer.

Open-Loop Lake Water Heat Pump and Direct Surface Cooling Systems

Open-loop surface water heat pump systems use heat pumps or chillers to provide heating and/or cooling, with surface water circulating through a heat exchanger to provide the heat source and/or sink. The heat pumps may be unitary or custom built.

Direct surface water cooling (DSWC) systems use cold lake or sea water to provide cooling without heat pumps. Because the total (horizontal + vertical) distance between the building(s) being cooled and the actual location of the cold water is often significant, the scale of the system that is economically feasible tends to be quite large.

In cases where the lake or sea water may not be cool enough to meet all demands, hybrid systems that can provide cooling with or without heat pumps or chillers have also been used. Published descriptions of all three types of systems have been reviewed by Mitchell and Spittle (2013).

As noted previously, open-loop systems with unitary heat pumps are not suitable for lake temperatures below 40°F because of the risk of freezing in the evaporator. However, larger installations that use custom-designed heat pumps are successfully operated in Scandinavia under even colder conditions. Their capacities can be as large as 100 million Btu/h. One such system takes water from the Baltic Sea at 37°F and returns it at 33°F using falling film evaporators (i.e., plate evaporators with the sea water sprayed on to the outside of the evaporator) (Mitchell and Spittle 2013).

Open-loop systems are generally designed with either a submersible pump in a wet sump pit connected to the water body or with a conventional centrifugal pump in a dry sump pit. It is also possible in some applications to place the pump just above the water level. Small (e.g., residential) systems are sometimes installed with a submersible pump in the water body.

Design guidelines for open-loop systems may be summarized as follows:

- HDPE is recommended for pipelines because of its flexibility, durability, and high thermal resistance. HDPE is also fusible and floats in water, which makes it possible to connect large sections of pipe together for surface installation.
- Design intakes to avoid entrainment and impingement of sediment and fish. A radial wedge wire intake screen with 0.08 to 0.375 in. openings placed 6.5 to 10 ft above the lake or seabed is recommended. Limit screened face velocity to 0.5 fps.
- For direct surface water cooling applications, intake water temperature should be no higher than 55°F for space air dehumidification. Water with higher temperatures may also be used for sensible only cooling or precooling.
- Pumps may be configured in a wet-sump or dry-sump configuration. For wet-sump pumping designs, a large-diameter intake pipeline or a deep sump pit may be necessary to achieve the required flow rate. For dry-sump pumping configurations, available net positive suction head should be calculated carefully to check against the pump specifications. Pump material should be chosen to resist corrosion and erosion.
- Heat exchangers operating in salt water should be constructed from titanium; those operating in freshwater may use stainless steel. Water quality should be tested and verified.
- Heat exchanger fouling may be a problem in warmer climates. Methods for addressing this concern include chlorine dosing, permanently installed brush systems, or disassembly and cleaning.
- Heat pumps for larger systems are typically custom designed units. If used for heating, multistage compression is common.
- Outfall structures should discharge at a depth that will not promote nutrient enhancement of the outfall area. They should also discharge near the lake or seabed and cover a large enough area so as to prevent a high thermal gradient in the source water body.

Antifreeze Requirements

Closed-loop horizontal and surface water heat exchanger systems often require antifreeze in the circulating water in locations with significant heating seasons. Antifreeze may not be needed in a comparable vertical borehole heat exchanger, because the deep ground temperature is essentially constant. At a depth of 6 ft, a typical value for horizontal heat exchangers, ground temperature varies by approximately $\pm 10^{\circ}\text{F}$. Even if the mean ground temperature is 60°F in late winter, ground temperature at a 6 ft depth drops to 50°F . The heat extraction process lowers the temperature even further around the heat exchanger pipes, probably by an additional 10°F or more. Even with good heat transfer to the circulating water, the entering water temperature (leaving the ground heat exchanger) is around 40°F . Lakes that freeze at the surface in the winter approach 39°F at the bottom, yielding nearly the same margin of safety against freezing of the circulating fluid. An additional 10°F temperature difference is usually needed in the heat pump's refrigerant-to-water heat exchanger to transfer heat to the refrigerant. Having a refrigerant-to-water coil surface temperature below the freezing point of water risks growing a layer of ice on the water side of the heat exchanger. In the best case, coil icing restricts and may eventually block the flow of water and cause a shutdown. In the worst case, ice could burst the tubing in the coil and require a major service expense.

Several factors must be considered when selecting an antifreeze for a ground-loop heat exchanger; the most important are (1) effect on system life-cycle cost, (2) corrosivity, (3) leakage, (4) health risks, (5) fire risks, (6) environmental risks from spills or disposal, and (7) risk of future use (acceptability of the antifreeze over the life of the system). A study by Heinonen and Tapscoff (1996) evaluating six antifreezes against these seven criteria is summarized in Table 22. No single material satisfies all criteria. Methanol and ethanol have good viscosity characteristics at low temperatures, yielding lower-than-average pumping power requirements. However, in concentrated forms they both pose a significant fire hazard. Methanol is also toxic, eliminating it from consideration in areas that require nontoxic antifreeze to be used. Propylene glycol had no major concerns, with only leakage and pumping-power requirements prompting minor concerns. Potassium acetate, calcium magnesium acetate (CMA), and urea have favorable environmental and safety performance, but are all subject to significant leakage problems, which has limited their use.

Key: * Potential problems, caution in use required
 ** Minor potential for problems
 *** Little or no potential for problems

Category	Notes
Life-cycle cost	1. Higher-than-average installation and energy costs.
Corrosion	2. High black iron and cast iron corrosion rates. 3. High black iron cast iron, copper and copper alloy corrosion rates. 4. Medium black iron, copper and copper alloy corrosion rates. 5. Medium black iron, high cast iron, and extremely high copper and copper alloy corrosion rates.
Leakage	6. Minor leakage observed. 7. Moderate leakage observed. Extensive leakage reported in installed systems. 8. Moderate leakage observed. 9. Massive leakage observed.
Health risk	10. Protective measures required with use. See Material Safety Data Sheet (MSDS). 11. Prolonged exposure can cause headaches, nausea, vomiting, dizziness, blindness, liver damage, and death. Use of proper equipment and procedures reduces risk significantly. 12. Confirmed human carcinogen.
Fire risk	13. Pure fluid only. Little risk when diluted with water in antifreeze. 14. Very minor potential for pure fluid fire at elevated temperatures.
Environment risk	15. Water pollution.
Future-use risk	16. Toxicity and fire concerns. Prohibited in some locations. 17. Toxicity, fire, and environmental concerns. 18. Potential leakage concerns. 19. Not currently used as GSHP antifreeze solution. May be difficult to obtain approval for use.

--	---

THE sun radiates considerable energy onto the earth. Putting that relatively low-intensity (rarely over 300 Btu/h·ft²) energy to work has led to the creation of many types of devices to convert that energy into useful forms, mainly heat and electricity. How that energy is valued economically drives the ebb and flow of the global solar industry. This chapter discusses several different types of solar equipment and system designs for various HVAC applications, as well as methods to determine the solar resource.

Worldwide, solar energy use varies in application and degree. In China and, to a lesser extent, Australasia, solar energy is widely used, particularly for water heating. In the Middle East, solar power is used for desalination and absorption air conditioning. Solar energy use in the United States is relatively modest, driven by tax policy and utility programs that generally react to energy shortages or the price of oil. In Europe, government incentives have fostered use of photovoltaic and thermal systems for both domestic hot-water and space heating (**solar combi systems**), which have a well-established market in several countries, and solar cooling is an emerging market with a significant growth potential. Combined solar space heating/cooling and domestic hot-water production (**solar combi-plus systems**) may lead to both high solar fractions and economical systems because of the continuous (annual) exploitation of the solar collector field and other system components.

Recent interest in sustainability and green buildings has led to an increased focus on solar energy devices for their nonpolluting and renewable qualities; replacing fossil fuel with domestic, renewable energy sources can also enhance national security by reducing dependence on imported energy.

For more information on the use of solar and other energy sources, see the Energy Information Administration (EIA) of the U.S. Department of Energy (www.eia.gov) and the International Energy Agency (www.iea.org).

1. QUALITY AND QUANTITY OF SOLAR ENERGY

Solar Constant

Solar energy approaches the earth as electromagnetic radiation, with wavelengths ranging from 0.1 μm (x-rays) to 100 m (radio waves). The earth maintains a thermal equilibrium between the annual input of shortwave radiation (0.3 to 2.0 μm) from the sun and the outward flux of longwave radiation (3.0 to 30 μm). Only a limited band need be considered in terrestrial applications, because 99% of the sun's radiant energy has wavelengths between 0.28 and 4.96 μm. The current value of the solar constant (which is defined as the intensity of solar radiation on a surface normal to the sun's rays, just beyond the earth's atmosphere at the average earth-sun distance) is 433.4 Btu/h·ft² (ASTM *Standard* E490). Chapter 14 of the 2013

Fig. 1 Variation of Declination δ (degrees) and Equation of Time ET as Function of Day of Year

ASHRAE Handbook—Fundamentals has further information on the available extraterrestrial solar radiation.

Solar Angles

The axis about which the earth rotates is tilted at an angle of 23.45° to the plane of the earth's orbital plane and the sun's equator. The earth's tilted axis results in a day-by-day variation of the angle between the earth-sun line and the earth's equatorial plane, called the **solar declination** δ . This angle varies with the date, as shown in Figure 1, and may be estimated by the following equation:

$$\delta = 23.45 \sin \left[360^\circ \times \frac{284 + N}{365} \right] \quad (1)$$

where N = day of year, with January 1 = 1.

The relationship between δ and the date from year to year varies to an insignificant degree. The daily change in the declination is the primary reason for the changing seasons, with their variation in the distribution of solar radiation over the earth's surface and the varying number of hours of daylight and darkness. Note that the following sections are based in the northern hemisphere; sites in the southern hemisphere will be 180° from the examples (e.g., a solar panel should face north).

The earth's rotation causes the sun's apparent motion (Figure 2). The position of the sun can be defined in terms of its altitude β above the horizon (angle HOQ) and its azimuth ϕ , measured as angle HOS in the horizontal plane.

At solar noon, the sun is exactly on the meridian, which contains the south-north line. Consequently, the solar azimuth ϕ is 0°. The noon altitude β_N is given by the following equation as

The preparation of this chapter is assigned to TC 6.7, Solar Energy Utilization.

Fig. 2 Apparent Daily Path of the Sun Showing Solar Altitude β and Solar Azimuth ϕ

$$\beta_N = 90^\circ - \text{LAT} + \delta \quad (2)$$

where LAT = latitude.

Because the earth's daily rotation and its annual orbit around the sun are regular and predictable, the solar altitude and azimuth may be readily calculated for any desired time of day when the latitude, longitude, and date (declination) are specified. Apparent solar time (AST) must be used, expressed in terms of the hour angle H , where

$$\begin{aligned} H &= (\text{Number of hours from solar noon}) \times 15^\circ \\ &= \frac{\text{Number of minutes from solar noon}}{4} \end{aligned} \quad (3)$$

Solar Time

Apparent solar time (AST) generally differs from local standard time (LST) or daylight saving time (DST), and the difference can be significant, particularly when DST is in effect. Because the sun appears to move at the rate of 360° in 24 h, its apparent rate of motion is 4 min per degree of longitude. The AST can be determined from the following equation:

$$\begin{aligned} \text{AST} &= \text{LST} + \text{ET} \\ &+ (4 \text{ min})(\text{LST meridian} - \text{Local longitude}) \end{aligned} \quad (4)$$

All standard meridians are multiples of 15° east or west of the prime meridian, which is at the Royal Observatory in Greenwich, U.K. The longitude correction is a positive value for the western hemisphere and negative for the eastern hemisphere. The longitudes of the seven standard time meridians that affect North America are Atlantic ST, 60°W ; Eastern ST, 75°W ; Central ST, 90°W ; Mountain ST, 105°W ; Pacific ST, 120°W ; Alaska ST, 135°W ; and Hawaii-Aleutian ST, 150°W . Starting with the prime meridian through Greenwich, many European countries define their standard meridians based on legal, political, and economic as well as purely physical or geographical criteria. The longitudes of the three standard time meridians that affect Europe are western European ST (U.K., Ireland, and Portugal), 0° ; central European ST, 15°E [e.g., Spain (except for Canary Islands) to the south, Serbia to the east, and Sweden to the north]; and eastern European ST, 30°E (e.g., Greece and Cyprus to the south, Turkey to the east, Finland to the north).

The equation of time (ET) is the measure, in minutes, of the extent by which solar time, as determined by a sundial, runs faster or slower than local standard time (LST), as determined by a clock

that runs at a uniform rate. The equation of time may be estimated by the following equation:

$$\text{ET} = 9.87 \sin 2B - 7.53 \cos B - 1.5 \sin B \quad (5)$$

where $B = 0.989(N - 81)$.

Example 1. Find AST at noon DST on July 21 for Washington, D.C., longitude = 77°W ; for Chicago, longitude = 87.6°W ; and for Athens, Greece, longitude = 23.75°E .

Solution: Noon DST is 11:00 AM LST. Washington is in the eastern time zone, and the LST meridian is 75°W . From Equation (5), the equation of time for July 21 ($N = 202$) is -6.07 min. Thus, from Equation (4), noon DST for Washington is

$$\text{AST} = 11:00 - 6.07 + 4(75 - 77) = 10:45.93 \text{ AST} = 10.77 \text{ h}$$

Chicago is in the central time zone, and the LST meridian is 90°W . Thus, from Equation (4), noon central DST is

$$\text{AST} = 11:00 - 6.07 + 4(90 - 87.6) = 11:03.53 \text{ AST} = 11.06 \text{ h}$$

Athens is in the eastern European time zone, and the LST meridian is 30°E . Thus, from Equation (4), noon DST is

$$\text{AST} = 11:00 - 6.07 - 4(30 - 23.75) = 10:28.93 \text{ AST} = 10.48 \text{ h}$$

The hour angles H for these three examples (see Figure 3) are

$$\begin{aligned} \text{for Washington, } H &= (12.00 - 10.77)15^\circ = 18.6^\circ \text{ east} \\ \text{for Chicago, } H &= (12.00 - 11.06)15^\circ = 14.1^\circ \text{ east} \\ \text{for Athens, } H &= (12.00 - 10.48)15^\circ = 22.8^\circ \text{ east} \end{aligned}$$

To find the solar altitude β and the azimuth ϕ when the hour angle H , latitude LAT, and declination δ are known, the following equations may be used:

$$\sin \beta = \cos(\text{LAT}) \cos \delta \cos H + \sin(\text{LAT}) \sin \delta \quad (6)$$

$$\sin \phi = \cos \delta \sin H / \cos \beta \quad (7)$$

$$\text{or } \cos \phi = (\cos H \cos \delta \sin \text{LAT} - \sin \delta \cos \text{LAT}) / \cos \beta \quad (8)$$

Tables 15 to 21 in Chapter 29 of the 1997 *ASHRAE Handbook—Fundamentals* give values for latitudes from 16 to 64° north. For any other date or latitude, interpolation between the tabulated values will give sufficiently accurate results.

Incident Angle

The angle between the line normal to the irradiated surface (OP' in Figure 3) and the earth-sun line OQ is called the incident angle θ . It is important in solar technology because it affects the intensity of the direct component of solar radiation striking the surface and the surface's ability to absorb, transmit, or reflect the sun's rays.

To determine θ , the surface azimuth ψ and the surface-solar azimuth γ must be known. The surface azimuth (angle POS in Figure 3) is the angle between the south-north line SO and the normal PO to the intersection of the irradiated surface with the horizontal plane, shown as line OM . The surface-solar azimuth, angle HOP, is designated by γ and is the angular difference between the solar azimuth ϕ and the surface azimuth ψ . For surfaces facing east of south, $\gamma = \phi - \psi$ in the morning and $\gamma = \phi + \psi$ in the afternoon. For surfaces facing west of south, $\gamma = \phi + \psi$ in the morning and $\gamma = \phi - \psi$ in the afternoon. For south-facing surfaces, $\psi = 0^\circ$, so $\gamma = \phi$ for all conditions. The angles δ , β , and ϕ are always positive.

For a surface with a tilt angle Σ (measured from the horizontal), the angle of incidence θ between the direct solar beam and the normal to the surface (angle QOP' in Figure 3) is given by

$$\cos \theta = \cos \beta \cos \gamma \sin \Sigma + \sin \beta \cos \Sigma \quad (9)$$

For vertical surfaces, $\Sigma = 90^\circ$, $\cos \Sigma = 0$, and $\sin \Sigma = 1.0$, so Equation (9) becomes

Fig. 3 Solar Angles with Respect to a Tilted Surface

$$\cos \theta = \cos \beta \cos \gamma \tag{10}$$

For horizontal surfaces, $\Sigma = 0^\circ$, $\sin \Sigma = 0$, and $\cos \Sigma = 1.0$, so Equation (9) leads to

$$\theta_H = 90^\circ - \beta \tag{11}$$

Example 2. Find θ for a south-facing surface tilted upward 30° from the horizontal at 40° north latitude at 4:00 PM, AST, on August 21.

Solution: From Equation (3), at 4:00 PM on August 21,

$$H = 4 \times 15^\circ = 60^\circ$$

From Equation (1) for August 21 ($N = 233$),

$$\delta = 11.8^\circ$$

From Equation (6),

$$\begin{aligned} \sin \beta &= \cos 40^\circ \cos 11.8^\circ \cos 60^\circ + \sin 40^\circ \sin 11.8^\circ \\ \beta &= 30.4^\circ \end{aligned}$$

From Equation (7),

$$\begin{aligned} \sin \phi &= \cos 11.8^\circ \sin 60^\circ / \cos 30.4^\circ \\ \phi &= 79.4^\circ \end{aligned}$$

The surface faces south, so $\phi = \gamma$. From Equation (9),

$$\begin{aligned} \cos \theta &= \cos 30.4^\circ \cos 79.4^\circ \sin 30^\circ + \sin 30.4^\circ \cos 30^\circ \\ \theta &= 58.8^\circ \end{aligned}$$

ASHRAE *Standard* 93-2010 provides tabulated values of θ for horizontal and vertical surfaces and for south-facing surfaces tilted upward at angles equal to the latitude minus 10° , the latitude, the latitude plus 10° , and the latitude plus 20° . These tables cover the latitudes from 24° to 64° north, in 8° intervals.

Solar Spectrum

Beyond the earth's atmosphere, the effective blackbody temperature of the sun is $10,370^\circ\text{R}$. The maximum spectral intensity occurs at $0.48 \mu\text{m}$ in the green portion of the visible spectrum. Thekaekara (1973) presents tables and charts of the sun's extraterrestrial spectral irradiance from 0.120 to $100 \mu\text{m}$, the range in which most of the sun's radiant energy is contained. The ultraviolet portion of the spectrum below $0.40 \mu\text{m}$ contains 8.73% of the total, another 38.15% is contained in the visible region between 0.40 and $0.70 \mu\text{m}$, and the infrared region contains the remaining 53.12%.

Solar Radiation at the Earth's Surface

In passing through the earth's atmosphere, some of the sun's direct radiation is scattered by nitrogen, oxygen, and other molecules, which are small compared to the wavelengths of the radiation; and by aerosols, water droplets, dust, and other particles with diameters comparable to the wavelengths (Gates 1966). This scattered

radiation causes the sky to appear blue on clear days, and some of it reaches the earth as diffuse radiation.

Attenuation of the solar rays is also caused by absorption, first by the ozone in the outer atmosphere, which causes a sharp cutoff at $0.29 \mu\text{m}$ of the ultraviolet radiation reaching the earth's surface (Figure 4). In the longer wavelengths, there are series of absorption bands caused by water vapor, carbon dioxide, and ozone. The total amount of attenuation at any given location is determined by (1) the length of the atmospheric path through which the rays travel and (2) the composition of the atmosphere. The path length is expressed in terms of the air mass m , which is the ratio of the mass of atmosphere in the actual earth-sun path to the mass that would exist if the sun were directly overhead at sea level ($m = 1.0$). For all practical purposes, at sea level, $m = 1.0/\sin \beta$. Beyond the earth's atmosphere, $m = 0$.

Before 1967, solar radiation data were based on an assumed solar constant of $419.7 \text{ Btu/h} \cdot \text{ft}^2$ and on a standard sea-level atmosphere containing the equivalent depth of 2.8 mm of ozone, 20 mm of precipitable moisture, and 300 dust particles per cm^3 . Threlkeld and Jordan (1958) considered the wide variation of water vapor in the atmosphere above the United States at any given time, and particularly the seasonal variation, which finds three times as much moisture in the atmosphere in midsummer as in December, January, and February. The basic atmosphere was assumed to be at sea-level barometric pressure, with 2.5 mm of ozone, 200 dust particles per cm^3 , and an actual precipitable moisture content that varied throughout the year from 8 mm in midwinter to 28 mm in mid-July. Figure 5 shows the variation of the direct normal irradiation I_{DN} with solar altitude, as estimated for clear atmospheres and for an atmosphere with variable moisture content.

The ASHRAE clear-sky model described in previous editions of this chapter suffered from several well-known limitations. For example, the clearness number was not universally available; its value varied between 0.85 and 1.20 according to location and season in the United States, and was often taken as unity for lack of better data in other countries. The model also lacked universal applicability and the values of its coefficients had to be altered according to location. In addition, the model was derived from a very limited number of measurements, and its applicability outside the United States had never been demonstrated. Finally, clear-sky diffuse irradiance was proportional to beam irradiance, a fact that runs contrary to intuition (i.e., hazier skies should lead to less direct but more diffuse solar irradiation). To overcome these limitations, ASHRAE research projects RP-1363 and RP-1453 developed a significant update of the model (Thevenard and Gueymard 2010). The objectives were to obtain a more accurate model that could enable calculation of clear-sky radiation for any location in the world for all 12 months of the year, while retaining a relatively simple formulation. The resulting model (Gueymard and Thevenard 2013) can be found in Chapter 14 of the 2013 *ASHRAE Handbook—Fundamentals*, along with the tabulated parameters that it requires at different locations.

Design Values of Total Solar Irradiation

The total solar irradiation $I_{t\theta}$ of a terrestrial surface of any orientation and tilt with an incident angle θ is the sum of the direct component $I_{DN} \cos \theta$ plus the diffuse component $I_{d\theta}$ coming from the sky plus whatever amount of reflected shortwave radiation I_r may reach the surface from the earth or from adjacent surfaces:

$$I_{t\theta} = I_{DN} \cos \theta + I_{d\theta} + I_r \tag{12}$$

The diffuse component is difficult to estimate because of its non-directional nature and its wide variations. Figure 5 shows typical values of diffuse irradiation of horizontal and vertical surfaces. For additional information on calculating clear-sky solar radiation, see Chapter 14 of the 2013 *ASHRAE Handbook—Fundamentals*.

Fig. 4 Spectral Solar Irradiation at Sea Level for Air Mass = 1.0

Fig. 5 Variation with Solar Altitude and Time of Year for Direct Normal Irradiation

The maximum daily amount of solar irradiation that can be received at any given location is that which falls on a flat plate with its surface kept normal to the sun's rays so it receives both direct and diffuse radiation. For fixed flat-plate collectors, the total amount of clear-day irradiation depends on the orientation and slope. As shown by Figure 6 for 40° north latitude, the total irradiation of horizontal surfaces reaches its maximum in midsummer, whereas vertical south-facing surfaces experience their maximum irradiation during the winter. These curves show the combined effects of the varying length of days and changing solar altitudes.

Fig. 6 Total Daily Irradiation for Horizontal, Tilted, and Vertical Surfaces at 40° North Latitude

In general, flat-plate collectors are mounted at a fixed tilt angle Σ (above the horizontal) to give the optimum amount of irradiation for each purpose. Collectors intended for winter heating benefit from higher tilt angles than those used to operate cooling systems in summer. Solar water heaters, which should operate satisfactorily throughout the year, require an angle that is a compromise between the optimal values for summer and winter. Figure 6 shows the monthly variation of total day-long irradiation on the 21st day of each month at 40° north latitude for flat surfaces with various tilt angles.

Tables in ASHRAE *Standard* 93 give the total solar irradiation for the 21st day of each month at latitudes 24 to 64° north on surfaces with the following orientations: normal to the sun's rays (direct normal data do not include diffuse irradiation); horizontal; south-facing, tilted at (LAT-10), LAT, (LAT+10), (LAT+20), and 90° from the horizontal. The day-long total irradiation for fixed

surfaces is highest for those that face south, but a deviation in azimuth of 15 to 20° causes only a small reduction.

Solar Energy for Flat-Plate Collectors

The preceding data apply to clear days. Irradiation for average days may be estimated for any specific location by referring to publications of the U.S. Weather Service. The *Climatic Atlas of the United States* (U.S. GPO 2005) gives maps of monthly and annual values of percentage of possible sunshine, total hours of sunshine, mean solar radiation, mean sky cover, wind speed, and wind direction. The European Solar Radiation Atlas (Page et al. 2001) is a database that provides spatial and temporal climatic information for different time scales, including irradiation (global and its components), sunshine duration, air temperature, precipitation, water vapor pressure, and air pressure for a number of stations. Chapter 14 in the 2013 *ASHRAE Handbook—Fundamentals* also provides several sources for obtaining solar data.

The total daily horizontal irradiation data reported by the U.S. Weather Bureau for approximately 100 stations before 1964 show that the percentage of total clear-day irradiation is approximately a linear function of the percentage of possible sunshine. The irradiation is not zero for days when the percentage of possible sunshine is reported as zero, because substantial amounts of energy reach the earth in the form of diffuse radiation. Instead, the following relationship exists for the percentage of possible sunshine (ratio of day-long horizon irradiation to clear-day total horizon irradiation):

$$\frac{\text{Day-long actual } I_{tH}}{\text{Clear day } I_{tH}} 100 = a + b \tag{13}$$

where *a* and *b* are empirical constants for any specified month at any given location. See also Duffie and Beckman (2006) and Jordan and Liu (1977).

Longwave Atmospheric Radiation

In addition to the shortwave (0.3 to 2.0 μm) radiation it receives from the sun, the earth receives longwave radiation (4 to 100 μm, with maximum intensity near 10 μm) from the atmosphere. In turn, a surface on the earth emits longwave radiation *q_{Rs}* in accordance with the Stefan-Boltzmann law:

$$q_{Rs} = e_s \sigma T_s^4 \tag{14}$$

where

- e_s* = surface emittance
- σ = Stefan-Boltzmann constant, 0.1712×10^{-8} Btu/h · ft² · °R⁴
- T_s* = absolute temperature of surface, °R

For most nonmetallic surfaces, the longwave hemispheric emittance is high, ranging from 0.84 for glass and dry sand to 0.95 for black built-up roofing. For highly polished metals and certain selective surfaces, *e_s* may be as low as 0.05 to 0.20.

Atmospheric radiation comes primarily from water vapor, carbon dioxide, and ozone (Bliss 1961); very little comes from oxygen and nitrogen, although they make up 99% of the air.

Approximately 90% of the incoming atmospheric radiation comes from the lowest 300 ft. Thus, air conditions at ground level *T_{at}* largely determine the magnitude of the incoming radiation. Downward radiation from the atmosphere *q_{Rat}* may be expressed as

$$q_{Rat} = e_{at} \sigma T_{at}^4 \tag{15}$$

The sky emittance *e_{at}* is a complex function of air temperature and moisture content. The dew point of the atmosphere near the ground determines the total amount of moisture in the atmosphere above the place where the dry-bulb (db) and dew-point (dp) temperatures of the atmosphere are determined (Reitan 1963). Bliss (1961)

found that the sky emittance is related to the dew-point temperature, as shown by Table 1.

The apparent sky temperature *T_{sky}* is defined as the temperature at which the sky (as a blackbody) emits radiation at the rate actually emitted by the atmosphere at ground level temperature with its actual emittance *e_{at}*. Then,

$$\sigma T_{sky}^4 = e_{at} \sigma T_{at}^4 \tag{16}$$

or
$$T_{sky}^4 = e_{at} T_{at}^4 \tag{17}$$

Example 3. Consider a summer night condition when ground-level temperatures are 65°F dew point and 85°F dry bulb. From Table 1, *e_{at}* at 65°F dew point is 0.87, and the apparent sky temperature is

$$T_{sky} = 0.87^{0.25}(85 + 459.6) = 526.0^\circ\text{R}$$

Thus, *T_{sky}* = 526.0 – 459.6 = 66.4°F, which is 18.6°F below the ground-level dry-bulb temperature.

For a winter night in Arizona, when temperatures at ground level are 60°F db and 25°F dp, from Table 1, the sky emittance is 0.78, and the apparent sky temperature is 488.3°R or 28.7°F.

A simple relationship, which ignores vapor pressure of the atmosphere, may also be used to estimate the apparent sky temperature:

$$T_{sky} = 0.0411 T_{at}^{1.5} \tag{18}$$

where *T* is in degrees Rankine.

If the temperature of the radiating surface is assumed to equal the atmospheric temperature, the heat loss from a black surface (*e_s* = 1.0) may be found from Figure 7.

Table 1 Sky Emittance and Amount of Precipitable Moisture Versus Dew-Point Temperature

Dew Point, °F	Sky Emittance, <i>e_{at}</i>	Precipitable Water, in.
-20	0.68	0.12
-10	0.71	0.16
0	0.73	0.18
10	0.76	0.22
20	0.77	0.29
30	0.79	0.41
40	0.82	0.57
50	0.84	0.81
60	0.86	1.14
70	0.88	1.61

Fig. 7 Radiation Heat Loss to Sky from Horizontal Blackbody

Example 4. For the conditions in the previous example for summer, 85°F db and 65°F dp, the rate of radiative heat loss is about 23 Btu/h·ft². For winter, 60°F db and 25°F dp, the heat loss is about 27 Btu/h·ft².

Where a rough, unpainted roof is used as a heat dissipater, the rate of heat loss rises rapidly as the surface temperature goes up. For the summer example, a painted metallic roof, $e_s = 0.96$, at 100°F (559.6°R) will have a heat loss rate of

$$q_{Rs} = 0.96 \times 0.1712 \times 10^{-8} [559.6^4 - 526.0^4] \\ = 35.4 \text{ Btu/h} \cdot \text{ft}^2$$

This analysis shows that radiation alone is not an effective means of dissipating heat under summer conditions of high dew-point and ambient temperatures. In spring and fall, when both the dew-point and dry-bulb temperatures are relatively low, radiation becomes much more effective.

On overcast nights, when cloud cover is low, the clouds act much like blackbodies at ground-level temperature, and virtually no heat can be lost by radiation. Exchange of longwave radiation between the sky and terrestrial surfaces occurs in the daytime as well as at night, but the much greater magnitude of the solar irradiation masks the longwave effects.

2. SOLAR ENERGY COLLECTION

Solar energy can be converted by (1) chemical, (2) electrical, and (3) thermal processes. Photosynthesis is a chemical process that produces food and converts CO₂ to O₂. Photovoltaic cells convert solar energy to electricity. The section on Photovoltaic Applications discusses some applications for these devices. The thermal conversion process, the primary subject of this chapter, provides thermal energy for space heating and cooling, domestic water heating, power generation, distillation, and process heating.

Solar Heat Collection by Flat-Plate Collectors

The solar irradiation calculation methods presented in the previous sections may be used to estimate how much energy is likely to be available at any specific location, date, and time of day for collection by either a concentrating device, which uses only the direct rays of the sun, or by a flat-plate collector, which can use both direct and diffuse irradiation. Temperatures needed for space heating and cooling do not exceed 200°F, even for absorption refrigeration, and they can be attained with carefully designed flat-plate collectors.

A flat-plate collector generally consists of the following components (see Figure 8):

- **Glazing.** One or more sheets of glass or other radiation-transmitting material.
- **Tubes, fins, or passages.** To conduct or direct the heat transfer fluid from the inlet to the outlet.
- **Absorber plates.** Flat, corrugated, or grooved plates, to which the tubes, fins, or passages are attached. The plate may be integral with the tubes.
- **Headers or manifolds.** To admit and discharge the heat transfer fluid.
- **Insulation.** To minimize heat loss from the back and sides of the collector.
- **Container or casing.** To surround the other components and protect them from dust, moisture, etc.

Flat-plate collectors have been built in a wide variety of designs from many different materials (Figure 9). They have been used to heat fluids such as water, water plus an antifreeze additive, or air. Their major purpose is to collect as much solar energy as possible at the lowest possible total cost. The collector should also have a long effective life, despite the adverse effects of the sun's ultraviolet radiation; corrosion or clogging because of acidity, alkalinity, or hardness of the heat transfer fluid; freezing or air binding in the case

Fig. 8 Exploded Cross Section Through Double-Glazed Solar Water Heater

of water, or deposition of dust or moisture in the case of air; and broken glazing because of thermal expansion, hail, vandalism, or other causes. These problems can be minimized by using tempered glass.

Glazing Materials

Glass has been widely used to glaze flat-plate solar collectors because it can transmit as much as 90% of the incoming shortwave solar irradiation while transmitting very little of the longwave radiation emitted outward from the absorber plate. Glass with low iron content has a relatively high transmittance for solar radiation (approximately 0.85 to 0.90 at normal incidence), but its transmittance is essentially zero for the longwave thermal radiation (5.0 to 50 μm) emitted by sun-heated surfaces.

Plastic films and sheets also have high shortwave transmittance, but because most usable varieties also have transmission bands in the middle of the thermal radiation spectrum, their longwave transmittances may be as high as 0.40.

Plastics are also generally limited in the temperatures they can sustain without deteriorating or undergoing dimensional changes. Only a few kinds of plastics can withstand the sun's ultraviolet radiation for long periods. However, they are not broken by hail and other stones and, in the form of thin films, they are completely flexible and have low mass.

The glass generally used in solar collectors may be either single-strength (0.085 to 0.100 in. thick) or double-strength (0.115 to 0.133 in. thick). Commercially available grades of window and greenhouse glass have normal incidence transmittances of about 0.87 and 0.85, respectively. For direct radiation, the transmittance varies markedly with the angle of incidence, as shown in Table 2, which gives transmittances for single and double glazing using double-strength clear window glass.

The 4% reflectance from each glass/air interface is the most important factor in reducing transmission, although a gain of about 3% in transmittance can be obtained by using water-white glass. Antireflective coatings and surface texture can also improve transmission significantly. The effect of dirt and dust on collector glazing may be quite small, and the cleansing effect of an occasional rainfall

Fig. 9 Various Types of Solar Collectors

Table 2 Variation with Incident Angle of Transmittance for Single and Double Glazing and Absorptance for Flat-Black Paint

Incident Angle, Deg	Transmittance		Absorptance for Flat-Black Paint
	Single Glazing	Double Glazing	
0	0.87	0.77	0.96
10	0.87	0.77	0.96
20	0.87	0.77	0.96
30	0.87	0.76	0.95
40	0.86	0.75	0.94
50	0.84	0.73	0.92
60	0.79	0.67	0.88
70	0.68	0.53	0.82
80	0.42	0.25	0.67
90	0.00	0.00	0.00

is usually adequate to maintain the transmittance within 2 to 4% of its maximum.

The glazing should admit as much solar irradiation as possible and reduce upward loss of heat as much as possible. Although glass is virtually opaque to the longwave radiation emitted by absorber plates, absorption of that radiation causes an increase in the glass temperature and a loss of heat to the surrounding atmosphere by radiation and convection. This type of heat loss can be reduced by using an infrared-reflective coating on the underside of the glass; however, such coatings are expensive and reduce the effective solar transmittance of the glass by as much as 10%.

In addition to serving as a heat trap by admitting shortwave solar radiation and retaining longwave thermal radiation, the glazing also reduces heat loss by convection. The insulating effect of the glazing is enhanced by using several sheets of glass, or glass plus plastic. Loss from the back of the plate rarely exceeds 10% of the upward loss.

Absorber Plates

The absorber plate absorbs as much of the irradiation as possible through the glazing, while losing as little heat as possible up to the

atmosphere and down through the back of the casing. The absorber plates transfer retained heat to the transport fluid. The absorptance of the collector surface for shortwave solar radiation depends on the nature and color of the coating and on the incident angle, as shown in Table 2 for a typical flat-black paint.

By suitable electrolytic or chemical treatments, selective surfaces can be produced with high values of solar radiation absorptance α and low values of longwave emittance e . Essentially, typical selective surfaces consist of a thin upper layer, which is highly absorbent to shortwave solar radiation but relatively transparent to longwave thermal radiation, deposited on a substrate that has a high reflectance and a low emittance for longwave radiation. Selective surfaces are particularly important when the collector surface temperature is much higher than the ambient air temperature.

For fluid-heating collectors, passages must be integral with or firmly bonded to the absorber plate. A major problem is obtaining a good thermal bond between tubes and absorber plates without incurring excessive costs for labor or materials. Materials most frequently used for absorber plates are copper, aluminum, and steel. UV-resistant plastic extrusions are used for low-temperature application. If the entire absorber area is in contact with the heat transfer fluid, the material's thermal conductance is not important.

Whillier (1964) concluded that steel tubes are as effective as copper if the bond conductance between tube and plate is good. Potential corrosion problems should be considered for any metals. Bond conductance can range from 1000 Btu/h·ft²·°F for a securely soldered or brazed tube, to 3 Btu/h·ft²·°F for a poorly clamped or badly soldered tube. Plates of copper, aluminum, or stainless steel with integral tubes are among the most effective types available. Figure 9 shows a few of the solar water and air heaters that have been used with varying degrees of success.

Concentrating Collectors

Temperatures far above those attainable by flat-plate collectors can be reached if a large amount of solar radiation is concentrated on a relatively small collection area. Simple **reflectors** can markedly increase the amount of direct radiation reaching a collector, as shown in Figure 10A.

Fig. 10 Types of Concentrating Collectors

Because of the apparent movement of the sun across the sky, conventional concentrating collectors must follow the sun's daily motion. There are two methods by which the sun's motion can be readily tracked. The altazimuth method requires the tracking device to turn in both altitude and azimuth; when performed properly, this method enables the concentrator to follow the sun exactly. **Paraboloidal solar furnaces** (Figure 10B) generally use this system. The polar, or equatorial, mounting points the axis of rotation at the North Star, tilted upward at the angle of the local latitude. By rotating the collector 15° per hour, it follows the sun perfectly (on March 21 and September 21). If the collector surface or aperture must be kept normal to the solar rays, a second motion is needed to correct for the change in the solar declination. This motion is not essential for most solar collectors.

The maximum variation in the angle of incidence for a collector on a polar mount is $\pm 23.5^\circ$ on June 21 and December 21; the incident angle correction then is $\cos 23.5^\circ = 0.917$.

Horizontal reflective parabolic troughs, oriented east and west (Figure 10C), require continuous adjustment to compensate for changes in the sun's declination. There is inevitably some morning and afternoon shading of the reflecting surface if the concentrator has opaque end panels. The necessity of moving the concentrator to accommodate the changing solar declination can be reduced by moving the absorber or by using a trough with two sections of a parabola facing each other, as shown in Figure 10D. Known as a **compound parabolic concentrator (CPC)**, this design can accept incoming radiation over a relatively wide range of angles. By using multiple internal reflections, any radiation that is accepted finds its way to the absorber surface located at the bottom of the apparatus. By filling the collector shape with a highly transparent material having an index of refraction greater than 1.4, the acceptance angle can be increased. By shaping the surfaces of the array properly, total internal reflection occurs at the medium/air interfaces, which results in a high concentration efficiency. Known as a **dielectric compound parabolic**

concentrator (DCPC), this device has been applied to the photovoltaic generation of electricity (Cole et al. 1977).

The parabolic trough of Figure 10E can be simulated by many flat strips, each adjusted at the proper angle so that all reflect onto a common target. By supporting the strips on ribs with parabolic contours, a relatively efficient concentrator can be produced with less tooling than the complete reflective trough.

Another concept applies this segmental idea to flat and cylindrical lenses. A modification is shown in Figure 10F, in which a **linear Fresnel lens**, curved to shorten its focal distance, can concentrate a relatively large area of radiation onto an elongated receiver. Using the equatorial sun-following mounting, this type of concentrator has been used to attain temperatures well above those that can be reached with flat-plate collectors.

One disadvantage of concentrating collectors is that, except at low concentration ratios, they can use only the direct component of solar radiation, because the diffuse component cannot be concentrated by most types. However, an advantage of concentrating collectors is that, in summer, when the sun rises and sets well to the north of the east-west line, the sun follower, with its axis oriented north-south, can begin to accept radiation directly from the sun long before a fixed, south-facing flat plate can receive anything other than diffuse radiation from the portion of the sky that it faces. At 40° north latitude, for example, the cumulative direct radiation available to a sun follower on a clear day is 3180 Btu/ft^2 , whereas the total radiation falling on the flat plate tilted upward at an angle equal to the latitude is only 2220 Btu/ft^2 each day. Thus, in relatively cloudless areas, the concentrating collector may capture more radiation per unit of aperture area than a flat-plate collector.

To get extremely high inputs of radiant energy, many flat mirrors or heliostats using altazimuth mounts can be used to reflect their incident direct solar radiation onto a common target. Using slightly concave mirror segments on the heliostats, large amounts of thermal energy can be directed into the cavity of a steam generator to produce steam at high temperature and pressure.

Collector Performance

The performance of collectors may be analyzed by a procedure originated by Hottel and Woertz (1942) and extended by Whillier (in Jordan and Liu 1977). The basic equation is

$$q_u = I_{t\theta}(\tau\alpha)_\theta - U_L(t_p - t_a) = \dot{m} c_p(t_{fe} - t_{fi})/A_{ap} \quad (19)$$

Equation (19) also may be adapted for use with concentrating collectors:

$$q_u = I_{DN}(\tau\alpha)_\theta(\rho\Gamma) - U_L(A_{abs}/A_{ap})(t_{abs} - t_a) \quad (20)$$

where

- q_u = useful heat gained by collector per unit of aperture area, Btu/h·ft²
- $I_{t\theta}$ = total irradiation of collector, Btu/h·ft²
- I_{DN} = direct normal irradiation, Btu/h·ft²
- $(\tau\alpha)_\theta$ = transmittance τ of cover times absorptance α of plate at prevailing incident angle θ
- U_L = overall heat loss coefficient, Btu/h·ft²·°F
- t_p = temperature of absorber plate, °F
- t_a = temperature of atmosphere, °F
- t_{abs} = temperature of absorber, °F
- \dot{m} = fluid flow rate, lb/h
- c_p = specific heat of fluid, Btu/lb·°F
- t_{fe}, t_{fi} = temperatures of fluid leaving and entering collector, °F
- $\rho\Gamma$ = reflectance of concentrator surface times fraction of reflected or refracted radiation that reaches absorber
- A_{abs}, A_{ap} = areas of absorber surface and of aperture that admit or receive radiation, ft²

The total and direct normal irradiation for clear days may be found in ASHRAE *Standard 93*. The transmittance for single and double glazing and the absorptance for flat-black paint may be found in Table 2 for incident angles from 0 to 90°. These values, and the products of τ and α , are also shown in Figure 11. The

Fig. 11 Variation of Absorptance and Transmittance with Incident Angle

solar-optical properties of the glazing and absorber plate change little until θ exceeds 30°, but, because all values reach zero when $\theta = 90^\circ$, they drop off rapidly for values of θ beyond 40°.

For nonselective absorber plates, U_L varies with the temperature of the plate and the ambient air, as shown in Figure 12. For selective surfaces, which strongly reduce the emittance of the absorber plate, U_L is much lower than the values shown in Figure 12. Ask manufacturers of such surfaces for values applicable to their products, or consult test results that give the necessary information.

Example 5. A flat-plate collector is operating in Denver, latitude = 40° north, on July 21 at noon solar time, and the total solar irradiation incident on the plane of the collector $I_{t\theta}$ is 306 Btu/h·ft². The atmospheric temperature is 85°F, and the average temperature of the absorber plate is 140°F. The collector is single-glazed with flat-black paint on the absorber. The collector faces south, and the tilt angle is 30° from the horizontal. Find the rate of heat collection and collector efficiency. Neglect losses from the back and sides of the collector.

Solution: From Equation (1) for July 21 ($N = 202$), $\delta = 20.4^\circ$.
From Equation (2),

$$\beta_N = 90^\circ - 40^\circ + 20.4^\circ = 70.4^\circ$$

From Equation (3), $H = 0$; therefore from Equation (7), $\sin \phi = 0$ and thus, $\phi = 0^\circ$. Because the collector faces south, $\psi = 0^\circ$, and $\gamma = \phi$. Thus $\gamma = 0^\circ$. Then Equation (9) gives

$$\begin{aligned} \cos \theta &= \cos 70.4^\circ \cos 0^\circ \sin 30^\circ + \sin 70.4^\circ \cos 30^\circ \\ &= (0.335)(1)(0.5) + (0.942)(0.866) \\ &= 0.983 \end{aligned}$$

$$\theta = 10.6^\circ$$

From Figure 11, for $n = 1$, $\tau = 0.87$ and $\alpha = 0.96$.

Fig. 12 Variation of Overall Heat Loss Coefficient U_L with Absorber Plate Temperature and Ambient Air Temperatures for Single-, Double-, and Triple-Glazed Collectors

Fig. 13 Efficiency Versus $(t_{fi} - t_a)/I_{t\theta}$ for Single-Glazed Solar Water Heater and Double-Glazed Solar Air Heater

From Figure 12, for an absorber plate temperature of 140°F and an air temperature of 85°F, $U_L = 1.3 \text{ Btu/h} \cdot \text{ft}^2 \cdot \text{°F}$.

Then from Equation (19),

$$q_u = 306(0.87 \times 0.96) - 1.3(140 - 85) = 184 \text{ Btu/h} \cdot \text{ft}^2$$

Collector efficiency η is

$$184/306 = 0.60$$

The general expression for collector efficiency is

$$\eta = (\tau\alpha)_\theta - U_L(t_p - t_a)/I_{t\theta} \quad (21)$$

For incident angles below about 35°, the product $\tau\alpha$ is essentially constant and Equation (21) is linear with respect to the parameter $(t_p - t_a)/I_{t\theta}$, as long as U_L remains constant.

ASHRAE (in Jordan and Liu 1977) suggested introducing an additional term, the **collector heat removal factor** F_R , to allow use of the fluid inlet temperature in Equations (19) and (21):

$$q_u = F_R [I_{t\theta}(\tau\alpha)_\theta - U_L(t_{fi} - t_a)] \quad (22)$$

$$\eta = F_R (\tau\alpha)_\theta - F_R U_L(t_{fi} - t_a)/I_{t\theta} \quad (23)$$

where F_R equals the ratio of the heat actually delivered by the collector to the heat that would be delivered if the absorber were at t_{fi} . F_R is found from the results of a test performed in accordance with ASHRAE Standard 93. The Solar Rating and Certification Corporation (SRCC) conducts this test in the United States and publishes the results, along with day-long performance outputs. Similar organizations around the world [e.g., the International Organization for Standardization (ISO), the European Committee for Standardization (CEN), Commonwealth Scientific and Industrial Research Organization (CSIRO)] provide similar test results. For additional information on SRCC ratings, see Chapter 37 of the 2012 ASHRAE Handbook—HVAC Systems and Equipment.

The results of such a test are plotted in Figure 13. When the parameter is zero, because there is no temperature difference between fluid entering the collector and the atmosphere, the value of the y -intercept equals $F_R(\tau\alpha)$. The slope of the efficiency line equals the overall heat loss factor U_L multiplied by F_R . For the single-glazed,

nonselective collector with the test results shown in Figure 13, the y -intercept is 0.82, and the x -intercept is $0.69 \text{ ft}^2 \cdot \text{h} \cdot \text{°F/Btu}$. This collector used high-transmittance single glazing, $\tau = 0.91$, and black paint with an absorptance of 0.97, thus $F_R = 0.82/(0.91 \times 0.97) = 0.93$.

Assuming that the relationship between η and the parameter is actually linear, as shown, then the slope is $-0.82/0.69 = -1.19$; thus $U_L = 1.19/F_R = 1.19/0.93 = 1.28 \text{ Btu/h} \cdot \text{ft}^2 \cdot \text{°F}$. The tests on which Figure 13 is based were run indoors. Wind speed and fluid velocity can affect measured efficiency.

Figure 13 also shows the efficiency of a double-glazed air heater with an unfinned absorber coated with flat-black paint. The y -intercept for the air heater B is considerably less than it is for water heater A because (1) transmittance of the double glazing used in B is lower than the transmittance of the single glazing used in A and (2) F_R is lower for B than for A because of the lower heat transfer coefficient between air and the unfinned metal absorber.

The x -intercept for air heater B is greater than it is for the water heater A because the upward loss coefficient U_L is much lower for the double-glazed air heater than for the single-glazed water heater. The data for both A and B were taken at near-normal incidence with high values of $I_{t\theta}$. For Example 5, using a single-glazed water heater, the value of the parameter would be close to $(140 - 85)/306 = 0.18 \text{ ft}^2 \cdot \text{h} \cdot \text{°F/Btu}$, and the estimated efficiency, 0.60, agrees closely with the test results.

As ASHRAE Standard 93 shows, the incident angles encountered with south-facing tilted collectors vary widely throughout the year. Considering a surface located at 40° north latitude with a tilt angle $\Sigma = 40^\circ$, the incident angle θ depends on the time of day and the declination δ . On December 21, $\delta = -23.45^\circ$; at 4 h before and after solar noon, the incident angle is 62.7° , and remains close to this value for the same solar time throughout the year. Total irradiation at these conditions varies from a low of $45 \text{ Btu/h} \cdot \text{ft}^2$ on December 21 to approximately $140 \text{ Btu/h} \cdot \text{ft}^2$ throughout most of the other months.

When irradiation is below about $100 \text{ Btu/h} \cdot \text{ft}^2$, losses from the collector may exceed the heat that can be absorbed. This situation varies with the temperature difference between the collector inlet temperature and the ambient air, as suggested by Equation (22).

When the incident angle rises above 30°, the product of the glazing's transmittance and the absorber plate's absorptance $\tau\alpha$ begins to diminish; thus, heat absorbed also drops. Losses from the collector are generally higher as time moves farther from solar noon, and consequently efficiency also drops. Thus, daylong efficiency is lower than near-noon performance. During early afternoon, efficiency is slightly higher than at the comparable morning time, because the ambient air temperature is lower in the morning than in the afternoon.

ASHRAE Standard 93 describes the **incident angle modifier**, which may be found by tests run when the incident angle is set at 30, 45, and 60°. The incident angle modifier is the ratio of the actual $(\tau\alpha)_\theta$ factor at some incidence angle θ to the normal $(\tau\alpha)_n$ factor at normal incident radiation; for normal angles of incidence, the modifier is unity. Simon (1976) showed that for many flat-plate collectors, the incident angle modifier is a linear function of the quantity $(1/\cos \theta - 1)$. For evacuated tubular collectors, the incident angle modifier may grow with rising values of θ . For additional information on the incident angle modifier, see ASHRAE Standard 93 and Chapter 37 of the 2012 ASHRAE Handbook—HVAC Systems and Equipment.

ASHRAE Standard 93 specifies that efficiency be reported in terms of the gross collector area A_g rather than the aperture area A_{ap} . The reported efficiency is lower than that given by Equation (23), but the total energy collected is not changed by this simplification:

$$\eta_g = \frac{\eta_{ap} A_{ap}}{A_g} \quad (24)$$

3. COMPONENTS

This section describes the major components involved in the collection, storage, transportation, control, and distribution of solar heat for a domestic hot-water system.

Collectors. Flat-plate collectors are most commonly used for water heating because of the year-round load requiring temperatures of 80 to 180°F. For discussions of other collectors and applications, see ASHRAE *Standard 93*, Chapter 37 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*, and previous sections of this chapter. Collectors must withstand extreme weather (e.g., freezing, stagnation, high winds), as well as system pressures.

Heat Transfer Fluids. Heat transfer fluids transport heat from the solar collectors to the domestic water. There are potential chemical and mechanical problems with this transfer, primarily in systems in which a heat exchanger interface exists with the potable water supply. Both the chemical compositions of the heat transfer fluids (pH, toxicity, and chemical durability) and their mechanical properties (specific heat and viscosity) must be considered.

Except in unusual cases, or when potable water is being circulated, the energy transport fluid is nonpotable and could contaminate potable water. Even potable or nontoxic fluids in closed circuits are likely to become nonpotable because of contamination from metal piping, solder joints, and packing, or by the inadvertent installation of a toxic fluid at a later date.

Thermal Energy Storage. Heat collected by solar domestic and service water heaters is virtually always stored in a liquid in tanks. Storage tanks and bins should be well insulated. In domestic hot-water systems, heat is usually stored in one or two tanks. The hot-water outlet is at the top of the tank, and cold (makeup) water enters the tank through a dip tube that extends down to within 4 to 6 in. of the tank bottom. The outlet on the tank to the collector loop should be approximately 4 in. above the tank bottom to prevent scale deposits from being drawn into the collectors. Water from the collector array returns to the top of the storage tank. A plumbing arrangement connecting the collector array to the middle to lower portion of the tank may take advantage of thermal stratification, depending on the delivery temperature from the collectors and the flow rate through the storage tank.

Single-tank electric auxiliary systems often incorporate storage and auxiliary heating in the same vessel. Conventional electric water heaters commonly have two heating elements: one near the top and one near the bottom. If a dual-element tank is used in a solar energy system, the bottom element should be disconnected and the top left functional to take advantage of fluid stratification. Standard gas- and oil-fired water heaters should not be used in single-tank arrangements. In gas and oil water heaters, heat is added to the bottom of the tanks, which reduces both stratification and collection efficiency in single-tank systems.

Dual-tank systems often use the solar domestic hot-water storage tank as a preheat tank. The second tank is normally a conventional domestic hot-water tank containing the auxiliary heat source. Multiple tanks are sometimes used in large institutions, where they operate similarly to dual-tank heaters. Although using two tanks may increase collector efficiency and the solar fraction, it increases tank heat losses. The makeup water inlet is usually a dip tube that extends near the bottom of the tank.

Estimates for sizing storage tanks usually range from 1 to 2.5 gal per square foot of solar collector area. The estimate used most often is 1.8 gal per square foot of collector area, which usually provides enough heat for a sunless period of about a day. Storage volume should be analyzed and sized according to the project water requirements and draw schedule; however, solar applications typically require larger-than-normal tanks, usually the equivalent of the average daily load.

Heat Exchangers. Indirect solar water heaters require one or more heat exchangers. Heat transfer from solar collectors to potable hot water has the potential for contaminating the water. Heat exchangers influence the effectiveness of energy collected to heat domestic water. They also separate and protect the potable water supply from contamination when nonpotable heat transfer fluids are used in the collector loop. For this reason, various codes regulate the need for and design of heat exchangers.

Heat exchanger selection should consider the following:

- Heat exchange effectiveness
- Pressure drop, operating power, and flow rate
- Design pressure, configuration, size, materials, and location
- Cost and availability
- Reliable protection of potable water supply from contamination by heat transfer fluid
- Leak detection, inspection, and maintainability
- Material compatibility with other elements (e.g., metals and fluids)
- Thermal compatibility with design parameters such as operating temperature, and fluid thermal properties

Heat exchanger selection depends on characteristics of fluids that pass through the heat exchanger and properties of the exchanger itself. Fluid characteristics to consider are fluid type, specific heat, mass flow rate, and hot- and cold-fluid inlet and outlet temperatures. Physical properties of the heat exchanger to consider are the overall heat transfer coefficient of the heat exchanger and the heat transfer surface area.

For most solar domestic hot-water designs, only the hot and cold inlet temperatures are known; the other temperatures must be calculated using the heat exchanger's physical properties. Two quantities that are useful in determining a heat exchanger's heat transfer and a collector's performance characteristics when it is combined with a given heat exchanger are the (1) fluid capacitance rate, which is the product of the mass flow rate and specific heat of fluid passing through the heat exchanger, and (2) heat exchanger effectiveness, which relates the capacitance rate of the two fluids to the fluid inlet and outlet temperatures. Effectiveness is equal to the ratio of the actual heat transfer rate to the maximum heat transfer rate theoretically possible. Generally, a heat exchanger effectiveness of 0.4 or greater is desired.

Expansion Tanks. An indirect solar water heater operating in a closed collector loop requires an expansion tank to prevent excessive pressure. Fluid in solar collectors under stagnation conditions can boil, causing excessive pressure to develop in the collector loop, and expansion tanks must be sized for this condition. Expansion tank sizing formulas for closed-loop hydronic systems, found in Chapter 13 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*, may be used for solar heater expansion tank sizing, with the volume of water in the system defined as the total volume of fluid in the solar collectors and of any piping located above the collectors, if significant. This sizing method provides a passive means for eliminating fluid loss through overtemperature or stagnation, common problems in closed-loop solar systems. It results in a larger expansion tank than typically found in hydronic systems, but the increase in cost is small compared to the savings in fluid replacement and maintenance costs (Lister and Newell 1989).

Pumps. Pumps circulate heat transfer liquid through collectors and heat exchangers. In solar domestic hot-water heaters, the pump is usually a centrifugal circulator driven by a motor of less than 300 W. The flow rate for collectors generally ranges from 0.015 to 0.04 gpm/ft². Pumps used in drainback systems must provide pressure to overcome friction and to lift the fluid to the collectors.

Piping. Piping can be plastic, copper, galvanized steel, or stainless steel. The most widely used is nonlead, sweat-soldered L-type copper tubing. M-type copper is also acceptable if allowed by local building codes. If water/glycol is the heat transfer fluid, galvanized

pipes or tanks must not be used because unfavorable chemical reactions will occur; copper piping is recommended instead. Also, if glycol solutions or silicone fluids are used, they may leak through joints where water would not. Piping should be compatible with the collector fluid passage material; for example, copper or plastic piping should be used with collectors having copper fluid passages.

Piping that carries potable water can be plastic, copper, galvanized steel, or stainless steel. In indirect systems, corrosion inhibitors must be checked and adjusted no less than annually, preferably every three months. Inhibitors should also be checked if the system overheats during stagnation. If dissimilar metals are joined, dielectric or nonmetallic couplings should be used. The best protection is sacrificial anodes or getters in the fluid stream. Their location depends on the material to be protected, anode material, and electrical conductivity of the heat transfer fluid. Sacrificial anodes of magnesium, zinc, or aluminum are often used to reduce corrosion in storage tanks. Because many possibilities exist, each combination must be evaluated. A copper-aluminum or copper-galvanized steel joint is unacceptable because of severe galvanic corrosion. Aluminum, copper, and iron have a greater potential for corrosion.

Elimination of air, accommodating thermal pipe expansion/contraction, and proper piping slope must be considered to avoid possible failures. Collector pipes (particularly manifolds) should be designed to allow expansion from stagnation temperature to extreme cold weather temperature. Expansion can be controlled with offset elbows in piping, hoses, or expansion couplings. Expansion loops should be avoided unless they are installed horizontally, particularly in systems that must drain for freeze protection. The collector array piping should slope 0.06 in. per foot for drainage (DOE 1978a).

Air can be eliminated by placing air vents at all piping high points and by air purging during filling. Flow control, isolation, and other valves in the collector piping must be chosen carefully so that these components do not restrict drainage significantly or back up water behind them. In systems without antifreeze, the collectors must drain completely.

Valves and Gages. Valves in solar domestic hot-water systems must be located to ensure system efficiency, satisfactory performance, and safety of equipment and personnel. Drain valves must be ball type; gate valves may be used if the stem is installed horizontally. Check valves or other valves used for freeze protection or for reverse thermosiphoning must be reliable to avoid significant damage.

Auxiliary Heat Sources. On sunny days, a typical solar energy system should supply water at a predetermined temperature, and the solar storage tank should be large enough to hold sufficient water for a day or two. Because of the intermittent nature of solar radiation, an auxiliary heater must be installed to handle hot-water requirements. If a utility is the source of auxiliary energy, auxiliary heater operation can be timed to take advantage of off-peak utility rates. The auxiliary heater should be carefully integrated with the solar energy heater to obtain maximum solar energy use. For example, the auxiliary heater should not destroy any stratification that may exist in the solar-heated storage tank, which would reduce collector efficiency.

Ductwork, particularly in systems with air-type collectors, must be sealed carefully to avoid leakage in duct seams, damper shafts, collectors, and heat exchangers. Ducts should be sized using conventional air duct design methods.

Control. Controls regulate solar energy collection by controlling fluid circulation, activate system protection against freezing and overheating, and initiate auxiliary heating when it is required. The three major control components are sensors, controllers, and actuators. Sensors detect conditions or measure quantities, such as temperature. Controllers receive output from the sensors, select a course of action, and signal a component to adjust the condition. Actuators,

such as pumps, valves, dampers, and fans, execute controller commands and regulate the system. The trend is to maintain a near-constant temperature difference between the collector outlet and inlet, to maximize daily heat collection. Currently, controls operate in a user-adjustable temperature difference range.

Temperature sensors measure the temperature of the absorber plate near the collector outlet and near the bottom of the storage tank. The sensors send signals to a controller, such as a differential temperature thermostat, for interpretation.

The differential thermostat compares signals from the sensors with adjustable set points for high and low temperature differentials. The controller performs different functions, depending on which set points are met. In liquid systems, when the temperature difference between the collector and storage reaches a high set point, usually 12 to 15°F, the pump starts, automatic valves are activated, and circulation begins. When the temperature difference reaches a low set point, usually 4°F, the pump is shut off and the valves are deenergized and returned to their normal positions. To restart the system, the differential temperature set point must again be met. If the system has either freeze or overheat protection, the controller opens or closes valves or dampers and starts or stops pumps or fans to protect the system when its sensors detect conditions indicating that either freezing or overheating is about to occur.

Sensors must be selected to withstand high temperature, such as may occur during collector stagnation. Collector loop sensors should be located as close as possible to the outlet of the collectors, either in or on a pipe above or near the collector, or in the collector outlet passage.

The storage temperature sensor should be near the bottom of the storage tank to detect the temperature of fluid before it is pumped to the collector or heat exchanger. Storage fluid is usually coldest at that location because of thermal stratification and the location of the makeup water supply. The sensor should be either securely attached to the tank and well insulated, or immersed inside the tank near the collector supply.

The freeze protection sensor, if required, should be located so that it detects the coldest liquid temperature when the collector is shut down. Common locations are the back of the absorber plate at the bottom of the collector, the collector intake or return manifolds, or the center of the absorber plate. The center absorber plate location is recommended because reradiation to the night sky freezes the collector heat transfer fluid, even though the ambient temperature is above freezing. Some system types, such as the recirculation system, have two sensors for freeze protection; others, such as the draindown, use only one.

Control of on/off temperature differentials affects system efficiency. If the differential is too high, the collector starts later than it should; if it is too low, the collector starts too soon. The turn-on differential for liquid systems usually ranges from 10 to 30°F and is commonly lower in warmer climates and higher in cold climates. For air systems, the range is usually 25 to 45°F.

The turn-off temperature differential is more difficult to estimate. Selection depends on a comparison between the value of the energy collected and the cost of collecting it. It varies with individual systems, but a value of 4°F is typical and generally the fixed default value in the control.

Water temperature in the collector loop depends on ambient temperature, solar radiation, radiation from the collector to the night sky, and collector loop insulation. Freeze protection sensors should be set to detect 40°F.

Sensors are important but often overlooked control components. They must be selected and installed properly because no control can produce accurate outputs from unreliable sensor inputs. Sensors are used in conjunction with a differential temperature controller and are usually supplied by the controller manufacturer. Sensors must survive the anticipated operating conditions without physical damage or

loss of accuracy. Low-voltage sensor circuits must be located away from high-voltage lines to avoid electromagnetic interference. Sensors attached to collectors should be able to withstand the stagnation temperature.

Sensor calibration, which is often overlooked by installers and maintenance personnel, is critical to system performance; a routine calibration maintenance schedule is essential.

Another control option is to use a photovoltaic (PV) panel that powers a dc pump. A properly sized and oriented PV panel converts sunlight into electricity to run a small circulating pump. No additional sensing is required because the PV panel and pump output increase with sunlight intensity and stop when no sunlight (collector energy) is available. However, to prevent operation when the collector outlet temperature is lower than the storage tank, a dc-powered differential controller may be used. Cromer (1984) showed that, with proper matching of pump and PV electrical characteristics, PV panel sizes as low as 5 W per 40 ft² of thermal panel may be used successfully. Difficulty with late starting and running too long in the afternoon can be alleviated by tilting the PV panel slightly to the east during commissioning of the installed system. Electronic devices such as a maximum power point tracker and linear current booster can also improve pump performance at start-up (Bai et al. 2011).

4. WATER HEATING

A solar water heater includes a solar collector that absorbs solar radiation and converts it to heat, which is then absorbed by a heat transfer fluid (water, a nonfreezing liquid, or air) that passes through the collector. The heat transfer fluid's heat is stored or used directly.

Portions of the solar energy system are exposed to the weather, so they must be protected from freezing. The system must also be protected from overheating caused by high insolation levels during periods of low energy demand.

In solar water heating, water is heated directly in the collector or indirectly by a heat transfer fluid that is heated in the collector, passes through a heat exchanger, and transfers its heat to domestic or service water. The heat transfer fluid is transported by either natural or forced circulation. Natural circulation occurs by natural convection (thermosiphoning), whereas forced circulation uses pumps or fans. Except for thermosiphon systems, which need no control, solar domestic and service water heaters are controlled by differential thermostats.

Five types of solar energy systems are used to heat domestic and service hot water: thermosiphon, direct circulation, indirect, integral collector storage, and site built. Recirculation and draindown are used to protect direct solar water heaters from freezing.

Thermosiphon Systems

Thermosiphon systems (Figure 14) heat potable water or a heat transfer fluid and rely on natural convection to transport it from the collector to storage. For direct systems, pressure-reducing valves are required when the city water pressure is greater than the working pressure of the collectors. In a thermosiphon system, the storage tank must be elevated above the collectors, which sometimes requires designing the upper level floor and ceiling joists to bear this additional load. Extremely hard or acidic water can cause scale deposits that clog or corrode the absorber fluid passages. Thermosiphon flow is induced whenever there is sufficient sunshine, so these systems do not need pumps.

Direct-Circulation Systems

A direct-circulation system (Figure 15) pumps potable water from storage to the collectors when there is enough solar energy available to warm it. It then returns the heated water to the storage tank until it is needed. Collectors can be mounted either above or

Fig. 14 Thermosiphon System

Fig. 15 Direct Circulation System

below the storage tank. Direct-circulation systems are only feasible in areas where freezing is infrequent. Freeze protection is provided either by recirculating warm water from the storage tank or by flushing the collectors with cold water. Direct water-heating systems should not be used in areas where the water is extremely hard or acidic because scale deposits may clog or corrode the absorber fluid passages, rendering the system inoperable.

Direct-circulation systems are exposed to city water line pressures and must withstand pressures as required by local codes. Pressure-reducing valves and pressure-relief valves are required when city water pressure is greater than the working pressure of the collectors. Direct-circulation systems often use a single storage tank for both solar energy storage and the auxiliary water heater, but two-tank systems can be used.

Draindown Systems. Draindown systems (Figure 16) are direct-circulation water-heating systems in which potable water is pumped from storage to the collector array where it is heated. Circulation continues until usable solar heat is no longer available. When a freezing condition is anticipated or a power outage occurs, the system drains automatically by isolating the collector array and exterior piping from the city water pressure and using one or more

Fig. 16 Draindown System

Fig. 17 Indirect Water Heating

valves for draining. Solar collectors and associated piping must be carefully sloped to drain the collector's exterior piping.

Indirect Water-Heating Systems

Indirect water-heating systems (Figure 17) circulate a freeze-protected heat transfer fluid through the closed collector loop to a heat exchanger, where its heat is transferred to the potable water. The most commonly used heat transfer fluids are water/ethylene glycol and water/propylene glycol solutions, although other heat transfer fluids such as silicone oils, hydrocarbons, and refrigerants can also be used (ASHRAE 1983). These fluids are nonpotable, sometimes toxic, and normally require double-wall heat exchangers. The double-wall heat exchanger can be located inside the storage tank, or an external heat exchanger can be used. The collector loop is closed and therefore requires an expansion tank and a pressure-relief valve. A one- or two-tank storage can be used. Additional overtemperature protection may be needed to prevent the collector fluid from decomposing or becoming corrosive.

Designers should avoid automatic water makeup in systems using water/antifreeze solutions because a significant leak may raise the freezing temperature of the solution above the ambient temperature, causing the collector array and exterior piping to freeze. Also,

Fig. 18 Drainback System

antifreeze systems with large collector arrays and long pipe runs may need a time-delayed bypass loop around the heat exchanger to avoid freezing the heat exchanger on start-up.

Drainback Systems. Drainback systems are generally indirect water-heating systems that circulate treated (typically demineralized water or 50% glycol/water) or untreated water through the closed collector loop to a heat exchanger, where its heat is transferred to the potable water. Circulation continues until usable energy is no longer available. When the pump stops, the collector fluid drains by gravity to a storage or tank. In a pressurized system, the tank also serves as an expansion tank, so it must have a temperature- and pressure-relief valve to protect against excessive pressure. In an unpressurized system (Figure 18), the tank is open and vented to the atmosphere.

The collector loop is isolated from the potable water, so valves are not needed to actuate draining, and scaling is not a problem. The collector array and exterior piping must be sloped to drain completely, and the pumping pressure must be sufficient to lift water to the top of the collector array.

Integral Collector Storage Systems

Integral collector storage (ICS) systems use hot-water storage as part of the collector. Some types use the surface of a single tank as the absorber, and others use multiple long, thin tanks placed side by side horizontally to form the absorber surface. In this latter type of ICS, hot water is drawn from the top tank, and cold replacement water enters the bottom tank. Because of the greater nighttime heat loss from ICS systems, they are typically less efficient than pumped systems, and using selective surfaces (see Chapter 37 of the 2012 *ASHRAE Handbook—Systems and Equipment*) is strongly recommended. ICS systems are normally installed as a solar preheater without pumps or controllers. Flow through the ICS system occurs on demand, as hot water flows from the collector to a hot-water auxiliary tank in the structure.

SRCC provides annual performance results for these various types of systems at www.solar-rating.org.

Site-Built Systems

Site-built, large-volume solar air- or water-heating equipment is used in commercial and industrial applications. These site-built systems are based on a transpired solar collector for air heating and shallow solar pond technologies.

Transpired Solar Collector. This collector preheats outdoor air by drawing it through small holes in a metal panel. It is typically installed on south-facing walls and is designed to heat outdoor air for

Fig. 19 Shallow Solar Pond

building ventilation or process applications (Kutscher 1996). The prefabricated panel, made of dark metal with thousands of small holes, efficiently heats and captures fresh air by drawing it through a perforated adsorber, eliminating the cost and reflection losses associated with a glazing. The sun heats the metal panel, which in turn heats a boundary layer of air on its surface. Air is heated as it is drawn through the small holes into a ventilation system for delivery as ventilation air, for crop drying, or other process applications (Shukla et al. 2012).

Shallow Solar Pond. The shallow solar pond (SSP) is a large-scale ICS solar water heater (Figure 19) capable of providing more than 5000 gal of hot water per day for commercial and industrial use. These ponds are built in standard modules and tied together to supply the required load. The SSP module can be ground mounted or installed on a roof. It is typically 16 ft wide and up to 200 ft long. The module contains one or two flat water bags similar to a water bed. The bags rest on a layer of insulation inside concrete or fiberglass curbs. The bag is protected against damage and heat loss by greenhouse glazing. A typical pond filled to a 4 in. depth holds approximately 6000 gal of water.

Pool Heaters

Solar pool heaters do not require a separate storage tank, because the pool itself serves as storage. In most cases, the pool's filtration pump forces the water through the solar panels or plastic pipes. In some retrofit applications, a larger pump may be required to handle the solar heater's needs, or a small pump may be added to boost pool water to the solar collectors.

Automatic control may be used to direct the flow of filtered water to the collectors when solar heat is available; this may also be accomplished manually. Normally, solar heaters are designed to drain down into the pool when the pump is turned off; this provides the collectors with freeze protection.

Four primary types of collector designs are used for swimming pool heat: (1) rigid black plastic panels (polypropylene), usually 4 by 10 ft or 4 by 8 ft; (2) tube-on-sheet panels, which usually have a metal deck (copper or aluminum) with copper water tubes; (3) an ethylene-propylene diene monomer (or ethylene-propylene terpolymer) (EPDM) rubber mat, extruded with water passages running its length; and (4) arrays of black plastic pipe, usually 1.5 in. diameter acrylonitrile butadiene styrene (ABS) plastic (Root et al. 1985).

Hot-Water Recirculation

Domestic hot-water (DHW) recirculation systems (Figures 20 and 21), which continuously circulate domestic hot water throughout a building, are found in motels, hotels, hospitals, dormitories, office buildings, and other commercial buildings. Recirculation heat losses in these systems are usually a significant part of the total water-heating load. In Figures 20 and 21, the three-way valve

Fig. 20 DHW Recirculation System

Fig. 21 DHW Recirculation System with Makeup Preheat

prevents heated water from returning to the solar storage tank when the return temperature is greater than the solar tank temperature. This ensures that heated water is used only when it is hot enough and prevents heating of the solar tank by the conventional heater. Using a cycle timer to control the DHW circulating pump that is synchronized with the building hot-water consumption profile can also help reduce circulation losses. The return line on the makeup preheat system can go directly to the conventional water heater to eliminate the three-way valve and prevent the solar tank from being heated by auxiliary energy.

5. SOLAR HEATING AND COOLING SYSTEMS

The components and subsystems discussed previously may be combined to create a wide variety of solar heating and cooling systems. These systems fall into two principal categories: passive and active.

Passive solar systems require little, if any, nonrenewable energy to make them function (Yellott 1977; Yellott et al. 1976). Every building is passive in the sense that the sun tends to warm it by day, and it loses heat at night. Passive systems incorporate solar collection, storage, and distribution into the architectural design of the building and make minimal or no use of fans to deliver the collected energy to the conditioned spaces. Passive solar heating, cooling, and lighting design must consider the building envelope and its orientation, the thermal storage mass, and window configuration and design. Athienitis and Santamouris (2002), Balcomb et al. (1984), DOE (1980/1982), LBL (1981), and Mazria (1979) give estimates of energy savings resulting from the application of passive solar design concepts.

Active solar systems use either liquid or air as the collector fluid. Active systems must have a continuous availability of electricity to operate pumps and fans. A complete system includes solar

collectors, energy storage devices, and pumps or fans for transferring energy to storage or to the load. The load can be space cooling, heating, or hot water. Although it is technically possible to construct a solar heating and cooling system to supply 100% of the design load, such a system would be uneconomical and oversized. The size of the solar system, and thus its ability to meet the load, is determined by life-cycle cost analysis that weighs the cost of energy saved against the amortized solar cost.

Active solar energy systems have been combined with heat pumps for water and/or space heating. The most economical arrangement in residential heating is a solar system in parallel with a heat pump, which supplies auxiliary energy when the solar source is not available. For domestic water systems requiring high water temperatures, a heat pump placed in series with the solar storage tank may be advantageous. Freeman et al. (1979) and Morehouse and Hughes (1979) present information on performance and estimated energy savings for solar-heat pumps.

Hybrid systems combine elements of both active and passive systems. They require some nonrenewable energy, but the amount is so small that they can maintain a coefficient of performance (COP) of about 50. An example is a floor slab thermal storage system that reradiates heat to a load (e.g., a building conditioned space) from a thermal mass surface after having been charged using an air collection system where insulated ducts feed warm air into cavities created within the heat storage slab (Howard 1986). Combining passive with active solar systems and other renewable energy sources is often the most satisfactory way to achieve very high annual solar savings (Swift and Lawrence 2010).

Passive Systems

A well-designed passive solar building needs (1) an appropriate thermal load (i.e., minimize heating loads first); (2) aperture, such as clear, glazed windows; (3) thermal storage (e.g., massive floors or walls, containers of water) to minimize overheating and to allow use of heat at night; (4) control, either manual or automatic, to address overheating; and (5) night insulation of the aperture so that there is not a net heat loss (Swift and Lawrence 2010). Passive systems may be divided into several categories. The first residence to which the name **solar house** was applied used a large expanse of south-facing glass to admit solar radiation; this is known as a **direct-gain** passive system. The solar collector (windows) and storage (e.g., floors, walls) are part of the occupied space and typically have the highest percent of heating load met by solar. The optimal amount of thermal mass is often around 8 in. thick high-density concrete for direct-gain floors over conditioned basements. Optimization requires a design concept that captures and stores the highest amount of solar energy without unnecessarily increasing cost or complexity. Direct-gain surfaces should have high absorptivity (dark color) and should not be covered by carpet, tile, much furniture, or other obstacles that prevent absorption of available solar radiation. To reduce heat losses, thermal mass should be well insulated from the outdoor environment or ground.

Indirect-gain passive systems use the south-facing wall surface or the roof to absorb solar radiation, which causes a rise in temperature that, in turn, conveys heat into the building in several ways. This principle was applied to the pueblos and cliff dwellings of the southwestern United States. Glass has led to modern adaptations of the indirect-gain principle (Balcomb et al. 1977; Trombe et al. 1977; Wilson 1979).

By glazing a large south-facing, massive masonry wall, solar energy can be absorbed during the day, and heat conduction to the inner surface provides radiant heating at night. The wall's mass and its relatively low thermal diffusivity delay the heat's arrival at the indoor surface until it is needed. The glazing reduces heat loss from the wall back to the atmosphere and increases the system's collection efficiency.

Openings in the wall near the floor and ceiling allow convection to transfer heat to the room. Air in the space between the glass and the wall warms as soon as the sun heats the outer surface of the wall. The heated air rises and enters the building through the upper openings. Cool air flows through the lower openings, and convective heat gain can be established as long as the sun is shining.

In another indirect-gain passive system, a metal roof/ceiling supports transparent plastic bags filled with water (Hay and Yellott 1969). Movable insulation above these water-filled bags is rolled away during the winter day to allow the sun to warm the stored water. The water then transmits heat indoors by convection and radiation. The insulation remains over the water bags at night or during overcast days. During the summer, the water bags are exposed at night for cooling by (1) convection, (2) radiation, and (3) evaporation of water on the bags. The insulation covers the water bags during the day to protect them from unwanted irradiation. Pittenger et al. (1978) tested a building for which water rather than insulation was moved to provide summer cooling and winter heating.

Attached greenhouses (sunspaces) can be used as solar attachments when the orientation and other local conditions are suitable. The greenhouse can provide a buffer between the exterior wall of the building and the outdoors. During daylight, warm air from the greenhouse can be introduced into the house by natural convection or a small fan.

In most passive systems, control is accomplished by moving a component that regulates the amount of solar radiation admitted into the structure. Manually operated window shades or venetian blinds are the most widely used and simplest controls, but they may also be operated automatically.

Passive heating and cooling systems have been effective in field demonstrations. A well-designed passive-solar-heated building may provide 45 to nearly 100% of daily heat requirements. Architectural design features can dramatically reduce air-conditioning loads through heat gain avoidance techniques and natural cooling, where climatically appropriate (Howard and Pollock 1982; Howard and Saunders 1989).

Passive solar daylighting has been shown to be cost effective, providing dual benefits: it both reduces electric power demand and lowers cooling costs in properly designed interiors and atrium spaces.

6. COOLING BY NOCTURNAL RADIATION AND EVAPORATION

Radiative cooling is a natural heat loss that causes formation of dew, frost, and ground fog. Because its effects are the most obvious at night, it is sometimes termed **nocturnal radiation**, although the process continues throughout the day. Thermal infrared radiation, which affects the surface temperature of a building wall or roof, may be estimated by using the **sol-air temperature** concept. Radiative cooling of window and skylight surfaces can be significant, especially under winter conditions when the dew-point temperature is low.

The most useful parameter for characterizing the radiative heat transfer between horizontal nonspectral emitting surfaces and the sky is the **sky temperature** T_{sky} . If S designates the total downward radiant heat flux emitted by the atmosphere, then T_{sky} is defined as

$$T_{sky}^4 = S/\sigma \quad (25)$$

where $\sigma = 0.1712 \times 10^{-8}$ Btu/h·ft²·°R⁴.

The sky radiance is treated as if it originates from a blackbody emitter of temperature T_{sky} . The **net radiative cooling rate** R_{net} of a horizontal surface with absolute temperature T_{rad} and a nonspectral emittance ϵ is then

$$R_{net} = \epsilon\sigma(T_{rad}^4 - T_{sky}^4) \quad (26)$$

Values of ϵ for most nonmetallic construction materials are about 0.9.

Radiative building cooling has not been fully developed. Design methods and performance data compiled by Hay and Yellott (1969) and Marlatt et al. (1984) are available for residential roof ponds that use a sealed volume of water covered by sliding insulation panels as the combined rooftop radiator and thermal storage. Other conceptual radiative cooling designs have been proposed, but more developmental work is required (Erell and Etzion 2000; Givoni 1981; Mitchell and Biggs 1979).

The sky temperature is a function of atmospheric water vapor, amount of cloud cover, and air temperature; the lowest sky temperatures occur under an arid, cloudless sky. The monthly average sky temperature depression, which is the average of the difference between the ambient air temperature and the sky temperature, typically is between 9 and 43°F throughout the continental United States. Martin and Berdahl (1984) calculated this quantity using hourly weather data from 193 sites, as shown in the contour map for the month of July (Figure 22).

The sky temperature may be too high at night to effectively cool the structure. Martin and Berdahl (1984) suggest that the sky temperature should be less than 61°F to achieve reasonable cooling in July (Figure 23). In regions where sky temperatures fall below 61°F 40% or more of the month, all nighttime hours are effectively available for radiative cooling.

Fig. 22 Average Monthly Sky Temperature Depression ($T_{air} - T_{sky}$) for July, °F
(Adapted from Martin and Berdahl 1984)

Fig. 23 Percentage of Monthly Hours when Sky Temperature Falls below 61°F
(Adapted from Martin and Berdahl 1984)

Clark (1981) modeled a horizontal radiator at various surface temperatures in convective contact with outdoor air for 77 U.S. locations. The average monthly cooling rates for a surface temperature of 76°F are plotted in Figure 24. If effective steps are taken to reduce the surface convection coefficient by modifying the radiator geometry or using an infrared-transparent glazing, it may be possible to improve performance beyond these values.

Argiriou et al. (1993) calculated the sky temperature depression and useful cooling energy of a typical flat-plate radiative air cooler at 28 southern European and four southeastern U.S. cities, to estimate the effectiveness and feasibility of radiative cooling applications. The mean daily useful cooling energy delivered ranges between 17 and 66 Btu/ft² for average sky conditions and 22 and 70 Btu/ft² for clear-sky conditions. For areas with high humidity levels, such as the southeastern United States, the potential effectiveness is limited to 13 to 43 Btu/ft² for average sky conditions and 22 to 58 Btu/ft² for clear-sky conditions. Using a wind screen can improve performance at locations that are dominated by high wind speeds.

Active Systems

Active systems absorb solar radiation with collectors and convey it to storage using a suitable fluid. As heat is needed, it is obtained from storage via heated air or water. Control is exercised by several types of thermostats, the first being a differential device that starts the flow of fluid through the collectors when they have been sufficiently warmed by the sun. It also stops fluid flow when the collectors no longer gain heat. In locations where freezing occurs only rarely, a low-temperature sensor on the collector controls a circulating pump when freezing is impending. This process wastes some stored heat, but it prevents costly damage to the collector panels. This system is not suitable for regions where freezing temperatures persist for long periods.

The space-heating thermostat is generally the conventional double-contact type that calls for heat when the temperature in the controlled space falls to a predetermined level. If the temperature in storage is adequate to meet the heating requirement, a pump or fan starts to circulate the warm fluid. If the temperature in the storage subsystem is inadequate, the thermostat calls on the auxiliary or standby heat source.

Space Heating and Service Hot Water

Solar combi systems are solar heating installations providing space heating as well as domestic hot water for the building occupants (IEA Task 26). The primary energy sources are solar and an

Fig. 24 July Nocturnal Net Radiative Cooling Rate from Horizontal Dry Surface at 76°F
(Adapted from Clark 1981)

auxiliary source such as biomass, gas, oil, or electricity, either direct or with a heat pump. The solar contribution (the part of the heating demand met by solar energy) varies from 10% to 100%, depending on the size of the solar collector surface, storage volume, heat load, and climate. Europe has the most well-developed market for different solar thermal applications (Balaras et al. 2010). The European market share of combi systems in 2006 was about 5% of the total solar thermal market. The total capacity of glazed and evacuated tube solar collectors for solar combi systems already have a market share of almost 40% in Austria, about 35% in Switzerland, 20% in the Netherlands, 15% in Denmark, and 5% in France; the German market share of combi systems reached 45% of newly installed solar systems in 2007.

Figure 25 shows one of the many systems for service hot water and space heating. In this case, a large, atmospheric-pressure storage tank is used, from which water is pumped to the collectors by pump P_1 in response to the differential thermostat T_1 . Drainback is used to prevent freezing, because the amount of antifreeze required would be prohibitively expensive. Service hot water is obtained by placing a heat exchanger coil in the tank near the top, where, even if stratification occurs, the hottest water will be found.

An auxiliary water heater boosts the temperature of the sun-heated water when required. Thermostat T_2 senses the indoor temperature and starts pump P_2 when heat is needed. If water in the storage tank becomes too cool to provide enough heat, the second contact on the thermostat calls for heat from the auxiliary heater.

Standby heat becomes increasingly important as heating requirements increase. The heating load, winter availability of solar radiation, and cost and availability of the auxiliary energy must be determined. It is rarely cost effective to do the entire heating job for either space or service hot water by using the solar heat collection and storage system alone.

Electric resistance heaters have the lowest first cost, but often have high operating costs. Water-to-air heat pumps, which use sun-heated water from the storage tank as the evaporator energy source, are an alternative auxiliary heat source. The heat pump's COP is 10 to 14 Btu of heat for each watt-hour of energy supplied to the compressor. When summer cooling as well as winter heating are needed, the heat pump is a logical solution, particularly in large systems where a cooling tower is used to dissipate the heat withdrawn from the system.

Fig. 25 Solar Collection, Storage, and Distribution System for Domestic Hot Water and Space Heating

The system shown in Figure 25 may be retrofitted into a warm-air furnace. In such systems, the primary heater is deleted from the space heating circuit, and the coil is located in the return duct of the existing furnace. Full back-up is thus obtained, and the auxiliary heater provides only the heat not available at the storage temperature.

7. COOLING BY SOLAR ENERGY

Peak cooling demand in summer coincides with high solar radiation availability; this creates an excellent opportunity to exploit solar energy with heat-driven cooling machines. The main obstacle for large-scale applications, beside the currently high first cost, is the lack of practical experience with the design, control, operation, installation, and maintenance of these systems. For low-power cooling systems, there are limited commercially available technologies, but strong ongoing research. Photovoltaic-operated refrigeration cycles and solar mechanical refrigeration have also applications of practical interest (Klein and Reindl 2005).

Swartman et al. (1974) emphasize various absorption systems. Newton (in Jordan and Liu 1977) discusses commercially available water vapor/lithium bromide absorption refrigeration systems. Standard absorption chillers are generally designed to give rated capacity for activating fluid temperatures well above 200°F at full load and design condenser water temperature. Few flat-plate collectors can operate efficiently in this range; therefore, a lower hot-fluid temperature is used when solar energy provides the heat. Both condenser water temperature and percentage of design load are determinants of the optimum energizing temperature, which can be quite low, sometimes below 120°F. Proper control can raise the COP at these part-load conditions.

Many large commercial or institutional cooling installations must operate year round, and Newton (in Jordan and Liu 1977) showed that the low-temperature cooling water available in winter enables the LiBr/H₂O to function well with a hot-fluid inlet temperature below 190°F. Residential chillers in sizes as low as 1.5 tons, with an inlet temperature in the range of 175°F, have been developed. An overview of various European installations is presented in Balaras et al. (2010). Ongoing international efforts are also reviewed in IEA Task 38.

Solar Cooling with Absorption Refrigeration

When solar energy is used for cooling as well as for heating, the absorption system shown in Figure 26 or one of its many modifications may be used. The collector and storage must operate at a temperature approaching 200°F on hot summer days when the water from the cooling tower exceeds 80°F, but considerably lower operating water temperatures may be used when cooler water is available from the tower. Controls for collection, cooling, and distribution are generally separated, with the circulating pump P_1 operating in response to the collector thermostat T_1 . Thermostat T_2 senses the indoor air-conditioned space temperature. When T_2 calls for heating, valves V_1 and V_2 direct water flow from the storage tank through the unactivated auxiliary heater to the fan-coil in the air distribution system. The fan F_2 in this unit may respond to the thermostat also, or it may have its own control circuit so that it can bring in outdoor air when the temperature is suitable.

When thermostat T_2 calls for cooling, the valves direct hot water into the absorption unit's generator, and pumps P_3 and P_4 are activated to pump cooling tower water through the absorber and condenser circuits and chilled water through the cooling coil in the air distribution system. A relatively large hot-water storage tank allows the unit to operate when no sunshine is available. A chilled-water storage tank (not shown) may be added so that the absorption unit can operate during the day whenever water is available at a sufficiently high temperature to make the unit function properly. The

Fig. 26 Space Heating and Cooling System Using Lithium Bromide/Water Absorption Chiller

COP of a typical lithium bromide/water absorption unit may be as high as 0.75 under favorable conditions, but frequent on/off cycling of the unit to meet a high variable load may cause significant loss in performance because the unit must be heated to operating temperature after each shutdown. Modulating systems are analyzed differently than on/off systems.

Water-cooled condensers are required with the absorption cycles, because the lithium bromide/water cycle operates with a relatively delicate balance among the temperatures of the three fluid circuits (cooling tower water, chilled water, and activating water). Steam-operated absorption systems, from which solar cooling systems are derived, customarily operate at energizing temperatures of 230 to 240°F, but these are above the capability of most flat-plate collectors. The solar cooling units are designed to operate at considerably lower temperature, but unit ratings are also lowered.

Smaller domestic units may operate with natural circulation, or **percolation**, which carries the lithium bromide/water solution from the generator (to which the activating heat is supplied) to the separator and condenser; there, the reconcentrated LiBr is returned to the absorber while the water vapor goes to the condenser before being returned to the evaporator, where cooling occurs. Larger units use a centrifugal pump to transfer the fluid.

Design, Control, and Operation Guidelines

Absorption is the most popular heat-driven cooling technology, although different sorption technologies are also available (e.g. adsorption, see Chapter 32 of the 2013 *ASHRAE Handbook—Fundamentals*). Each technology has specific characteristics that match the building's HVAC design, loads, and local climatic conditions. A good design must first exploit all available solar radiation and then cover the remaining loads from conventional sources (Henning 2007).

Proper calculations for collector and storage size depend on the solar cooling technology used. A hot-water storage may be integrated between the solar collectors and the heat-driven chiller to dampen fluctuations in the return temperature of the hot water from the chiller. Storage size depends on the application: when cooling loads mainly occur during the day, a smaller storage is necessary than when the loads peak in the evening. Strictly avoid heating the hot-water storage by the back-up heat source. The storage only

exists to store excess heat of the solar system and to make it available when sufficient solar heat is not available.

The single-effect absorption machine gives best results with a heat supply temperature of 176 to 212°F. Double- and triple-effect machines require higher supply temperatures. Therefore, these machines require a higher-temperature collector. However, with a double-effect system, if the solar-supplied temperature drops below 212°F, the performance drops sharply, below that of a single-effect.

Most large-scale applications (85 ton and up) use LiBr/H₂O and produce chilled water at about 43 to 45°F; the COP is relatively higher than for H₂O/ammonia (NH₃). However, LiBr systems must be water cooled and thus usually require a cooling tower, whereas NH₃ systems can have an air-cooled condenser. Because of the large vapor volume of the water refrigerant, LiBr/H₂O chillers usually have large physical dimensions. For small cooling loads and for applications where it is not possible to use water cooling, an H₂O/NH₃ system is preferred.

In hot and sunny climates, the required solar collector area is approximately 114 to 152 ft²/ton. Higher heat supply temperature for multieffect chillers require higher-cost evacuated tube or concentrating collectors, and may need a high-temperature (i.e., thermochemical) storage.

In LiBr/H₂O systems, the refrigerant freezes at 32°F, so care is necessary while the machine is idle, especially in winter. Another potential problem is crystallization of the LiBr solution at high concentrations, which may result from high generator temperatures or from inadequate temperature control at other parts of the machine. Thus, the heat supply temperature from the solar collectors or heat storage must be adequately controlled. The cooling water temperature, particularly to the absorber, must also be monitored. Chiller capacity may be controlled by increasing the heat supply temperature or decreasing the cooling water temperature; both techniques increase capacity as well as the COP.

A fuel-fired boiler usually covers the need for a back-up system to heat the desorber of the heat-driven chiller. However, use caution because, during periods of low solar radiation availability, collectors connected in series with a back-up boiler can turn into a heat sink instead of a heat source. Alternatively, one may use a back-up conventional chiller alongside the solar-assisted machine, but this requires an additional full-sized chiller, which would be idle for long periods. A viable design solution for a single-effect absorption cycle is to incorporate an auxiliary desorber powered by the back-up, whereas the original desorber is powered by solar heat. The weak solution goes first to the solar-powered desorber, where it is concentrated as much as possible with the available solar heat, and then proceeds to the auxiliary desorber, where it is concentrated further using heat from the back-up source. Vapor from both desorbers is then supplied to the condenser.

8. SIZING SOLAR HEATING AND COOLING SYSTEMS: ENERGY REQUIREMENTS

Methods used to determine solar heating and/or cooling energy requirements for both active and passive/hybrid systems are described by Feldman and Merriam (1979) and Hunn et al. (1987). Descriptions of public- and private-domain methods are included. The following simulation techniques are suitable for active heating and cooling systems analysis, and for passive/hybrid heating, cooling, and lighting analysis.

Performance Evaluation Methods

The performance of any solar energy system is directly related to the (1) heating load, (2) amount of solar radiation available, and (3) solar energy system characteristics. Various calculation methods use different procedures and data when considering the available solar radiation. Some simplified methods consider only average

annual incident solar radiation; complex methods may use hourly data.

Solar energy system characteristics, as well as individual component characteristics, are required to evaluate performance. The degree of complexity with which these systems and components are described varies from system to system.

The cost effectiveness of a solar domestic and service hot-water heating system depends on the initial cost and energy cost savings. A major task is to determine how much energy is saved. The **annual solar fraction** (the annual solar contribution to the water-heating load divided by the total water-heating load) can be used to estimate these savings. It is expressed as a decimal or percentage and generally ranges from 0.3 to 0.8 (30 to 80%), although more extreme values are possible.

Simplified Analysis Methods

A very simplified way to initially estimate the size of a solar heating system is to divide the average daily load by the daily output of a particular collector based on its SRCC rating for the application and solar conditions. This requires knowledge of the average daily incident solar radiation for the site and the type of collector best suited to the application. See Chapter 37 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for more information.

Simplified analysis methods have the advantages of computational speed, low cost, rapid turnaround (especially important during iterative design phases), and ease of use by persons with little technical experience. Disadvantages include limited flexibility for design optimization, lack of control over assumptions, and a limited selection of systems that can be analyzed. Thus, if the application, configuration, or load characteristics under consideration are significantly nonstandard, a detailed computer simulation may be required to achieve accurate results. This section describes the *f*-Chart method for active solar heating and the solar load ratio method for passive solar heating (Dickinson and Cheremisinoff 1980; Klein and Beckman 1979; Lunde 1980).

Water-Heating Load

The amount of hot water required must be estimated accurately because it affects component selection. Oversized storage may result in low-temperature water that requires auxiliary heating to reach the desired supply temperature. Undersizing can prevent the collection and use of available solar energy. Chapter 50 gives methods to determine the load.

Active Heating/Cooling

Beckman et al. (1977) developed the *f*-Chart method using an hourly simulation program (Klein et al. 1976) to evaluate space heating and service water heating in many climates and conditions. The results of these analyses correlate the fraction *f* of the heat load met by solar energy. The correlations give the fraction *f* of the monthly heating load (for space heating and hot water) supplied by solar energy as a function of collector characteristics, heating loads, and weather. The standard error of the differences between detailed simulations in 14 locations in the United States and the *f*-Chart predictions was about 2.5%. Correlations also agree within the accuracy of measurements of long-term performance data. Beckman et al. (1977, 1981) and Duffie and Beckman (2006) discuss the method in detail.

The *f*-Chart method requires the following data:

- Monthly average daily radiation on a horizontal surface
- Monthly average ambient temperatures
- Collector thermal performance curve slope and intercept from standard collector tests; that is, $F_R U_L$ and $F_R(\tau\alpha)_n$ (see ASHRAE Standard 93 and Chapter 37 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*)
- Monthly space- and water-heating loads

Standard Systems

The *f*-Chart assumes several standard systems and applies only to these liquid configurations. The standard **liquid heater** uses water, an antifreeze solution, or air as the heat transfer fluid in the collector loop and water as the storage medium (Figure 27). Energy is stored in the form of sensible heat in a water tank. A water-to-air heat exchanger transfers heat from the storage tank to the building. A liquid-to-liquid heat exchanger transfers energy from the main storage tank to a domestic hot-water preheat tank, which in turn supplies solar-heated water to a conventional water heater. A conventional furnace or heat pump is used to meet the space heating load when energy in the storage tank is depleted.

Figure 28 shows the assumed configuration for a **solar air heater** with a pebble-bed storage unit. Energy for domestic hot water is provided by heat exchange from air leaving the collector to a domestic water preheat tank, as in the liquid system. The hot water is further heated, if necessary, by a conventional water heater. During summer operation, a seasonal, manually operated storage bypass damper is used to avoid heat loss from the hot bed into the building.

The standard **solar domestic water heater** collector heats either air or liquid. Collected energy is transferred by a heat exchanger to a domestic water preheat tank that supplies solar-heated water to a conventional water heater. The water is further heated to the desired temperature by conventional fuel if necessary.

Fig. 28 Solar Air Heating System

(Adapted from Beckman et al. 1977)

f-Chart Method

Computer simulations correlate dimensionless variables and the long-term performance of the systems. The fraction f of the monthly space- and water-heating loads supplied by solar energy is empirically related to two dimensionless groups. The first dimensionless group X is collector loss; the second Y is collector gain:

$$X = \frac{F_R U_L A_c \Delta \theta \left(\frac{F_r}{F_R} \right) (t_{ref} - \bar{t}_a)}{L} \quad (27)$$

$$Y = \frac{F_R (\tau \alpha)_n \bar{H}_T N A_c \left(\frac{F_r}{F_R} \right) \left[\frac{(\bar{\tau} \alpha)}{(\tau \alpha)_n} \right]}{L} \quad (28)$$

where

- A_c = area of solar collector, ft²
- F_r = collector heat exchanger efficiency factor
- F_R = collector efficiency factor
- U_L = collector overall energy loss coefficient, Btu/h·ft²·°F
- $\Delta \theta$ = total number of hours in month
- \bar{t}_a = monthly average ambient temperature, °F
- L = monthly total heating load for space heating and hot water, Btu
- \bar{H}_T = monthly averaged daily radiation incident on collector surface per unit area, Btu/day·ft²
- N = number of days in month
- $(\bar{\tau} \alpha)$ = monthly average transmittance-absorptance product
- $(\tau \alpha)_n$ = normal transmittance-absorptance product
- t_{ref} = reference temperature, 212°F

$F_R U_L$ and $F_R (\tau \alpha)_n$ are obtained from collector test results. The ratios F_r/F_R and $(\bar{\tau} \alpha)/(\tau \alpha)_n$ are calculated using methods given by Beckman et al. (1977). The value of \bar{t}_a is obtained from meteorological records for the month and location desired. \bar{H}_T is calculated from the monthly averaged daily radiation on a horizontal surface by the methods previously discussed in this chapter or in Duffie and Beckman (2006). The monthly load L can be determined by any appropriate load-estimating method, including analytical techniques or measurements. Values of the collector area A_c are selected for the calculations. Thus, all the terms in these equations can be determined from available information.

Transmittance τ of the transparent collector cover and the absorptance α of the absorber plate depend on the angle of incidence of solar radiation on the collector surface. Collector tests are usually run with the radiation nearly perpendicularly incident on the collector. Thus, the value of $F_R (\tau \alpha)_n$ determined from these tests ordinarily corresponds to the transmittance and absorptance values for radiation at normal incidence. Depending on collector orientation and time of year, the monthly average values of transmittance and absorptance can be significantly lower. The f -Chart method requires knowledge of the ratio of the monthly average to normal incidence transmittance-absorptance.

The f -Chart method for liquid systems is similar to that for air systems. The fraction of the monthly total heating load supplied by the solar air heating system is correlated with the dimensionless groups X and Y , as shown in Figure 29. To determine the fraction of the heating load supplied by solar energy for a month, values of X and Y are calculated for the collector and heating load in question. The value of f is determined at the intersection of X and Y on the f -Chart, or from the following equivalent equations.

Air system:

$$f = 1.04Y - 0.065X - 0.159Y^2 + 0.00187X^2 - 0.0095Y^3 \quad (29)$$

Fig. 29 Chart for Air System
(Adapted from Beckman et al. 1977)

Liquid system:

$$f = 1.029Y - 0.065X - 0.245Y^2 + 0.0018X^2 - 0.025Y^3 \quad (30)$$

This is done for each month of the year. The solar energy contribution for the month is the product of f and the total heating load L for the month. Finally, the fraction F of the annual heating load supplied by solar energy is the sum of the monthly solar energy contributions divided by the annual load:

$$F = \sum fL / \sum L$$

Example 6. Calculating the heating performance of a residence, assume that a solar heating system is to be designed for use in Madison, WI, with two-cover collectors facing south, inclined 58° with respect to the horizontal. The air heating collectors have the characteristics $F_R U_L = 0.50$ Btu/h·ft²·°F and $F_R (\tau \alpha)_n = 0.49$. The \bar{t}_a is 19.4°F, the total space and water-heating load for January is 34.1×10^6 Btu, and the solar radiation incident on the plane of the collector is 1.16×10^3 Btu/day·ft². Determine the fraction of the load supplied by solar energy with a system having a collector area of 538.2 ft².

Solution: For air systems, there is no heat exchanger penalty factor and $F_r/F_R = 1$. The value of $(\bar{\tau} \alpha)/(\tau \alpha)_n$ is 0.94 for a two-cover collector in January. Therefore, the values of X and Y are

$$X = 0.50(1)(212 - 19.4)(31)(24)(538.2)/(34.1 \times 10^6) = 1.13$$

$$Y = (0.49)(1)(0.94)(1.16 \times 10^3)(31)(538.2)/(34.1 \times 10^6) = 0.26$$

Then the fraction f of the energy supplied for January is 0.19. The total solar energy supplied by this system in January is

$$fL = (0.19)(34.1 \times 10^6) = 6.4 \times 10^6 \text{ Btu}$$

The annual system performance is obtained by summing the energy quantities for all months. The result is that 37% of the annual load is supplied by solar energy.

The collector heat removal factor F_R that appears in X and Y is a function of the collector fluid flow rate. Because of the higher cost of power for moving fluid through air collectors than through liquid collectors, the capacitance rate used in air heaters is ordinarily much lower than that in liquid heaters. As a result, air heaters generally have a lower F_R . Values of F_R corresponding to the expected airflow in the collector must be used to calculate X and Y .

Increased airflow rate tends to improve collector performance by increasing F_R , but it tends to decrease performance by reducing the degree of thermal stratification in the pebble bed (or water storage tank). The f -Chart for air systems is based on a collector airflow rate of 2 scfm per square foot of collector area. The performance with different collector airflow rates can be estimated by using the appropriate values of F_R in both X and Y . A further modification to the value of X is required to account for the change in degree of stratification in the pebble bed.

Air system performance is less sensitive to storage capacity than that of liquid systems for two reasons: (1) air systems can operate with air delivered directly to the building in which storage is not used, and (2) pebble beds are highly stratified and additional capacity is effectively added to the cold end of the bed, which is seldom heated and cooled to the same extent as the hot end. The f -Chart for air systems is for a nominal storage capacity. Performance of systems with other storage capacities can be determined by modifying the dimensionless group X as described in Beckman et al. (1977).

With modification, f -Charts can be used to estimate performance of solar water heating operating in the range of 120 to 160°F. The main water supply temperature and minimum acceptable hot-water temperature (i.e., desired delivery temperature) both affect the performance of solar water heating. The dimensionless group X , which is related to collector energy loss, can be redefined to include these effects. If monthly values of X are multiplied by a correction factor, the f -Chart for liquid-based solar space- and water-heating systems can be used to estimate monthly values of f for water heating. Experiments and analysis show that the load profile for a well-designed heater has little effect on long-term performance. Although the f -Chart was originally developed for two-tank systems, it may be applied to single- and double-tank domestic hot-water systems with and without collector tank heat exchangers. The standard f -Chart method is not designed to provide performance estimates of thermosiphon and ICS systems.

For industrial process heating, absorption air conditioning, or other processes for which the delivery temperature is outside the normal f -Chart range, modified f -Charts are applicable (Klein et al. 1976). The concept underlying these charts is that of solar usability, which is the fraction of the total solar energy that is useful in the given process. This fraction depends on the required delivery temperature as well as collector characteristics and solar radiation. The procedure allows the energy delivered to be calculated in a manner similar to that for f -Charts. An example of applying this method to solar-assisted heat pumps is presented in Svard et al. (1981).

Other Active Collector Methods

The **relative areas method**, based on correlations of the f -Chart method, predicts annual rather than monthly active heating performance (Barley and Winn 1978). An hourly simulation program was used to develop the **monthly solar-load ratio (SLR) method**, another simplified procedure for residential systems (Dickinson and Cheremisinoff 1980). Based on hour-by-hour simulations, a method was devised to estimate performance based on monthly values of horizontal solar radiation and heating degree-days. This SLR method has also been extended to nonresidential buildings for a range of design water temperatures (Dickinson and Cheremisinoff 1980; Schnurr et al. 1981).

Passive Heating

A widely accepted simplified passive space heating design tool is the solar-load ratio (SLR) method (Balcomb et al. 1984; DOE 1980/1982). It can be applied manually, although like the f -Chart, software is also available. The SLR method for passive systems is based on correlating results of multiple hour-by-hour computer simulations, the algorithms of which have been validated against test cell

data for the following generic passive heating types: direct gain, thermal storage wall, and attached sunspace. Monthly and annual performance, as expressed by the auxiliary heating requirement, is predicted by this method. The method applies to single-zone, envelope-dominated buildings. A simplified, annual-basis distillation of SLR results, the **load collector ratio (LCR) method**, and several simple-to-use rules have grown out of the SLR method. Several hand-held calculator and microcomputer programs have been written using the method (Nordham 1981).

The SLR method uses a single dimensionless correlating parameter (SLR), which Balcomb et al. (1982) define as a particular ratio of solar energy gains to building heating load:

$$\text{SLR} = \frac{\text{Solar energy absorbed}}{\text{Building heating load}} \quad (31)$$

A correlation period of 1 month is used; thus the quantities in the SLR are calculated for a 1 month period.

The parameter that is correlated to the SLR, the **solar savings fraction (SSF)**, is defined as

$$\text{SSF} = 1 - \frac{\text{Auxiliary heat}}{\text{Net reference load}} \quad (32)$$

The SSF measures the energy saving expected from the passive solar building, relative to a reference nonpassive solar building.

In Equation (32), the net reference load is equal to the degree-day load DD of the nonsolar elements of the building:

$$\text{Net reference load} = (\text{NLC})(\text{DD}) \quad (33)$$

where NLC is the net load coefficient, which is a modified UA coefficient computed by leaving out the solar elements of the building. The nominal units are Btu/°F·day. The term DD is the temperature departure in degree-days computed for an appropriate base temperature. A building energy analysis based on the SLR correlations begins with a calculation of the monthly SSF values. The monthly auxiliary heating requirement is then calculated by

$$\text{Auxiliary heat} = (\text{NLC})(\text{DD})(1 - \text{SSF}) \quad (34)$$

Annual auxiliary heat is calculated by summing the monthly values.

By definition, SSF is the fraction of the heat load of the nonsolar portions of the building met by the solar element. If the solar elements of the building (south-facing walls and window in the northern hemisphere) were replaced by other elements so that the net annual flow of heat through these elements was zero, the building's annual heat consumption would be the net reference load. The savings achieved by the solar elements would therefore be the net reference load in Equation (33) minus the auxiliary heat in Equation (34), which gives

$$\text{Solar savings} = (\text{NLC})(\text{DD})(\text{SSF}) \quad (35)$$

Although simple, in many situations and climates, Equation (35) is only approximately true because a normal solar-facing wall with a normal complement of opaque walls and windows has a near-zero effect over the entire heating season. In any case, the auxiliary heat estimate is the primary result and does not depend on this assumption.

The hour-by-hour simulations used as the basis for the SLR correlations are done with a detailed model of the building in which all the design parameters are specified. The only parameter that remains a variable is the solar collector area, which can be expressed in terms of the load collector ratio (LCR):

$$\text{LCR} = \frac{\text{NLC}}{A_p} = \frac{\text{Net load coefficient}}{\text{Projected collector area}} \quad (36)$$

Performance variations are estimated from the correlations, which allow the user to account directly for thermostat set point, internal heat generation, glazing orientation, and configuration, shading, and other solar radiation modifiers. Major solar system characteristics are accounted for by selecting one of 94 reference designs. Other design parameters, such as thermal storage thickness and conductivity, and the spacing between glazings, are included in a series of sensitivity calculations obtained using hour-by-hour simulations. The results are generally presented in graphic form so that the designer can see the effect of changing a particular parameter.

Solar radiation correlations for the collector area have been determined using hour-by-hour simulation and typical meteorological year (TMY) weather data. These correlations are expressed as ratios of incident-to-horizontal radiation, transmitted-to-incident radiation, and absorbed-to-transmitted radiation as a function of the latitude minus mid-month solar declination and the atmospheric clearness index (i.e., ratio between the actual clear-day direct irradiation intensity at a specific location and the intensity calculated for the standard atmosphere for the same location and date).

Performance predictions of the SLR method have been compared to predictions made by the detailed hour-by-hour simulations for a variety of climates in the United States. The standard error in the prediction of the annual SSF, compared to the hour-by-hour simulation, is typically 2 to 4%.

The annual solar savings fraction calculation involves summing the results of 12 monthly calculations. For a particular city, the resulting SSF depends only on the LCR of Equation (36), system type, and the temperature base used in calculating the temperature departure. Thus, tables that relate SSF to LCR for various systems and for various degree-day base temperatures may be generated for a particular city. Such tables are easier for hand analysis than are the SLR correlations.

Annual SSF versus LCR tables have been developed for 209 locations in the United States and 14 cities in southern Canada for 94 reference designs and 12 base temperatures (Balcomb et al. 1984). Fernandez-Gonzalez (2007) evaluates the thermal performance of five passive solar strategies (direct gain, Trombe wall, water wall, sunspace, and roof pond) under severe winter climates with predominant overcast sky conditions.

Example 7. [Abstracted from the detailed version in Balcomb et al. (1982).] Consider a small office building located in Denver, Colorado, with 3000 ft² of usable space and a sunspace entry foyer that faces due south; the vertically projected collector area A_p is 420 ft². A sketch and preliminary plan are shown in Figure 30. Distribution of solar heat to the offices is primarily by convection through the doorways from the sunspace. The principal thermal mass is in the common wall that separates the sunspace from the offices and in the sunspace floor. Even though lighting and cooling are likely to have the greatest energy costs for this building, heating is a significant energy item and should be addressed by a design that integrates passive solar heating, cooling, and lighting.

Solution: Table 3 shows calculations of the net load coefficient. Then,

$$\text{NLC} = 24 \times 525 = 12,600 \text{ Btu}/^\circ\text{F}\cdot\text{day}$$

and the total load coefficient includes the solar aperture

$$\text{TLC} = 24 \times 676 = 16,224 \text{ Btu}/^\circ\text{F}\cdot\text{day}$$

From Equation (36), the load collector ratio is

$$\text{LCR} = 12,600/420 = 30 \text{ Btu}/\text{ft}^2\cdot^\circ\text{F}\cdot\text{day}$$

If the daily internal heat is 130,000 Btu/day, and the average thermostat setting is 68°F, then

Fig. 30 Commercial Building in Example 7

Table 3 Calculations for Example 7

	Area A , ft ²	U-Factor, Btu/h·ft ² ·°F	UA , Btu/ h·°F
Opaque wall	2000	0.04	80
Ceiling	3000	0.03	90
Floor (over crawl space)	3000	0.04	120
Windows (E, W, N)	100	0.55	55
		Subtotal	345
Infiltration			180
		Subtotal	525
Sunspace (treated as unheated space)			151
		Total	676

ASHRAE procedures are approximated with V = volume, ft³; c = heat capacity of Denver air, Btu/ft³·°F; ACH = air changes/h; equivalent UA for infiltration = $Vc\text{ACH}$. In this case, $V = 24,000$ ft³, $c = 0.015$ Btu/ft³·°F, and ACH = 0.5.

$$T_{\text{base}} = 68 - 130,000/16,224 = 60^\circ\text{F}$$

(Note that solar gains to the space are not included in the internal gain term as they customarily are for nonsolar buildings.)

In this example, the solar system is type SSD1, defined in Balcomb et al. (1982, 1984). It is a semiclosed sunspace with a 12 in. masonry common wall between it and the heated space (offices). The aperture is double-glazed, with a 50° tilt and no night insulation. To achieve a vertically projected area of 420 ft², a sloped glazed area of $420/\sin 50^\circ = 548$ ft² is required.

The SLR correlation for solar system type SSD1 is shown in Figure 31. Values of the absorbed solar energy S and heating degree-days DD to base temperature 60°F are determined monthly. For S , the solar radiation correlation presented in Balcomb et al. (1984) for tabulated Denver, CO, weather data is used. For January, the horizontal surface incident radiation is 840 Btu/ft²·day. The 60°F base degree-days are 933. Using the tabulated incident-to-absorbed coefficients found in Balcomb et al. (1984), $S = 43,681$ Btu/ft². Thus $S/\text{DD} = 46.8$ Btu/ft²·°F·day. From Figure 31, at an LCR = 30 Btu/ft²·°F·day, the SSF = 0.51. Therefore, for January,

$$\text{Net reference load} = (933)(12,600) = 11.76 \times 10^6 \text{ Btu}$$

$$\text{Solar savings} = (11.76 \times 10^6)(0.51) = 6.00 \times 10^6 \text{ Btu}$$

$$\text{Auxiliary heat} = (11.76 \times 10^6) - (6.00 \times 10^6) = 5.76 \times 10^6 \text{ Btu}$$

Repeating this calculation for each month and adding the results for the year yields an annual auxiliary heat of 19.94×10^6 Btu.

Other Passive Heating Methods

The concept of usability has been applied to passive buildings. In this approach, the energy requirements of zero- and infinite-capacity buildings are calculated. The amount of solar energy that enters the building and exceeds the instantaneous load of the zero-capacity building is then calculated. This excess energy must be dumped in the zero-capacity building, but it can be stored to offset heating loads in a finite-capacity building. Methods are provided

Fig. 31 Monthly SSF Versus Monthly S/DD for Various LCR Values

to interpolate between the zero- and infinite-capacity limits for finite-capacity buildings. Equations and graphs for direct gain and collector-storage wall systems are given in Monsen et al. (1981, 1982).

9. INSTALLATION GUIDELINES

Most solar components are the same as those in HVAC and hot-water systems (pumps, piping, valves, and controls), and their installation is not much different from a conventional installation. Solar collectors are the most unfamiliar component in a solar heater. They are located outdoors, which requires penetration of the building envelope. They also require a structural element to support them at the proper tilt and orientation toward the sun.

The site must be taken into account. Collectors should be (1) located so that shading is minimized and (2) installed so that they are attractive both on and off site. They should also be located to minimize vandalism and to avoid a safety hazard.

Collectors should be placed near the storage tank to reduce piping cost and heat loss. The collector and piping must be installed so that they can be drained without trapping fluid in the system.

For best annual performance, collectors should be installed at a tilt angle above the horizontal that is appropriate for the local latitude. In the northern hemisphere they should be oriented toward true south, not magnetic south. Small variations in tilt ($\pm 10^\circ$) and orientation ($\pm 20^\circ$) do not reduce performance significantly.

Collector Mounting

Solar thermal collectors are usually mounted on the ground or on flat or pitched roofs. A roof location necessitates penetration of the building envelope by mounting hardware, piping, and control wiring. Ground or flat-roof-mounted collectors are generally rack mounted.

Pitched-roof mounting can be done several ways. Collectors can be mounted on structural **standoffs**, which support them at an angle other than that of the roof to optimize solar tilt. In another pitched-roof-mounting technique known as **direct mounting**, collectors are placed on a waterproof membrane on top of the roof sheeting. The finished roof surface together with the necessary collector structural attachments and flashing are then built up around the collector. A weatherproof seal between the collector and the roof must be maintained to prevent leakage, mildew, and rotting.

Integral mounting can be done for new pitched-roof or curtain-wall construction. The collector is attached to and supported by the structural framing members. The top of the collector then serves as the finished roof surface. Weathertightness is crucial to avoid damage and mildew. This building-integrated approach is often incorporated in green building design and generally is used for photovoltaic modules, rather than thermal collectors.

Collectors should support snow loads that occur on the roof area they cover. The collector tilt usually expedites snow sliding with only a small loss in efficiency. The roof structure should be free of objects that could impede snow sliding, and the collectors should be raised high enough to prevent snow buildup over them.

The mounting structure should be built to withstand winds of at least 100 mph, which impose a wind load of 40 lb/ft² on a vertical surface or an average of 25 lb/ft² on a tilted roof (HUD 1977). Wind load requirements may be higher, depending on local building codes, especially in coastal areas exposed to hurricanes. Flat-plate collectors mounted flush with the roof surface should be constructed to withstand the same wind loads. See Chapter 55 for additional information.

The collector array becomes more vulnerable to wind gusts as the angle of the mount increases. This wind load, in addition to the equivalent roof area wind loads, should be determined according to accepted engineering procedures (ASCE *Standards* 7, 8, and 9).

Expansion and contraction of system components, material compatibility, and use of dissimilar metals must be considered. Collector arrays and mounting hardware (bolts, screws, washers, and angles) must be well protected from corrosion. Steel mounting hardware in contact with aluminum and copper piping in contact with aluminum hardware are both examples of metal combinations that have a high potential for corrosion. Dissimilar metals can be separated by washers made of fluorocarbon polymer, phenolic, or neoprene rubber.

Freeze Protection

Freeze protection is extremely important and is often the determining factor when selecting a system in the United States. Freezing can occur at ambient temperatures as high as 42°F because of radiation to the night sky. Manual freeze protection should not be used for commercial installations.

One simple way of protecting against freezing is to drain fluid from the collector array and interior piping when potential freezing conditions exist. Drainage may be automatic, as in draindown and drainback systems, or manual, as in direct thermosiphon systems. Automatic systems should be capable of fail-safe drainage operation, even in the event of pump failure or power outage. In some cases water may be designed to drain back through the pump, so the design must allow refilling without causing cavitation.

In areas where freezing is infrequent, recirculating water from storage to the collector array can be used as freeze protection.

Freeze protection can also be provided by using fluids that resist freezing. Fluids such as water/glycol solutions, silicone oils, and hydrocarbon oils are circulated by pumps through the collector array and double-wall heat exchanger. Draining the collector fluid is not required, because these fluids have freezing points well below the coldest anticipated outdoor temperature.

In mild climates where recirculation freeze protection is used, a second level of freeze protection should be provided by flushing the collector with cold supply water when the collector approaches near-freezing temperatures. This can be accomplished with a temperature-controlled valve that will automatically open a small port at a near-freezing temperature of about 40°F and then close at a slightly higher temperature.

Overheat Protection

During periods of high insolation and low hot-water demand, overheating can occur in the collectors or storage tanks. Protection against overheating must be considered for all portions of the solar hot-water system. Liquid expansion or excessive pressure can burst piping or storage tanks. Steam or other gases within a system can restrict liquid flow, making the system inoperable.

The most common methods of overheat protection stop circulation in the collection loop until the storage temperature decreases, discharge the overheated water and replace it with cold makeup water, or use a heat exchanger as a means of heat rejection. Some freeze protection methods can also provide overheat protection by circulating the collector fluid at night to radiate excess heat.

For nonfreezing fluids such as glycol antifreezes, overheat protection is needed to limit fluid degradation at high temperatures during collector stagnation.

Safety

Safety precautions required for installing, operating, and servicing a solar domestic hot-water heater are essentially the same as those for a conventional domestic hot-water heater. One major exception is that some solar systems use nonpotable heat transfer fluids. Local codes may require a double-wall heat exchanger for potable water installations.

Pressure relief must be provided in all parts of the collector array that can be isolated by valves. The outlet of these relief valves should be piped to a container or drain, and not where people could be affected.

Start-Up Commissioning Procedure

After completing installation, tests must be performed before charging or filling the system. The system must be checked for leakage, and pumps, fans, valves, and sensors must be checked to see that they function. Testing procedures vary with system type.

Closed-loop systems should be hydrostatically tested. The system is filled and pressurized to 1.5 times the operating pressure for one hour and inspected for leaks and any appreciable pressure drop.

Draindown systems should be tested to be sure that all water drains from the collectors and piping located outdoors. All lines should be checked for proper pitch so that gravity drains them completely. All valves should be verified to be in working order.

Drainback systems should be tested to ensure that collector fluid drains back to the reservoir tank when circulation stops and that the system refills properly.

Air systems should be tested for leaks before insulation is applied by starting the fans and checking the ductwork for leaks.

Pumps and sensors should be inspected to verify that they are in proper working order. Proper cycling of the pumps can be checked by a running time meter. A sensor that is suspected of being faulty can be dipped alternately in hot and cold water to see if the pump starts or stops.

After system testing and before filling or charging it with heat transfer fluid, the system should be flushed to remove debris.

Maintenance

All systems should be checked at least once a year in addition to any periodic maintenance that may be required for specific components. A log of all maintenance performed should be kept. The system designer and installer should provide the building owner with an operating manual that describes maintenance procedures and operating modes in sufficient detail to support ongoing performance.

The collectors' outer glazing should be hosed down periodically. Leaves, seeds, dirt, and other debris should be carefully swept from the collectors. Take care not to damage plastic covers.

Without opening a sealed collector panel, check the absorber plate for surface coating damage caused by peeling, crazing, or scratching. Also, inspect the collector tubing to ensure that it contacts the absorber. If the tubing is loose, consult the manufacturer for repair instructions.

Heat transfer fluids should be tested and replaced at intervals suggested by the manufacturer. Also, the solar energy storage tank should be drained about every six months to remove sediment.

Performance Monitoring/Minimum Instrumentation

Temperature sensors and temperature differential controllers are required to operate most solar systems. However, additional instruments should be installed for monitoring, checking, and troubleshooting.

Thermometers should be located on the collector supply and return lines so that the temperature difference in the lines can be determined visually.

A pressure gage should be inserted on the discharge side of the pump. The gage can be used to monitor the pressure that the pump must work against and to indicate if the flow passages are blocked.

Running time meters on pumps and fans may be installed to determine if the system is cycling properly.

10. DESIGN, INSTALLATION, AND OPERATION CHECKLIST

The following checklist is for designers of solar heating and cooling systems. Specific values have not been included because these vary for each application. The designer must decide whether design figures are within acceptable limits for any particular project [see DOE (1978b) for further information]. The review order listed does not reflect their precedence or importance during design.

Collectors

- Check flow rate for compliance with manufacturer's recommendation.
- Check that collector area matches the application and claimed solar fraction of the load.
- Review collector instantaneous efficiency curve and check match between collector and system requirements.
- Relate collector construction to end use; two cover plates are not required for low-temperature collection in warm climates and may, in fact, be detrimental. Two cover plates are more efficient when the temperature difference between the absorber plate and outdoor air is high, such as in severe winter climates or when collecting at high temperatures for cooling. Radiation loss only becomes significant at relatively high absorber plate temperatures. Selective surfaces should be used in these cases. Flat-black surfaces are acceptable and sometimes more desirable for low collection temperatures.

- Check match between collector tilt angle, latitude, and collector end use.
- Check collector azimuth.
- Check collector location for potential shading and exposure to vandalism or accidental damage.
- Review provisions for high stagnation temperature. If not used, are liquid collectors drained or left filled in summer?
- Check for snow hang-up and ice formation. Will casing vents become blocked?
- Review precautions, if any, against outgassing.
- Check access for cleaning covers.
- Check mounting for stability in high winds.
- Check for architectural integration. Do collectors on roof present rainwater drainage or condensation problems? Do roof penetrations present potential leak problems?
- Check collector construction for structural integrity and durability. Will materials deteriorate under operating conditions? Will any pieces fall off?
- Are liquid collector passages organized in such a way as to allow natural fill and drain? Does mounting configuration affect this?
- Does air collector duct connection promote balanced airflow and uniform heat transfer? Are connections potentially leaky?

Heat Transfer Fluid

- Check that flow rate through the collector array matches system parameters.
- If antifreeze is used, check that flow rate has been modified to allow for the viscosity and specific heat.
- Review properties of proposed antifreeze. Some fluids are highly flammable. Check toxicity, vapor pressure, flash point, and boiling and freezing temperatures at atmospheric pressure.
- Check means of makeup into antifreeze system. An automatic water makeup system can result in freezing.
- Check that provisions are made for draining and filling the system (air vents at high points, drains at low points, pipes correctly graded in-between, drainback vented to storage or expansion tank).
- If system uses drainback freeze protection, check that
 - Provision is made for drainback volume and back venting
 - Pipes are graded for drainback
 - Solar primary pump is sized for lift head
 - Pump is self-priming if tank is below pump
- Check that collector pressure drop for drainback is slightly higher than static pressure between supply and return headers.
- Optimum pipe arrangement is reverse-return with collectors in parallel. Series collectors reduce flow rate and increase head. A combination of parallel/series can sometimes be beneficial, but check that equipment has been sized and selected properly.
- Cross-connections under different operating modes sometimes result in pumps operating in opposition or tandem, causing severe hydraulic problems.
- If heat exchangers are used, check that approach temperature differential has been recognized in the calculations.
- Check that adequate provisions are made for water expansion and contraction. Use specific volume/temperature tables for calculation. Each unique circuit must have its own provision for expansion and contraction.
- Three-port valves tend to leak through the closed port. This, together with reversed flows in some modes, can cause potential hydraulic problems. As a general rule, simple circuits and controls are better.

Airflow

- Check that flow rate through the collector array matches system design values.

- Check temperature rise across collectors using air mass flow and specific heat.
- Check that duct velocities are within design limits.
- Check that cold air or water cannot flow from collectors by gravity under “no-sun” conditions.
- Verify duct material and construction methods. Ductwork must be sealed to reduce loss.
- Check duct configuration for balanced flow through collector array.
- Check number of collectors in series. More than two collectors in series can reduce collection efficiency.

Thermal Storage

- Check that thermal storage capacity matches values of collector area, collection temperature, use temperature, and load.
- Verify that thermal inertia does not impede effective operation.
- Check provisions for promoting temperature stratification during both collection and use.
- Check that pipe and duct connections to storage are compatible with the control, ensuring that only the coolest air goes to the collectors and connections.
- If liquid storage is used for high-temperature (above 200°F) applications, check that tank material and construction can withstand the temperature and pressure.
- Check that storage location does not promote unwanted heat loss or gain and that adequate insulation is provided.
- Verify that liquid storage tanks are treated to resist corrosion. This is particularly important in tanks that are partially filled.
- Check that provision is made to protect liquid tanks from exposure to either overpressure or vacuum.

Uses

Domestic Hot Water

- Characteristics of domestic hot-water loads include short periods of high draw interspersed with long dormant periods. Check that domestic hot-water storage matches solar heat input.
- Check that provisions have been made to prevent reverse heating of the solar thermal storage by the domestic hot-water back-up heater.
- Check that the design allows cold makeup water preheating on days of low solar input.
- Verify that the antiscald valve limits domestic hot-water supply to a safe temperature during periods of high solar input.
- Depending on total dissolved solids, city water heated above 150°F may precipitate a calcium carbonate scale. If collectors are used to heat water directly, check provisions for preventing scale formation in absorber plate waterways.
- Check whether the heater is required to have a double-wall heat exchanger and that it conforms to appropriate codes if the collector uses nonpotable fluids.

Heating

- Warm-air heating systems can use solar energy directly at moderate temperatures. Check that air volume is sufficient to meet the heating load at low supply temperatures and that the limit thermostat has been reset.
- At times of low solar input, solar heat can still be used to meet part of the load by preheating return air. Check location of solar heating coil in system.
- Baseboard heaters require relatively high supply temperatures for satisfactory operation. Their output varies as the 1.5 power of the log mean temperature difference and falls off drastically at low temperatures. If solar is combined with baseboard heating, check that supply temperature is compatible with heating load.

- Heat exchangers imply an approach temperature difference that must be added to the system operating temperature to derive the minimum collection temperature. Verify calculations.
- Water-to-air heat pumps rely on a constant solar water heat source for operation. When the heat source is depleted, the back-up system must be used. Check that storage is adequate.

Cooling

- Solar-activated absorption cooling with fossil fuel back-up is currently the only commercially available active cooling. Be assured of all design criteria and a large amount of solar participation. Verify calculations.
- Storing both hot and chilled water may make better use of available storage capacity.

Controls

- Check that control design matches desired modes of operation.
- Verify that collector loop controls recognize solar input, collector temperature, and storage temperature.
- Verify that controls allow both the collector and usage loops to operate independently.
- Check that control sequences are reversible and always revert to the most economical mode.
- Check that controls are as simple as possible within the system requirements. Complex controls increase the frequency and possibility of breakdowns.
- Check that all controls are fail-safe.

Performance

- Check building heating, cooling, and domestic hot-water loads as applicable. Verify that building thermal characteristics are acceptable.
- Check solar energy collected on a monthly basis. Compare with loads and verify solar participation.

11. PHOTOVOLTAIC APPLICATIONS

Photovoltaic (PV) solar collectors, called PV modules, convert solar radiation directly into electricity. Chapter 37 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* discusses the fundamentals of their operation. Photovoltaics are used for utility-interactive power generation to power remotely located communications equipment, remote monitoring, lighting, water pumping, battery charging, and cathodic protection. The first step for any PV application is to analyze electric loads and then minimize them wherever possible. PV array size can be reduced substantially by using high-efficiency HVAC, appliances, motors, and other power-consuming devices. Using this strategy is almost always more cost effective than adding more PV modules.

Grid-Connected Systems. Grid-connected or utility-interactive PV systems use an inverter that converts dc output from the PV array to ac current. It is designed to operate in conjunction with the electric utility mains, synchronizing the ac output (phase, frequency, and voltage) with the utility. The PV output is directly connected to the inverter, and the ac output from the inverter is connected to the ac load circuit. Excess power generated during the day is fed back to the utility grid, and grid power is used at night. **Net metering** uses a single utility meter; when energy is fed back to the utility grid, the meter runs backwards.

Communications. Photovoltaics can provide reliable power with little maintenance for communications systems, especially those in remote areas (away from the power grid) with extreme weather conditions such as high winds, heavy snows, and ice. Examples include communication relay towers, travelers' information transmitters, cellular telephones, mobile radio systems, emergency call boxes, and military test facilities. These systems range in

size from a few watts for call boxes to several kilowatts for microwave repeater stations. For larger systems at remote sites, an engine generator is often combined with the photovoltaic-battery system. These hybrid systems with two or more generators can achieve nearly 100% availability.

Remote Site Electrification. Photovoltaics are used to provide power to rural residences, visitor centers in parks, vacation cabins, island and villages, remote research facilities, and military test areas. The varied loads include lighting, small appliances, water pumps (including circulators on solar water-heating systems), and communications equipment. The load demand varies from a few watts to tens of kilowatts. Deep-cycle battery back-up is most often used in this application for nighttime power, and is typically sized to meet the load for two to three days without PV input. Hybrid systems are also common, using wind or small hydro generation equipment.

Remote Monitoring. Photovoltaics provide power at remote sites to sensors, data loggers, and associated transmitters for meteorological monitoring, structural condition measurement, seismic recording, irrigation control, highway/traffic monitoring, security monitoring, and scientific research. Most of these applications require less than 200 W, and many can be powered by a single photovoltaic module. Vandalism may be a problem in some areas, so non-glass-covered modules are sometimes used. Mounting the modules on a tall pole or in an unobtrusive manner may also help avoid damage or theft. The batteries are often located in the same weather-resistant enclosure as the data acquisition/monitoring equipment. This enclosure is sometimes camouflaged or buried for protection. Some data loggers come with their own battery and charge regulator.

Signs and Signals. The most popular application for photovoltaics is warning signs. Typical devices include navigational beacons, audible signals such as sirens, highway warning signs, railroad signals, and aircraft warning beacons. Because these signals are critical to public safety, they must be operative at all times, and thus the reliability of the photovoltaic system is extremely important. High reliability can be achieved by using large-capacity batteries. Many of these systems operate in harsh environments. For maritime applications, special modules that are resistant to corrosion from salt water are used.

Water Pumping and Control. Photovoltaics are typically used for intermediate-sized water pumping applications (those larger than hand pumps and smaller than large engine-powered pumps). The range of sizes for photovoltaic-powered pumps is a few hundred watts to a few kilowatts. Applications include domestic use, water for campgrounds, irrigation, village water supplies, and livestock watering. Photovoltaics for livestock watering can be more economical than maintaining a distribution line to a remote pump on a ranch. Most pumping systems do not use batteries but store water in holding tanks. For this application, photovoltaic modules may be mounted on tracking frames that maximize energy production by tracking the sun each day.

Rest Room Facilities. Highway rest stops, public beach facilities, outdoor recreation parks, and public campgrounds may have photovoltaics to operate air circulation and ventilation fans, interior and exterior lights, and auxiliary water pumps for sinks and showers. For most of these applications, the initial cost for photovoltaic power is the least expensive option.

Charging Auto, Boat, and RV Batteries. Batteries self-discharge over time if they are not used. This is a problem for organizations that maintain a fleet of vehicles such as fire-fighting or snow removal equipment, some of which are infrequently used. Photovoltaic battery chargers can solve this problem by providing a trickle charging current that keeps the battery highly charged. Often the PV module can be placed inside the windshield and plugged into the vehicle's power socket, thus using existing wiring and protection circuits and providing a quick disconnect for the module. Modules

are installed on the roof or engine hood of larger vehicles. Another successful application is using PV modules to charge the batteries in electric vehicles.

12. SYMBOLS

a = constant for specified month at specified location
 A_{abs}, A_{ap} = areas of absorber surface and of aperture that admit or receive radiation, ft²
 A_c = area of solar collector, ft²
 ACH = air changes per hour, ach
 A_g = gross collector area, ft²
 A_p = projected collector area, ft²
 AST = apparent solar time, decimal h
 b = constant for specified month at specified location
 c_p = specific heat of fluid, Btu/lb·°F
 DD = temperature departure in degree-days computed for an appropriate base temperature
 DST = daylight saving time, decimal h
 e_{at} = sky emittance
 e_s = surface emittance
 ET = equation of time, min
 f = fraction of monthly space- and water-heating loads supplied by solar energy
 F_r = collector heat exchanger efficiency factor
 F_R = collector heat removal factor; ratio of heat actually delivered by collector to heat that would be delivered if absorber were at t_{fi}
 H = hour angle, degrees
 H_T = monthly averaged daily radiation incident on collector surface per unit area, Btu/day·ft²
 I_{DN} = direct normal irradiation, Btu/h·ft²
 I_{d0} = diffuse component of solar radiation from sky, Btu/h·ft²
 I_r = reflected shortwave radiation, Btu/h·ft²
 I_{TH} = total horizon irradiation, Btu/h·ft²
 I_{t0} = total solar irradiation of terrestrial surface or collector, Btu/h·ft²
 L = monthly total heating load for space heating and hot water, Btu
 LCR = load collector ratio; net load coefficient divided by projected collector area, Btu/ft²·°F·day
 LST = local standard time, decimal h
 m = air mass; = 1.0/sin β at sea level and 0 outside earth's atmosphere; also fluid flow rate, lb/h
 \dot{m} = fluid flow rate, lb/h
 N = day of year, with January 1 = 1; also number of days in month
 NLC = net load coefficient, Btu/°F·day
 q_{Rat} = downward radiation from atmosphere, Btu/h·ft²
 q_{Rs} = longwave radiation emitted by surface on earth, Btu/h·ft²
 q_u = useful heat gained by collector per unit of aperture area, Btu/h·ft²
 R_{net} = net radiative cooling rate of horizontal surface, Btu/h·ft²
 S = total downward radiant heat flux from atmosphere, Btu/h·ft²
 SSF = solar savings fraction
 SLR = solar energy absorbed divided by building heating load
 t_a = temperature of atmosphere, or monthly average ambient temperature, °F
 \bar{t}_a = monthly average ambient temperature, °F
 t_{abs} = temperature of absorber, °F
 T_{at} = ground-level dry-bulb temperature, °R
 T_{base} = base temperature, °F
 t_{fe}, t_{fi} = temperatures of fluid leaving and entering collector, respectively, °F
 TLC = total load coefficient, Btu/°F·day
 t_p = temperature of absorber plate, °F
 T_{rad} = absolute temperature of horizontal surface, °R
 t_{ref} = reference temperature, 212°F
 \bar{T}_s = absolute temperature of surface, °R
 T_{sky} = apparent sky temperature, °R
 \dot{U}_L = overall heat loss coefficient, Btu/h·ft²·°F
 X = reference collector loss divided by heating load
 Y = absorbed solar energy divided by heating load

Greek

α = absorptance
 β = sun's altitude above horizon, degrees

γ = surface-solar azimuth, degrees
 δ = solar declination, degrees
 $\Delta\theta$ = total number of hours in month
 ϵ = nonspectral emittance of horizontal surface; about 0.9 for most nonmetallic construction materials
 η = collector efficiency, %
 θ = solar incident angle, degrees
 $\rho\Gamma$ = reflectance of concentrator surface times fraction of reflected or refracted radiation that reaches absorber
 σ = Stefan-Boltzmann constant, 0.1712×10^{-8} Btu/h·ft²·°R⁴
 Σ = tilt angle of surface, measured from horizontal, degrees
 τ = transmittance
 $(\bar{\tau}\alpha)$ = monthly average transmittance-absorptance product
 $(\tau\alpha)_n$ = normal transmittance-absorptance product
 $(\tau\alpha)_\theta$ = transmittance τ of cover times absorptance α of plate at prevailing incident angle θ
 ϕ = solar azimuth, degrees
 ψ = surface azimuth, degrees

--	---

ENERGY management in buildings is the control of energy use and cost while maintaining indoor environmental conditions to provide comfort and to fully meet functional needs. This chapter provides guidance on establishing an effective, ongoing energy management program, as well as information on planning and implementing energy management projects. The energy manager should understand how energy is used in the building, to manage it effectively. There are opportunities for savings by reducing the unit price of purchased energy, and by improving the efficiency and reducing the use of energy-consuming systems.

Water/sewer costs and use may be included in the energy management activity. This could be called “utility management,” but “energy management” is used in this chapter.

1. ENERGY MANAGEMENT

The specific processes by which building owners and operators control energy consumption and costs are as variable as their building types. Small buildings, such as residences and small commercial businesses, usually involve the efforts of one person. Energy management procedures should be as simple, specific, and direct as possible. General energy management advice, such as from utility energy surveys or state or provincial energy offices, can provide ideas, but these must be evaluated to determine whether they are applicable to the target building. Owners and operators of smaller buildings may only need advice on specific energy projects (e.g., boiler replacement, lighting retrofit). On the other hand, large or complex facilities, such as hospital or university campuses, industrial complexes, or large office buildings, usually require a team effort and process as represented in Figure 1.

Figure 1 is adapted from the ENERGY STAR® web site (www.energystar.gov). On the ENERGY STAR web site, each box in the flowchart refers the reader to numerous useful tips.

Energy management for existing buildings has these basic steps:

1. Appoint an energy manager to oversee the process and to ensure that someone is dedicated to the initiatives and accountable to the company.
2. Early communication to solicit feedback for other steps of the process.
3. Establish an energy accounting system that records energy and water consumption and associated costs. It should include comparisons with similar buildings, to benchmark and set performance goals.
4. Validate and analyze current and historical energy use data to help identify conservation energy-efficiency measures
5. Carry out energy surveys and walk-through audits to identify low-cost/no-cost operations, maintenance, and energy-efficiency measures. Having a qualified energy professional do this is recommended.

6. Using the survey results, change building operating procedures to eliminate energy waste.
7. Evaluate energy-efficiency measures for expected savings, estimated implementation costs, risks, and nonenergy benefits. Recommend a number of prioritized energy-efficiency projects for implementation.
8. Implement approved energy-efficiency measures (EEMs). Tender projects that must be outsourced.
9. Track results using the energy accounting system for overall performance, supplemented as needed by energy monitoring related to specific projects.
10. Compare results to past goals, revise as necessary, and develop new goals. Report to management and tenants. Return to step 7 and continue the process to maintain and continually improve building performance.

Each of these energy management program components is discussed in detail in the following sections.

ASHRAE *Standard 100* details useful in energy management planning in existing buildings. Information on energy efficiency in new design can be found in all volumes of the *ASHRAE Handbook* and in *ASHRAE Standards 90.1* and *90.2*. The area most likely to be overlooked in new design is the ability to measure and monitor energy consumption and trends for each energy use category given in Chapter 41. Additional guidelines for this area can be found in Chapter 34 of the 2013 *ASHRAE Handbook—Fundamentals*.

Fig. 1 An Energy Management Process

The preparation of this chapter is assigned to TC 7.6, Building Energy Performance.

Organizing for Energy Management

To be effective, energy management must be given the same emphasis as management of any other cost/profit center. Top management should

- Establish the energy cost/profit center
- Assign management responsibility for the program
- Assign an energy manager and provide training
- Allocate resources
- Clearly communicate the energy management program to all departments and personnel
- Set clear program goals
- Encourage ownership of the program by all levels of the organization
- Set up an ongoing reporting and analysis procedure to monitor results
- Develop a feedback mechanism to allow timely revisions

It is common for a facility to allocate 3 to 10% of the annual energy cost for administration of an energy management program. The budget should include funds for continuing education of the energy manager and staff.

Energy Managers

The functions of an energy manager fall into four broad categories: technical, policy-related, planning and purchasing, and public relations. A list of specific tasks and a plan for their implementation must be clearly documented and communicated to building occupants. An energy manager in a large commercial complex may perform most of the following functions; one in a smaller facility may have only a few from each category to consider.

Technical functions

- Conduct energy audits and identifying energy-efficiency measures
- Act as in-house technical consultant on new energy technologies, alternative fuel sources, and energy-efficient practices
- Evaluate energy efficiency of proposed new construction, building expansion, remodeling, and new equipment purchases
- Set performance standards for efficient operation and maintenance of equipment and facilities
- Review state-of-the-art energy management hardware
- Review building operation and maintenance procedures for optimal energy management
- Implement energy-efficiency measures (EEMs)
- Establish an energy accounting system
- Establish a baseline from which energy-saving improvements can be measured
- Measure and maintain effectiveness of EEMs
- Measure energy use in the field to verify design and operating conditions

Policy-related functions

- Fulfill energy policy established by top management
- Monitor federal and state (provincial) legislation and regulatory activities, and recommend policy/response
- Adhere to energy management building codes
- Represent the organization in energy associations
- Administer government-mandated reporting programs

Planning and purchasing functions

- Take advantage of fuel-switching and load management opportunities
- Purchase equipment based on life-cycle cost
- Take advantage of energy-efficiency programs offered by utilities and agencies
- Negotiate or advise on major utility contracts
- Develop contingency plans for supply interruptions or shortages

- Forecast and budget for short- and long-term energy requirements and costs
- Report regularly to top management and other stakeholders.

Public relations functions

- Make occupants aware of the benefits of efficient energy use
- Establish a mechanism to elicit and evaluate suggestions
- Recognize successful energy projects
- Establish an energy communications network
- Increase community awareness with press releases and appearances at civic group meetings

General qualifications

- A technical background, preferably in engineering
- Experience in energy-efficient design of building systems and processes
- Practical, hands-on experience with systems and equipment
- Goal-oriented management style
- Ability to work with people at all levels
- Technical report-writing and verbal communication skills

Desirable educational and professional qualifications

- Bachelor of science degree, preferably in mechanical, electrical, industrial, or chemical engineering
- Thorough knowledge of energy resource planning and conservation
- Ability to
 - Analyze and compile technical and statistical information and reports
 - Interpret plans and specifications for building facilities
- Knowledge of
 - Utility rates, energy efficiency, and planning
 - Automatic controls and systems instrumentation
 - Energy-related metering equipment and practices
 - Project management

If it is not possible to add a full-time manager, an existing employee with a technical background should be considered and trained. Energy management should not be a collateral duty of an employee who is already fully occupied. Another option is to hire a professional energy management consultant. Energy services companies (ESCOs) provide energy services as part of a contract, with payments based on realized savings. Other companies charge a fee to perform a variety of energy management functions.

2. COMMUNICATIONS

Energy management requires careful planning and help from all personnel that operate and use the facility. A communication plan should be regularly reviewed by both the energy manager and senior management. The initial communiqué should introduce the plan and express the support of top management for high-level goals. Providing early information to tenants and staff is important, because it takes time to change behaviors. Once the communication plan is launched, the energy manager should be prepared to answer a variety of questions from different areas of the company.

An effective communication strategy may include these tasks:

- Produce a regular newsletter
- Post energy-saving tips or reminders
- Hold annual seminars with maintenance and cleaning staff
- Meet with operations staff for training and feedback
- Report regularly to management and operations staff

Message content should be tailored to the specific audience. The more successful the communication is, the more quickly the energy management activities will become second nature. Diligent reporting promotes accountability and persistence of performance.

3. ENERGY ACCOUNTING SYSTEMS

An energy accounting system that tracks consumption and costs on a continuing basis is essential. It provides energy use data needed to confirm savings from energy-efficiency projects. The primary data source is utility bills, but other sources include

- Printouts from time-of-use meters
- Combustion efficiency, eddy current, and water quality tests
- Recordings of temperature and relative humidity
- Submetered energy use
- Event recordings
- Occupancy schedules and occupant activity levels
- Climate data
- Data from similar buildings in similar climates
- Infrared scans
- Production records
- Computer modeling

Energy Accounting Process

The energy manager establishes procedures for meter reading, monitoring, and tabulating facility energy use and profiles. The energy manager also periodically reviews utility rates, rate structures, and trends, and should subscribe to free utility mailing lists to track changes in their rate tariffs. The energy manager provides periodic reports to top management, summarizing the work accomplished, its cost-effectiveness, plans for future work, and projections of utility costs. Utility bill analysis software can be used to track avoided costs. If energy-efficiency measures are to be cost-effective, continued monitoring and periodic reauditing are necessary to ensure persistence. The procedures in ASHRAE *Guideline 14* can be used for measurement and verification of energy savings.

Energy Accounting

Energy accounting means tracking utility bill data on a monthly basis to provide a current picture of building energy performance and to identify trends and instances of excess use. An Internet search for “energy accounting” will produce web sites for the major commercial providers. In some cases software is sold for computer installation, or the accounting system is web-based and the user has a subscription. For many users, a simple spreadsheet is all that is needed. A comparison of the features of many available energy accounting software packages can be found at <http://www.betterbricks.com/DetailPage.aspx?ID=518>. Portfolio Manager, from the ENERGY STAR web site, allows users to enter monthly energy usage, in kWh, therms, etc. The Portfolio Manager simultaneously calculates the facility’s EUI and develops a normalized ENERGY STAR score (<http://www.energystar.gov/benchmark>). Portfolio Manager facilitates comparison of multiple buildings and goal setting, is useful for numerous building types, and is normalized by building type for weather.

Utility Rates

Because most energy management activities are dictated by economics, the energy manager must understand the utility rates that apply to each facility. Electric rates are more complex than gas or water rates and some rate structures make cost calculations difficult. In addition to general commercial or institutional electric rates, special rates may exist such as time of day, interruptible service, on peak/off peak, summer/winter, and peak demand. Electric rate schedules vary widely in North America; Chapters 37 and 56 discuss these in detail. Energy managers should work with local utility companies to identify the most favorable rates for their buildings, and must understand how demand is computed as well as the distinction between marginal and average costs (see the section on Improving Discretionary Operations). The utility representative can help develop the most cost-effective methods of metering and billing.

4. ANALYZING ENERGY DATA

Preparing for Cost and Efficiency Improvements

Opportunities for savings come in reducing (1) the cost per unit of energy, and then (2) energy consumption. Historically, energy users had little choice in selecting energy suppliers, and regulated tariffs applied based on certain customer characteristics. In recent years there has been a move in North America and other parts of the world to deregulate energy markets, and there is more flexibility in supply and pricing. Electric rate structures vary widely in North America; Chapter 37 discusses these in detail.

Electric utilities commonly meter both consumption and demand. **Demand** is the peak rate of consumption, typically averaged over a 15 or 30 min period. Electric utilities may also use a ratchet billing procedure for demand. Contact the local electric utility to fully understand the demand component.

Some utilities use **real-time pricing (RTP)**, in which the utility calculates the marginal cost of power per hour for the next day, determines the price, and sends this hourly price to customers. The customer can then determine the power consumption at different times of the day. A variation on RTP was introduced in some areas: **demand exchange and active load management** pays customers to shed loads during periods of high utility demand. Also called **demand reduction** or **demand response**, the utilities ask participating customers to reduce their consumption for a period of time on as little as a few hours’ notice.

Caution is advised in designing or installing systems that take advantage of utility rate provisions, because the structure or provisions of utility rates cannot be guaranteed for the life of the system. Provisions that change include on-peak times, declining block rates, and demand ratchets. Chapter 56 has additional information on billing rates.

Analyzing Energy Use Data

Any reliable utility data should be examined. Utilities often provide metered data with measurement intervals as short as 15 min. Data from shorter time intervals make anomalies more apparent. High consumption at certain periods may reveal opportunities for cost reduction (Haberl and Komor 1990a, 1990b). If monthly data are used, they should be analyzed over several years.

A base year should be established as a reference point. Record the dates of meter readings so that energy use can be normalized for the number of days in a billing period. Any periods in which consumption was estimated rather than measured should be noted.

If energy data are available for more than one building or department, each should be tabulated separately. Initial tabulations should include both energy and cost per unit area (in an industrial facility, this may be energy and cost per unit of goods produced). Document variables such as heating or cooling degree-days, percent occupancy, quantity of goods produced, building occupancy, hours of operation, or daily weather conditions (see Chapter 14 in the 2013 *ASHRAE Handbook—Fundamentals*). Because these variables may not be directly proportional to energy use, it is best to plot information separately or to superimpose one plot over another. Examples of ways to normalize energy consumption for temperature and other variations are provided in ASHRAE *Guideline 14*.

Potential savings areas can be identified by separating base energy consumption from weather-dependent energy consumption. **Base-load energy use** is the amount of energy consumed independent of weather, such as for lighting, motors, domestic hot water, and miscellaneous office equipment. When a building has electric cooling and no electric heating, the base-load electric energy use is normally the energy consumed during the winter. The annual base-load energy use may also be estimated by taking the average monthly use during nonheating or noncooling months and multiplying by 12. For many buildings, subtracting the base-load energy use from

Table 1 Electricity Consumption for Atlanta Example Building

^aMaximum or minimum value for year.^bPeak demand for year.^cMinimum demand used in seasonal ELF calculation.

total annual energy use yields a good estimate of heating or cooling energy consumption. This approach is not valid when building operation differs from summer to winter, when cooling operates year-round, or when space heating is used during summer (e.g., for reheat). Base-load analysis can be improved by using hourly load data. **Electric load factors (ELFs)** and occupancy factors can also be used instead of hourly energy profiles (Haberl and Komor 1990a, 1990b).

Although it can be difficult to relate heating and cooling energy directly to weather, several authors, including Fels (1986) and Spielvogel (1984), suggest that this is possible using a curve-fitting method to calculate the balance point of a building (discussed in Chapter 19 of the 2013 *ASHRAE Handbook—Fundamentals*). For this method, building use must be regular, and actual rather than estimated data must be used, along with accurate dates and weather data.

More detailed breakdown of energy use requires that some metered data be collected daily (winter versus summer days, weekdays versus weekends) and that some hourly information be collected to develop profiles for night (unoccupied), morning warm-up, day (occupied), and shutdown. Submetering of energy end uses is recommended for optimal energy management. For more information, see Chapter 41.

An example spreadsheet using three years of electricity bill data for a two-story office building in Atlanta, Georgia, is presented in Table 1. (See Chapter 18 of the 2013 *ASHRAE Handbook—Fundamentals* for floor plans and elevations of the building.)

Electrical Use Profile

The **electrical use profile (EUP)** report, shown in Figure 2, divides electrical consumption into base and weather-dependent consumption. The average daily consumption for each month

Fig. 2 Electrical Use Profile for Atlanta Example Building

appears in the daily use column in Table 1, and is plotted in the EUP graph. The average daily consumption is calculated by dividing the consumption for a particular month by its billing days.

The lowest value in the daily-use column is used to plot the facility's base electrical consumption (shown as the base use line) in Figure 2. Where a facility uses electricity only for cooling or heating, or in an all-electric facility where there is no overlap between cooling and heating, the difference between these two lines represents the weather-dependent electrical consumption.

Weather-dependent energy consumption (either electric or other fuels) may then be compared to the **cooling degree-days (CDD)** or **heating degree-days (HDD)** totals for the same time period (see Chapter 14 of the 2013 *ASHRAE Handbook—Fundamentals*). This comparison shows how the building performs from month to month or year to year. The HDDs stop and CDDs start at the balance point, defined as the outdoor temperature at which, for a specified interior temperature, the total heat loss is equal to the heat gain from the sun, occupants, lights, etc. Note that all-electric buildings may have periods of overlap between heating and cooling, causing the base load to be overestimated and the heating and cooling estimates to be conservative.

Examine the average daily use line to see whether it follows the expected seasonal curve. For example, the shoulders of the curve for an electrically cooled, gas-heated hospital should closely follow the base electrical use line in the winter. As summer approaches, this curve should rise steadily to reflect the increased cooling load. Errors in meter readings, reading dates, or consumption variances appear as unusual peaks or valleys. Reexamine the data and correct errors as necessary.

If an unusual profile remains after correcting any errors, an area of potential energy savings may exist. For example, if the average daily use line for the facility is running near summer levels during March, April, May, October, and November, simultaneous heating and cooling may be occurring. This situation is illustrated in Figure 2, and often occurs with dual-duct systems.

Simultaneous heating and cooling is also indicated in the percent excess use column of Table 1. The values show the percent difference between the value appearing in the monthly base use column and the billed consumption for the month. In Figure 2, note how the excess consumption for spring and fall months runs close to the summer percentages. The monthly base use is the lowest value from the daily use column multiplied by the number of billing days for each month.

For electrically cooled, gas-heated facilities, weather-dependent consumption is the difference between the totals of the monthly base use column and the billed use column.

For an all-electric facility, subtract the total monthly consumption from total billed use for the cooling months, then do the same

calculations for heating months to determine the electric cooling and heating loads, respectively.

Calculating Electrical Load and Occupancy Factors

Another method for detecting potential energy savings is to compare the facility's electrical load factor to its occupancy factor. An ELF exceeding its occupancy factor indicates a higher-than-expected electric use occurring outside normal occupancy (e.g., lights or fans are left on or air conditioning is not shut off as early in the day as possible in summer). Setback thermostats, direct digital control (DDC) strategies, time-of-day scheduling, and lighting controls can address this.

The ELF is the ratio between the average daily use and the maximum possible use if peak demand operated for a 24 h period. The occupancy factor is the ratio between the hours a building actually is occupied and 24 h/day occupancy.

To calculate the ELF, find the month with the lowest demand on the utility data analysis spreadsheet. This value represents the base monthly peak demand, and is usually found in the same or adjacent month as the month with the lowest consumption. From the EUP report, find the lowest value in the daily use column. For example, the lowest average daily use for the office building in Table 1 is 1704 kWh (in November 2003), and the lowest monthly demand from the spreadsheet is 122 kW (in October 2003). The ELF is calculated as follows:

$$\text{ELF} = \frac{\text{Lowest average daily use}}{\text{Lowest monthly demand} \times 24} = \frac{1704}{122 \times 24} = 58\%$$

The office is normally occupied from 7:30 AM to 6:30 PM, Monday to Friday. Therefore, the occupancy factor is calculated as

$$\text{Occupancy factor} = \frac{\text{Actual weekly occupied hours}}{24 \text{ h} \times 7 \text{ days}} = \frac{55}{168} = 33\%$$

Calculating Seasonal ELFs

ELFs can also be calculated for cooling and heating seasons. Typical defaults are May to August as cooling months, and the rest of the year as heating months, but these change based on climate.

The steps for calculating a seasonal ELF are as follows:

1. The daily base consumption is determined from the daily use column of the EUP report. Subtract the lowest value of the year from the highest value of the season.
2. The base demand is determined by subtracting the lowest monthly demand for the year from the demand recorded for the month with the highest daily use. These calculations can be refined further if on- and off-peak data are available.

For example, because the electrically cooled Atlanta example building operates year-round, the summer ELF must also be calculated. The daily base consumption (1089) is determined by subtracting the lowest value (1665) from the highest cooling-season value (2754) in the daily use column of the EUP report.

From the spreadsheet, take the demand from September 2002 (the month with the peak cooling-season actual demand) and subtract the lowest monthly demand from the spreadsheet (195 – 140) to determine the cooling-season base demand (55). Thus, the summer ELF is

$$\text{Summer ELF} = \frac{1089}{55 \times 24} = 82\% \text{ (for 2002)}$$

These calculations show that the cooling equipment is operating beyond building occupancy (82% versus 33%). Therefore, excessive equipment run times should be investigated. Note that comparing

Fig. 3 Comparison Between Actual and Billed Demand for Atlanta Example Building

the ELF to the occupancy factor is meaningless for buildings occupied 24 h a day, such as hospitals.

Similar tables and charts may be created for natural gas, water, and other utilities.

Electric Demand Billing

The Atlanta example building has a ratchet-type demand rate (see Chapter 56), and billed demand is determined as a percentage of actual demand in the summer months. The ratchet is illustrated in Figure 3, where billed demand is the greater of the measured demand or 95% of the highest measured demand within the past 12 months. The billed demand for January of year 3 was 171 kW ($171 = 0.95 \times 180$), or 95% of the actual demand from July of year 2.

In Table 1, the actual demand in the first six months of 2003 had no effect on the billed demand, and therefore no effect on the dollar amount of the bill; the same is true for the last three months of the year. Because of the demand ratchet, the billed demand in January 2004 (171 kW) was set in July 2003. This means that any conservation measures that reduce peak demand will not affect billed demand until the following summer (e.g., June to September 2004); however, consumption savings begin at the next billing cycle. The effect of demand ratchet rates is that any conservation measures implemented have a longer initial payback period simply because of the utility rate structure. The energy manager should investigate other rate structures, such as a time-of-use (TOU) or seasonal rates. Rate structures for smaller buildings may not include demand charges.

Benchmarking Energy Use

Benchmarking (comparing a building’s normalized energy consumption to that of similar buildings) can be a useful first measure of energy efficiency. Relative energy use is commonly expressed in **energy utilization index (EUI)**; energy use per unit area per year) and **cost utilization index (CUI)**; energy cost per unit area per year). The Atlanta example building is 30,700 ft² in size, so its 2004 EUI is 76,200 Btu/ft² and its CUI is \$1.47/ft².

Two sources of benchmarking data for U.S. buildings are ENERGY STAR (www.energystar.gov) and the U.S. Department of Energy’s Energy Information Administration (DOE/EIA). Data on U.S. buildings in all sectors are summarized in periodic reports by the DOE/EIA. Tables 2 to 4 present DOE/EIA CBECS data in a combined format. Table 2 lists EUI input data and EUI distributions for the buildings surveyed in 2003. Table 3 lists the 2003

Commercial Buildings Energy Consumption Survey (CBECS) electricity per unit of floor area, and Table 4 shows CUI distributions. More complete and up-to-date information on the CBECS is available at www.eia.doe.gov/emeu/cbecs. When referring to these tables, keep in mind the facility’s operating or occupied hours of facility and current utility rates.

Databases. Compiling a database of past energy use and cost is important. All reliable utility data should be examined. ASHRAE *Standard 105* contains information that allows uniform, consistent expressions of energy consumption in new and existing buildings.

The energy use database for a new building may consist solely of typical data for similar buildings, as in Table 2. This may be supplemented by energy simulation data developed during design. A new building should be commissioned to ensure proper operation of all systems, including any energy-efficiency features (see ASHRAE *Guideline 1.1* and Chapter 43).

All the data presented in these tables come from detailed reports of consumption patterns, and it is important to understand how they were derived. When using the data, verify correct use with the original EIA documents.

Mazucchi (1992) lists data elements useful for normalizing and comparing utility billing information. Metered energy consumption and cost data are also published by trade associations, such as the Building Owners and Managers Association International (BOMA), the National Restaurant Association (NRA), and the American Hotel and Lodging Association (AH&LA). In some cases, local energy consumption data may be available from local utility companies or state or provincial energy offices.

Additional energy use information for homes and commercial buildings in Canada can be found at the Office of Energy Efficiency at http://www.oee.nrcan.gc.ca/corporate/statistics/neud/dpa/data_e/publications.cfm. In Europe, benchmarking data are defined on a national basis in the frame of the European Directive on the Energy Performance of Buildings (EPBD) (EC 2010). Balaras et al. (2007) provides an overview of relevant data for residential buildings, although detailed data for commercial buildings are rather limited (Gaglia et al 2007).

5. SURVEYS AND AUDITS

This section provides guidance on conducting building surveys and describes the levels of intensity of investigation.

Energy Audits

The objective of an energy audit is to identify opportunities to reduce energy use and/or cost. The results should provide the information needed by an owner/operator to decide which recommendations to implement. Energy audits may include the following:

1. Collect and analyze historical energy use

- Review more than one year of energy bills (preferably three years)

- Review billing rate class options with utility
 - Review monthly patterns for irregularities
 - Derive target goals for energy, demand, and cost indices for a building with similar characteristics and climate
- #### 2. Study the building and its operational characteristics
- Acquire a basic understanding of the mechanical and electrical systems
 - Perform a walk-through survey to become familiar with its construction, equipment, operation, and maintenance

- Meet with owner/operator and occupants to learn of special problems or needs
- Identify any required repairs to existing systems and equipment
3. Identify potential modifications to reduce energy use or cost
 - Identify low-cost/no-cost changes to the facility or to operating and maintenance procedures
 - Identify potential equipment retrofit opportunities
 - Identify training required for operating staff
 - Perform a rough estimate of the breakdown of energy consumption for significant end-use categories
4. Perform an engineering and economic analysis of potential modifications
 - For each practical measure, determine resultant savings
 - Estimate effects on building operations and maintenance costs
 - Prepare a financial evaluation of estimated total potential investment
5. Prepare a rank-ordered list
 - List all possible energy savings modifications
 - Select those that may be considered practical by the building owner
 - Assume that modifications with highest operational priority and/or best return on investment will be implemented first
 - Provide preliminary implementation costs and savings estimates

Table 4 Energy Cost Percentiles from 2003 Commercial Survey

Building Use	Weighted Energy Cost Values, \$/yr per gross square foot					Mean

- Assume that modifications with highest operational priority and/or best return on investment will be implemented first
6. Report results
- Provide description of building, operating requirements, and major energy-using systems
 - Clearly state savings from each modification and assumptions on which each is based
 - Review list of practical modifications with the owner
 - Prioritize modifications in recommended order of implementation
 - Recommend measurement and verification methods

ASHRAE (2004) identifies the following four levels of effort in the audit process.

Preliminary Energy Use Analysis. This involves analysis of historic utility use and cost and development of the energy utilization index (EUI) of the building. Compare the building's EUI to similar buildings to determine if further engineering study and analysis are likely to produce significant energy savings.

Level I: Walk-Through Analysis. This assesses a building's current energy cost and efficiency by analyzing energy bills and briefly surveying the building. The auditor should be accompanied by the building operator. Level I analysis identifies low-cost/no-cost measures and capital improvements that merit further consideration, along with an initial estimate of costs and savings. The level of detail depends on the experience of the auditor and the client's specifications. The Level I audit is most applicable when there is

some doubt about the energy savings potential of a building, or when an owner wishes to establish which buildings in a portfolio have the greatest potential savings. The results can be used to develop a priority list for a Level II or III audit.

Level II: Energy Survey and Analysis. This includes a more detailed building survey and energy analysis, including a breakdown of energy use in the building, a savings and cost analysis of all practical measures that meet the owner's constraints, and a discussion of any effect on operation and maintenance procedures. It also lists potential capital-intensive improvements that require more thorough data collection and analysis, along with an initial judgment of potential costs and savings. This level of analysis is adequate for most buildings.

Level III: Detailed Analysis of Capital-Intensive Modifications. This focuses on potential capital-intensive projects identified during Level II and involves more detailed field data gathering and engineering analysis. It provides detailed project cost and savings information with a level of confidence high enough for major capital investment decisions.

The levels of energy audits do not have sharp boundaries. They are general categories for identifying the type of information that can be expected and an indication of the level of confidence in the results. In a complete energy management program, Level II audits should be performed on all facilities.

A thorough systems approach produces the best results. This approach has been described as starting at the end rather than at the beginning. For example, consider a factory with steam boilers in constant operation. An expedient (and often cost-effective) approach is to measure the combustion efficiency of each boiler and to improve boiler efficiency. Beginning at the end requires finding all or most of the end uses of steam in the plant, which could reveal considerable waste by venting to the atmosphere, defective steam traps, uninsulated lines, and lines through unused heat exchangers. Eliminating end-use waste can produce greater savings than improving boiler efficiency.

A detailed process for conducting audits is outlined in ASHRAE (2004).

6. IMPROVING DISCRETIONARY OPERATIONS

Basic Energy Management

Control Energy System Use. The most effective method to reduce energy costs is through discretionary operations, such as turning off equipment when not needed. Ways to conserve energy include the following:

- Shut down HVAC&R systems when not required
- Reduce air leakage
- Reduce ventilation rates during periods of low occupancy
- Shut down exhaust fans when not required
- Seal or repair leaks in ducts and pipes
- Reduce water leakage
- Turn off lighting: remove unnecessary lighting, add switched circuits, use motion sensors and light-sensitive controls
- Use temperature setup and setback
- Cool with outside air
- Seal unused vents and ducts to the outside
- Tune up systems before heating and cooling seasons
- Take transformers offline during idle periods

Purchase Lower-Cost Energy. This is the second most effective method for reducing energy costs. Building operators and managers must understand all the options in purchasing energy and design systems to take advantage of changing energy costs. The following options should be considered:

- Choosing or negotiating lower-cost utility rates

- Procuring electricity or fuels through brokers
- Correcting power factor penalties
- Controlling peak electric billing demand
- Utility-sponsored demand response programs
- Transportation and interruptible natural gas rates
- Cogeneration
- Lower-cost liquid fuels
- Increasing volume for on-site storage
- Avoiding sales or excise taxes where possible
- Incentive rebates from utilities and manufacturers

Optimize Energy Systems Operation. The third most effective method for reducing energy costs is to tune energy systems to optimal performance, an ongoing process combining training, preventive maintenance, and system adjustment. Tasks for optimizing performance include

- Training operating personnel
- Tuning combustion equipment
- Adjusting gas burners to optimal efficiency
- Following an established maintenance program
- Cleaning or replacing filters
- Cleaning fan blades and ductwork
- Cycling ventilation systems to coincide with occupied spaces
- Using water treatment

Purchase Efficient Replacement Systems. This method is more expensive than the other three, presents energy managers with the greatest liability, and may be less cost-effective. It is critical to ensure that possible equipment or system replacements are objectively evaluated to confirm both the replacement costs and benefits to the owner. The optimum time for replacing less-efficient equipment is near the end of its expected life or when major repairs are needed. Systems commonly replaced include

- Lighting systems and lamps
- Heating and cooling equipment
- Energy distribution systems (pumps and fans)
- Motors
- Thermal envelope components
- Controls and energy management systems

Optimizing More Complex System Operation

As the complexity of building systems increases, additional strategies are needed to optimize energy systems. According to ASHRAE *Guideline 0-2005*, approaches include **recommissioning** (applied to a project that has been delivered using the commissioning process), **retrocommissioning** (applied to an existing facility that was not previously commissioned), and **ongoing commissioning** (continuation of the commissioning process well into the occupancy and operations phase to verify that a project continues to meet current and evolving owner's project requirements). See Chapter 43 for more information.

These approaches typically require a strong team effort of the facility staff and third-party consultants to identify and fix comfort problems as well as aggressively optimize HVAC operation and control. Some important measures typically implemented include

- Optimizing hot and cold deck reset schedules
- Optimizing duct static pressure reset schedules
- Optimizing pump control
- Optimizing terminal box settings/control
- Optimizing sequencing and water temperature reset schedules of boilers and chillers
- Identifying and repairing stuck or leaky valves and dampers
- Training operating personnel in optimum operating strategies
- Setting up monitoring and reporting of key system performance indicators

Implementing these measures has been found to reduce energy use by an average of about 20% (Claridge et al. 1998). Approaches to commissioning and optimizing operation of existing buildings can be found in ASHRAE *Guideline* 1.1-2007, Claridge and Liu (2000), Haasl and Sharp (1999), Kurt et al. (2003), Liu et al. (1997), Poulos (2007), and Tseng (2005).

7. ENERGY-EFFICIENCY MEASURES

Identifying Energy-Efficiency Measures

Various energy-efficiency measures (EEMs) can be quantitatively evaluated from end-use energy profiles. Important considerations in this process are as follows:

- System interaction
- Utility rate structure
- Payback
- Alignment with corporate goals
- Installation requirements
- Life of the measure
- Energy measurement and verification requirements
- Maintenance costs
- Tenant/occupant comfort
- Effect on building operation and appearance

Accurate energy savings calculations can be made only if system interaction is allowed for and fully understood. Annual simulation models may be necessary to accurately estimate the interactions between various EEMs.

Using average costs per unit of energy in calculating the energy cost avoidance of a particular measure is likely to result in incorrect energy costs and cost avoidance, because actual energy cost avoidance may not be proportional to the energy saved, depending on the billing method for energy used.

PNNL (1990) discusses 118 EEMs, including the following:

Boilers	Condensate systems
Envelope infiltration	Water treatment
Weather-stripping	Caulking
Fuel systems	Vestibules
Chillers	Steam distribution
Vapor barrier	Hydronic systems
Glazing	Pumps
Piping insulation	Steam traps
Instrumentation	Domestic water heating
Shading	Fixtures
Thermal shutters	Swimming pools
Surface color	Cooling towers
Roof covering	Condensing units
Lamps	Air-handling units
Ballasts	Unitary equipment
Light switching options	Outside air control
Photo cell controls	Balancing
Demand limiting	Shutdown
Power factor correction	Minimizing reheat
Energy recovery	Power distribution
Filters	Cooking practices
Humidification	Refrigeration
Dishwashing	System air leakage
Vending machines	System interaction
Heat/cool storage	Space segregation
Time-of-day rates	Computer controls
Cogeneration	Heat pumps
Active solar systems	Staff training
Occupant indoctrination	Documentation
Controls	Thermostats
Setback	Space planning
T5 lighting	Variable-frequency drives

In addition, previously implemented energy-efficiency measures should be evaluated to (1) ensure that devices are in good working order and measures are still effective, and (2) consider revising them to reflect changes in technology, building use, and/or energy cost.

Evaluating Energy-Efficiency Measures

In establishing EEM priorities, the capital cost, cost-effectiveness, effect on indoor environment, and resources available must be considered. Factors involved in evaluating the desirability of energy-efficiency measures are as follows:

- Rate of return (simple payback, life-cycle cost, net present value)
- Total savings (energy, cost avoidance)
- Initial cost (required investment)
- Other benefits (safety, comfort, improved system reliability, improved productivity)
- Liabilities (increased maintenance costs, potential obsolescence)
- Risk of failure (confidence in predicted savings, rate of increase in energy costs, maintenance complications, success of others with the same measures)

Project success also depends on the availability of

- Management attention, commitment, and follow-through
- Technical expertise
- Personnel
- Investment capital

Some owners are reluctant to implement EEMs because of bad experiences with energy projects. To reduce the risk of failure, documented performance of EEMs in similar situations should be obtained and evaluated. One common problem is that energy consumption for individual end uses is overestimated, and the predicted savings are not achieved. When doubt exists about energy consumption, temporary monitoring or spot measurements should be made and evaluated.

Heating Effects of Electrical Equipment

Electrical equipment and appliances, from lighting systems and office equipment to motors and water heaters, provide useful services; however, the electrical energy they use eventually appears as heat within the building, which can either be useful or detrimental, depending on the season. In cold weather, heat produced by electrical equipment can help reduce the load on the building's heating system. In contrast, during warm weather, it adds to the air-conditioning load.

Energy-efficient equipment and appliances consume less energy to produce the same useful work, but they also produce less heat. As a result, efficient electrical equipment increases the load on heating systems in winter and reduces the load on air-conditioning systems in summer. Effects of energy-efficient equipment and appliances on energy use for building heating and air conditioning systems are commonly called **interactive effects** or **cross effects**.

When considering the overall net savings of an energy-efficiency measure, it is important to consider its interactive effects on building heating, cooling, and refrigeration systems. Weighing the interactive effects results in better-informed decisions and realistic expectations of savings.

The percentage of heat that is useful in a specific building or room depends on several factors, including the following:

- Location of light fixtures
- Location of heaters and their thermostats or other sensors
- Type of ceiling
- Size of building
- Whether room is an interior or exterior space
- Extent of heating and cooling seasons

- Type of heating, ventilation, and air-conditioning system used in each room

Unfortunately, interactive effects are often quite complex and may require assessment by a specialist; for details, see Rundquist et al. (1993).

Exploring Financing Options

Financing alternatives also need to be considered. When evaluating proposed energy management projects, particularly those with a significant capital cost, it is important to include a life-cycle cost analysis. This not only provides good information about the financial attractiveness (or otherwise) of a project, but also assures management that the project has been carefully considered and evaluated before presentation.

Several life-cycle cost procedures are available. Chapter 37 contains details on these and other factors that should be considered in such an analysis.

Capital for energy-efficiency improvements is available from various public and private sources, and can be accessed through a wide and flexible range of financing instruments. There are variations and combinations, but the five general mechanisms for financing investments in energy efficiency are the following:

- **Internal funds**, or direct allocations from an organization's own internal capital or operating budget
- **Debt financing**, with capital borrowed directly by an organization from private lenders
- **Lease or lease-purchase agreements**, in which equipment is acquired through an operating or financing lease with little or no up-front costs, and payments are made over five to ten years
- **Energy performance contracts**, in which improvements are financed, installed, and maintained by a third party, which guarantees savings and payments based on those savings
- **Utility (or other) incentives**, such as rebates, grants, or other financial assistance offered by an energy utility or public benefits fund for design and purchase of energy-efficient systems and equipment

An organization may use several of these financing mechanisms in various combinations. The most appropriate set of options depends on the type of organization (public or private), size and complexity of a project, internal capital constraints, in-house expertise, and other factors (Turner 2001).

8. IMPLEMENTING ENERGY-EFFICIENCY MEASURES

When all desirable EEMs have been considered and a list of recommendations is developed, a report should be prepared for management. Each recommendation should include the following:

- Present condition of the system or equipment to be modified
- Recommended action
- Who should accomplish the action
- Necessary documentation or follow-up required
- Measurement and verification protocol to be used
- Potential interferences to successful completion
- Disruption to workplace or production
- Staff effort and training required
- Risk of failure
- Interactions with other end uses and EEMs
- Economic analysis (including payback, investment cost, and estimated savings figures) using corporate economic evaluation criteria
- Schedule for implementation

The energy manager must be prepared to sell the plans to upper management. Energy-efficiency measures must generally be financially justified if they are to be adopted. Every organization has limited funds available that must be used in the most effective way. The energy manager competes with others in the organization for the same funds. A successful plan must be presented in a form that is easily understood by the decision makers. Finally, the energy manager must present nonfinancial benefits, such as improved product quality or the possibility of postponing other expenditures.

After approval by management, the energy manager directs the completion of energy-efficiency measures. If utility rebates are used, the necessary approvals should be acquired before proceeding with the work. Some measures require that an architect or engineer prepare plans and specifications for the retrofit. The package of services required usually includes drawings, specifications, assistance in obtaining competitive bids, evaluation of the bids, selection of contractors, construction observation, final check-out, and assistance in training personnel in the proper application of the revisions.

9. MONITORING RESULTS

Once energy-efficiency measures are under way, procedures need to be established to record, frequently and regularly, energy consumption and costs for each building and/or end-use category in a manner consistent with functional cost accountability. Turner et al. (2001) found that consumption increased by more than 5% over two years because of component failures and controls changes after implementing optimum practices in a group of 10 buildings. Data may be obtained from the utility, but additional metering may be needed to monitor energy consumption accurately. Metering can use devices that automatically read and transmit data to a central location, or less expensive metering devices that require regular readings by building maintenance and/or security personnel. Costs for automatic metering devices, such as adding points to a DDC system, must be weighed against the benefits. Many energy managers find it helpful to collect energy consumption information hourly.

The energy manager should review data while they are current and take immediate action if profiles indicate a trend in the wrong direction. These trends could be caused by uncalibrated controls, changes in operating practices, or mechanical system failure, which should be isolated and corrected as soon as possible.

10. EVALUATING SUCCESS AND ESTABLISHING NEW GOALS

Comparing facility performance before and after implementing EEMs helps keep operating staff on track with their energy-efficiency efforts, ensuring that performance is maintained. Evaluating and reporting energy performance involves four steps:

1. Establishing key performance indicators
2. Tracking performance
3. Developing new goals
4. Reporting

Establishing Key Performance Indicators

It is important to determine performance factors of the energy management program. These are expressed in terms of key performance indicators (KPIs). The definition of key performance indicators determines what data need to be collected, how often to collect it, and how to present it to senior management. Suggested basic key performance indicators are

- Energy use index (EUI), total energy use per unit of gross floor area
- Cost utilization index (CUI), total energy cost per unit of total gross floor area
- Electrical energy use per unit of total gross floor area

Energy Policy Act. The Energy Policy Act (EPAAct 2005) set goals for federal buildings to decrease their energy consumption by 2% per year between 2006 and 2015, compared to a baseline of 2004 consumption. Thus, by 2010, for example, the target percentage reduction from 2004 values was 10%. For this initiative, the following sample KPI definitions could be used:

- 2004 benchmark measurement (energy use per unit area) reduced by 4% to set 2007 target, and by 10% to set the 2010 target, and by 16% to set the 2013 target
- Energy use data, summed monthly and annually for reporting against targets

Executive Order 13514 October 2009. Executive Order 13514 further set goals for U.S. federal agencies to develop and implement strategic energy sustainability plans for 2011 through 2021 to reduce buildings' energy use intensity (EUI), increase renewable energy use, obtain net-zero-energy buildings by 2030, and ensure that all products and services are ENERGY STAR or Federal Energy Management Program (FEMP) designated.

ENERGY STAR Tools. The U.S. Environmental Protection Agency's (EPA) ENERGY STAR web site offers the free online benchmarking tool, Target Finder (I-P units only; accessible from <https://portfoliomanager.energystar.gov/pm/targetFinder>). This tool compares actual building performance to target values, and to other similar buildings. Figure 4 shows sample results for the Atlanta example building's general office space (omitting the computer center's floor space and electricity use). ENERGY STAR also offers an online Portfolio Manager (<https://portfoliomanager.energystar.gov/pm>), which provides secure performance data management and benchmarking for multiple buildings. Annual benchmarking with these (or similar) tools helps track improvements, both over time and in comparison with other buildings.

Building Energy Labels

The ASHRAE Building Energy Quotient (beQ) labeling program rates new and existing buildings (Jarnagin 2009). Like the EPA's ENERGY STAR program, beQ focuses solely on energy, but provides additional features, including potential side-by-side comparison of operational and asset (as-designed) ratings; peak-demand reduction and demand management opportunities;

on-site renewable energy; indoor environmental quality indicators; and a list of operational features, including commissioning activities, energy-efficiency improvements, and information on improving performance. The beQ scale allows differentiation among buildings at the highest levels of performance and encourages the design and operation of net-zero-energy buildings.

The beQ program provides an easily understood scale to convey a building's energy use to the public. Through an on-site assessment, the building owner is provided with building-specific information that can be used to improve the building. Documentation on previous energy-efficiency upgrades and commissioned systems is also included. With procedures for both an asset and operational rating, building owners can make side-by-side comparisons that could further reconcile differences between designed and measured energy use.

The label itself is the most visible aspect of the program (Figure 5). It is simple to understand and is targeted at the general public. It could be posted in a building lobby and could satisfy compliance with many of the programs being developed at the state and local level requiring display of energy use. The certificate contains technical information that explains the score on the label and provides information useful to the building owner, prospective owners and tenants, and operations and maintenance personnel. This includes many of the value-added features described previously. The documentation accompanying the label and certificate provides background information useful for engineers, architects, and technically savvy building owners or prospective owners in determining the current state of the building and opportunities for improving its energy use. More information is available at <http://buildingeq.com/>.

Throughout the European Union, the European Commission's directive on the energy performance of buildings (EPBD) has been in effect since January 4, 2006. Despite difficulties, all EU member states have brought into force national laws, regulations, and administrative provisions for setting minimum requirements on the energy performance of new buildings and for existing buildings that are being renovated, as well as energy performance certification of buildings. Additional requirements include regular inspection of building systems and installations, assessment of existing facilities, and provision of advice on possible improvements and alternative solutions. The objective is to properly design new buildings and renovate existing buildings in a manner that will use the minimum non-renewable energy, produce minimum air pollution as a result of the building operating systems, and minimize construction waste, all with acceptable investment and operating costs, while improving the indoor environment for comfort, health, and safety.

An energy performance certificate (EPC) is issued when buildings are constructed, sold, or rented out. The EPC documents the energy performance of the building, expressed as a numeric indicator that allows benchmarking. The certificate includes recommendations for cost-effective improvement of the energy performance, and it is valid for up to 10 years.

According to the EPBD, minimum energy performance requirements are set for new buildings and for major renovations of large existing buildings in each EU member state. Energy performance should be upgraded to meet minimum requirements that are technically, functionally, and economically feasible. In the case of large new buildings, alternative energy supply systems should be considered (e.g., decentralized energy supply systems based on renewable energy, combined heat and power, district or block heating or cooling, heat pumps). The concerted action (CA) EPBD that was launched by the European Commission provides updated information on the implementation status in the various European countries (www.epbd-ca.eu).

Tracking Performance

The next step is to create a tracking mechanism to provide high-level KPI views, giving an overall indication of energy performance. Daily monitoring can be a valuable, proactive tool. Most DDC systems can monitor energy performance and notify the energy engineer when energy usage is off track.

For example, using the data presented in Table 1, a daily target usage/day could be determined based on outside air temperature and building occupancy schedule. If the daily use rises above the target use by a predetermined amount, the DDC system can indicate an alarm and send a notification. The energy manager can then investigate the cause of the discrepancy and correct any operational errors before long-term performance is affected. When implementing this type of performance-monitoring strategy, it is important that the measurement and verification plan provide standard operating procedures (SOPs) to facilitate troubleshooting of energy performance alarms. Procedures are discussed in ANSI/ASHRAE *Standard 105*.

Establishing New Goals

Implementing the baseline model is a three-step process: (1) the baseline period is selected, (2) the baseline model is created, and (3) one or more target models are identified to track energy performance. The baseline period should most closely reflect the current or expected building use and occupancy. Utility bill data can be used to create a steady-state baseline model of energy consumption for each building. Steady-state models are useful when using monthly, weekly, or daily data. Utility bills for an entire year are collected and used for baseline development. Many energy managers use spreadsheets to compile and compare the data. For more information on energy estimating using steady-state, data-driven models, see Chapter 19 of the 2013 *ASHRAE Handbook—Fundamentals*.

Cooling degree-days and heating degree-days are commonly used to track successes compared to EEM targets with respect to weather-dependent energy consumption. Local CDD and HDD information is traditionally based on a balance point of 65°F, which is not typically the actual balance point for any commercial or residential building; therefore, regional or local HDD values are only a general reference point. A building's weather-affected energy consumption may be calculated by using spreadsheets, regression analysis, or building energy modeling software.

For larger, more complex facilities, regression analysis can be used to analyze energy consumption if the energy manager has the analytical expertise. Through linear regression, utility bills are normalized to their daily average values. Repeated regression is done until the regression data represent the best fit to the utility bill data. Figure 6 shows the scatter plot of a best-fit baseline and target models. In this example, cooling degree-days significantly affected building energy consumption, with a best fit for a base temperature (balance point) of 54°F (Sonderegger 1998). Reducing the slope and intercept constants of the baseline by 20% creates a straight-line model equation that represents a target goal for a 20% energy reduction.

The utility bill data steady-state model is also referred to as whole-building measurement and verification. More information about this process can be found in ASHRAE *Guideline 14* and EVO (2002).

Reporting

When developing presentation materials to document energy performance, make sure that report content shows performance as related to key performance indicators (KPIs) used by the organization. Reports should be pertinent to the audience. Whereas a report to the company's administration would show how the energy management program affects operating and maintenance costs, a separate report to the operations staff might show how their daily decisions and actions change daily load profiles.

Figure 7 shows progress toward energy reduction goals for federal buildings presented to the U.S. Congress for fiscal year 2001 (DOE 2004). The figure compares energy performance against energy goals established in 1999.

Reports must be easy to understand by their readers. Keep management aware of the progress of changes to resource consumption, utility costs, and any effects (positive or negative) on the indoor environment as perceived by staff. Provide information on any major activities, savings to date, and future planned activities. Provide narrative reports with pie charts or bar graphs of cost per resource. Figure 8 shows an example of monthly gas use in a facility from year to year.

Fig. 6 Scatter Plot, Showing Best-Fit Baseline Model and Target Models

Fig. 8 Monthly Comparison of Natural Gas Use by Year

11. BUILDING EMERGENCY ENERGY USE REDUCTION

This section provides information to help building owners and operators maintain the best operating condition for the facilities during various energy emergencies. The need for occasional short-term reductions in energy use has increased because of rising energy costs and supply reductions (voluntary or mandatory) or equipment failures. In limited instances, utilities have implemented rolling blackouts, requested voluntary reductions, and asked users to operate emergency generators.

Implementing Emergency Energy Use Reductions

Each building manager or operator should use the energy team approach and identify an individual with the necessary authority and knowledge to review and fit recommendations into a building energy management plan. Because energy reduction requirements may occur with little or no advance notice, contingency plans should be developed and reviewed by the energy team. Each type of energy emergency requires a specific plan to reduce building energy use and still maintain the best possible building environment. The plan should include measures to reduce specific types of energy use in the building, as well as provisions for both slight and major energy use reduction. In some cases, existing building energy management systems can be used to implement demand shedding. The plan should be tested regularly. The following steps should be taken in developing a building emergency energy use reduction plan:

1. Develop a list of measures applicable to each building.

2. Estimate the amount and type of energy savings for each measure and appropriate combination of measures (e.g., account for air-conditioning savings from reduced lighting and other internal loads). Tabulate demand and usage savings separately for response to different types of emergencies.
3. For various levels of possible energy emergency, develop a plan that maintains the best building environment under the circumstances. Develop the plan so that actions taken can be energy-source-specific. That is, group actions to be taken to reduce energy consumption for each type of energy used in the building. Include both short- and long-term measures in the plan. Operational changes may be implemented quickly and prove adequate for short-term emergencies.
4. Experiment with the plan; record energy consumption and demand reduction data, and revise the plan as necessary. Much of the experimentation may be done on weekends to minimize disruption.
5. Meet with the local utility provider(s) and back-up fuel suppliers to review the plan.
6. Meet with building occupants annually to review the plan to ensure that actions taken do not cause major disruptions or compromise life safety or security provisions. Establish a procedure for notification of building occupants before actions are taken.
7. Be certain that there is a plan to minimize entrapment of occupants in elevators in case of emergency disruptions.
8. Review the plan annually with building security and the fire department to ensure that emergency efforts are not hindered by the plan and that security or emergency people know what to expect (reduced lighting, lower temperatures, elevators out of operation, etc.).
9. When preparing the plan, **do not**
 - Take lighting fixtures out of service that are on night lighting circuits, provide lighting for security cameras, or provide egress lighting during a power failure
 - Remove elevators or lifts from service that will be required for emergency or ADA purposes
 - Reduce ventilation or exhaust in laboratories or other areas where hazardous conditions exist

Some measures can be implemented permanently. Depending on the level of energy emergency and the building priority, the following actions may be considered in developing the plan for emergency energy reduction:

General

- Change operating hours
- Move personnel into other building areas (consolidation)
- Ensure that emergency generators are tuned up and run frequently enough to increase dependability, service the expected electrical load, and keep alternative fuel supply at optimal level
- Shut off nonessential equipment
- Review the amount of uninterruptible power supply (UPS) time available for critical equipment, and upgrade if necessary

Thermal Envelope

- Use all existing blinds, draperies, and window coverings
- Install interior window insulation
- Caulk and seal around unused exterior doors and windows (but do not seal doors required for emergency egress or that may be required by the fire department in an emergency).
- Install solar shading devices in summer
- Seal all unused vents and ducts to outside

HVAC Systems and Equipment

- Modify controls or control set points to raise and lower temperature and humidity as necessary

- Shut off or isolate all nonessential equipment and spaces
- Lower thermostat set points in winter
- Raise chilled-water temperature
- Lower hot-water temperature (*Note:* Keep hot-water temperature higher than 145°F if a noncondensing gas boiler is used)
- Reduce or eliminate reheat and recool
- Reduce (and eliminate during unoccupied hours) mechanical ventilation and exhaust airflow
- Raise thermostat set points in summer or turn cooling equipment off

Lighting Systems

- Evaluate overlit areas and remove lamps or reduce lamp wattage
- Use task lighting where appropriate
- Move building functions to exterior or daylit areas
- Turn off electric lights in areas with adequate natural light
- Revise building cleaning and security procedures to minimize lighting periods
- Consolidate parking and turn off unused parking security lighting

Special Equipment

- Take transformers offline during periods of nonuse
- Shut off or regulate the use of vertical transportation systems
- Shut off unused or unnecessary equipment, such as photocopiers, music systems, and computers
- Reduce or turn off potable hot-water supply

Building Operation Demand Reduction

- Sequence or interlock heating or air-conditioning systems
- Disconnect or turn off all nonessential loads
- Reduce lighting levels
- Preheat or precool, if possible, before utility-imposed emergency periods

When Power Is Restored

- To prevent overloading the system, turn equipment back on gradually
- Test and verify proper operation of critical equipment, security, and fire and smoke alarms
- Check monitors on temperature-sensitive equipment
- Discuss lessons learned with staff and make any necessary changes to emergency plan
- Restock whatever emergency supplies were used, including alternative fuels

CHAPTER 37

OWNING AND OPERATING COSTS

<i>Owning Costs</i>	37.1
<i>Operating Costs</i>	37.4
<i>Maintenance Costs</i>	37.7
<i>Refrigerant Phaseouts</i>	37.8
<i>Other Issues</i>	37.8
<i>Economic Analysis Techniques</i>	37.9
<i>Symbols</i>	37.13

OWNING and operating cost information for the HVAC system should be part of the investment plan of a facility. This information can be used for preparing annual budgets, managing assets, and selecting design options. Table 1 shows a representative form that summarizes these costs.

A properly engineered system must also be economical, but this is difficult to assess because of the complexities surrounding effective money management and the inherent difficulty of predicting future operating and maintenance expenses. Complex tax structures and the time value of money can affect the final engineering decision. This does not imply use of either the cheapest or the most expensive system; instead, it demands intelligent analysis of financial objectives and the owner's requirements.

Certain tangible and intangible costs or benefits must also be considered when assessing owning and operating costs. Local codes may require highly skilled or certified operators for specific types of equipment. This could be a significant cost over the life of the system. Similarly, intangible items such as aesthetics, acoustics, comfort, safety, security, flexibility, and environmental impact may vary by location and be important to a particular building or facility.

1. OWNING COSTS

The following elements must be established to calculate annual owning costs: (1) initial cost, (2) analysis or study period, (3) interest or discount rate, and (4) other periodic costs such as insurance, property taxes, refurbishment, or disposal fees. Once established, these elements are coupled with operating costs to develop an economic analysis, which may be a simple payback evaluation or an in-depth analysis such as outlined in the section on Economic Analysis Techniques.

Initial Cost

Major decisions affecting annual owning and operating costs for the life of the building must generally be made before completing contract drawings and specifications. To achieve the best performance and economics, alternative methods of solving the engineering problems peculiar to each project should be compared in the early stages of design. Oversimplified estimates can lead to substantial errors in evaluating the system.

The evaluation should lead to a thorough understanding of installation costs and accessory requirements for the system(s) under consideration. Detailed lists of materials, controls, space and structural requirements, services, installation labor, and so forth can be prepared to increase accuracy in preliminary cost estimates. A reasonable estimate of capital cost of components may be derived from cost records of recent installations of comparable design or from quotations

Building Construction and Alteration
Mechanical and electric space
Chimneys and flues
Building insulation
Solar radiation controls
Acoustical and vibration treatment
Distribution shafts, machinery foundations, furring

submitted by manufacturers and contractors, or by consulting commercially available cost-estimating guides and software. Table 2 shows a representative checklist for initial costs.

Analysis Period

The time frame over which an economic analysis is performed greatly affects the results. The analysis period is usually determined by specific objectives, such as length of planned ownership or loan repayment period. However, as the length of time in the analysis period increases, there is a diminishing effect on net present-value calculations. The chosen analysis period is often unrelated to the equipment depreciation period or service life, although these factors may be important in the analysis.

Service Life

For many years, this chapter included estimates of service lives for various HVAC system components, based on a survey conducted in 1976 under ASHRAE research project RP-186 (Akalin 1978). These estimates have been useful to a generation of practitioners, but changes in technology, materials, manufacturing techniques, and maintenance practices now call into question the continued validity of the original estimates. Consequently, ASHRAE research project TRP-1237 developed an Internet-based data collection tool

Table 3 Median Service Life

Equipment Type	Median Service Life, Years	Total No. of Units	No. of Units Replaced
DX air distribution equipment	>24	1907	284
Chillers, centrifugal	>25	234	34
Cooling towers, metal	>22	170	24
Boilers, hot-water, steel gas-fired	>22	117	24
Controls, pneumatic	>18	101	25
electronic	>7	68	6
Potable hot-water heaters, electric	>21	304	36

and database on HVAC equipment service life and maintenance costs, to allow equipment owning and operating cost data to be continually updated and current. The database was seeded with information gathered from a sample of 163 commercial office buildings located in major metropolitan areas across the United States. Abramson et al. (2005) provide details on the distribution of building size, age, and other characteristics. Table 3 presents estimates of median service life for various HVAC components in this sample.

Median service life in Table 3 is based on analysis of survival curves, which take into account the units still in service and the units replaced at each age (Hiller 2000). Conditional and total survival rates are calculated for each age, and the percent survival over time is plotted. Units still in service are included up to the point where the age is equal to their current age at the time of the study. After that point, these units are censored (removed from the population). Median service life in this table indicates the highest age at which the survival rate remains at or above 50% while the sample size is 30 or more. There is no hard-and-fast rule about the number of units needed in a sample before it is considered statistically large enough to be representative, but usually the number should be larger than 25 to 30 (Lovvorn and Hiller 2002). This rule-of-thumb is used because each unit removal represents greater than a 3% change in survival rate as the sample size drops below 30, and that percentage increases rapidly as the sample size gets even smaller.

The database initially developed and seeded under research project TRP-1237 (Abramson et al. 2005) is now available online, providing engineers with equipment service life and annual maintenance costs for a variety of building types and HVAC systems. The database can be accessed at www.ashrae.org/database.

As of the end of 2009 this database contained more than 300 building types, with service life data on more than 38,000 pieces of equipment.

The database allows users to access up-to-date information to determine a range of statistical values for equipment owning and operating costs. Users are encouraged to contribute their own service life and maintenance cost data, further expanding the utility of this tool. Over time, this input will provide sufficient service life and maintenance cost data to allow comparative analysis of many different HVAC systems types in a broad variety of applications. Data can be entered by logging into the database and registering, which is free. With this, ASHRAE is providing the necessary methods and information to assist in using life-cycle analysis techniques to help select the most appropriate HVAC system for a specific application. This system of collecting data also greatly reduces the time between data collection and when users can access the information.

Figure 1 presents the survival curve for centrifugal chillers, based on data in Abramson et al. (2005). The point at which survival rate drops to 50% based on all data in the survey is 31 years. However, because the sample size drops below the statistically relevant number of 30 units at 25 years, the median service life of centrifugal chillers can only be stated with confidence as >25 years.

Table 4 Comparison of Service Life Estimates

Equipment Item	Median Service Life, Years		Equipment Item	Median Service Life, Years		Equipment Item	Median Service Life, Years	
	Abramson et al. (2005)	Akalin (1978)		Abramson et al. (2005)	Akalin (1978)		Abramson et al. (2005)	Akalin (1978)

Electric	N/A*	10	Wood	N/A*	20			
Hot-water or steam	N/A*	25	Ceramic	N/A*	34			

*N/A: Not enough data yet in Abramson et al. (2005). Note that data from Akalin (1978) for these categories may be outdated and not statistically relevant. Use these data with caution until enough updated data are accumulated in Abramson et al.

Fig. 1 Survival Curve for Centrifugal Chillers
[Based on data in Abramson et al. (2005)]

Table 4 compares the estimates of median service life in Abramson et al. (2005) with those developed with those in Akalin (1978). Most differences are on the order of one to five years.

Estimated service life of new equipment or components of systems not listed in Table 3 or 4 may be obtained from manufacturers, associations, consortia, or governmental agencies. Because of the proprietary nature of information from some of these sources, the variety of criteria used in compiling the data, and the diverse objectives in disseminating them, extreme care is necessary in comparing service life from different sources. Designs, materials, and components of equipment listed in Tables 3 and 4 have changed over time and may have altered the estimated service lives of those equipment categories. Therefore, establishing equivalent comparisons of service life is important.

As noted, service life is a function of the time when equipment is replaced. Replacement may be for any reason, including, but not limited to, failure, general obsolescence, reduced reliability, excessive maintenance cost, and changed system requirements (e.g., building characteristics, energy prices, environmental considerations). Service lives shown in the tables are based on the age of the equipment when it was replaced, regardless of the reason it was replaced.

Locations in potentially corrosive environments and unique maintenance variables affect service life. Examples include the following:

- **Coastal and marine environments**, especially in tropical locations, are characterized by abundant sodium chloride (salt) that is carried by sea spray, mist, or fog.

Many owners require equipment specifications stating that HVAC equipment located along coastal waters will have corrosion-resistant materials or coatings. Design criteria for systems installed under these conditions should be carefully considered.

- **Industrial applications** provide many challenges to the HVAC designer. It is very important to know if emissions from the industrial plant contain products of combustion from coal, fuel oils, or releases of sulfur oxides (SO₂, SO₃) and nitrogen oxides (NO_x) into the atmosphere. These gases typically accumulate and return to the ground in the form of acid rain or dew.

Not only is it important to know the products being emitted from the industrial plant being designed, but also the adjacent upwind or downwind facilities. HVAC system design for a plant located downwind from a paper mill requires extraordinary corrosion protection or recognition of a reduced service life of the HVAC equipment.

- **Urban** areas generally have high levels of automotive emissions as well as abundant combustion by-products. Both of these contain elevated sulfur oxide and nitrogen oxide concentrations.
- **Maintenance** factors also affect life expectancy. The HVAC designer should temper the service life expectancy of equipment with a **maintenance factor**. To achieve the estimated service life values in Table 3, HVAC equipment must be maintained properly, including good filter-changing practices and good maintenance procedures. For example, chilled-water coils with more than four rows and close fin spacing are virtually impossible to clean even using extraordinary methods; they are often replaced with multiple coils in series, with a maximum of four rows and lighter fin spacing.

Depreciation

Depreciation periods are usually set by federal, state, or local tax laws, which change periodically. Consult applicable tax laws for more information on depreciation.

Interest or Discount Rate

Most major economic analyses consider the opportunity cost of borrowing money, inflation, and the time value of money. **Opportunity cost** of money reflects the earnings that investing (or lending) the money can produce. **Inflation** (price escalation) decreases the purchasing or investing power (value) of future money because it can buy less in the future. **Time value** of money reflects the fact that money received today is more useful than the same amount received a year from now, even with zero inflation, because the money is available earlier for reinvestment.

The cost or value of money must also be considered. When borrowing money, a percentage fee or interest rate must normally be paid. However, the interest rate may not necessarily be the correct cost of money to use in an economic analysis. Another factor, called the **discount rate**, is more commonly used to reflect the true cost of money [see Fuller and Petersen (1996) for detailed discussions]. Discount rates used for analyses vary depending on individual investment, profit, and other opportunities. Interest rates, in contrast, tend to be more centrally fixed by lending institutions.

To minimize the confusion caused by the vague definition and variable nature of discount rates, the U.S. government has specified particular discount rates to be used in economic analyses relating to federal expenditures. These discount rates are updated annually (Rushing et al. 2010) but may not be appropriate for private-sector economic analyses.

Periodic Costs

Regularly or periodically recurring costs include insurance, property taxes, income taxes, rent, refurbishment expenses, disposal fees (e.g., refrigerant recycling costs), occasional major repair costs, and decommissioning expenses.

Insurance. Insurance reimburses a property owner for a financial loss so that equipment can be repaired or replaced. Insurance often indemnifies the owner from liability, as well. Financial recovery may include replacing income, rents, or profits lost because of property damage.

Some of the principal factors that influence the total annual insurance premium are building size, construction materials, amount and size of mechanical equipment, geographic location, and policy deductibles. Some regulations set minimum required insurance coverage and premiums that may be charged for various forms of insurable property.

Property Taxes. Property taxes differ widely and may be collected by one or more agencies, such as state, county, or local governments or special assessment districts. Furthermore, property taxes may apply to both real (land, buildings) and personal

(everything else) property. Property taxes are most often calculated as a percentage of assessed value, but are also determined in other ways, such as fixed fees, license fees, registration fees, etc. Moreover, definitions of assessed value vary widely in different geographic areas. Tax experts should be consulted for applicable practices in a given area.

Income Taxes. Taxes are generally imposed in proportion to net income, after allowance for expenses, depreciation, and numerous other factors. Special tax treatment is often granted to encourage certain investments. Income tax professionals can provide up-to-date information on income tax treatments.

Other Periodic Costs. Examples of other costs include changes in regulations that require unscheduled equipment refurbishment to eliminate use of hazardous substances, and disposal costs for such substances.

Replacement Costs and Salvage Value. Replacement costs and salvage value should be evaluated when calculating owning cost. Replacement cost is the cost to remove existing equipment and install new equipment. Salvage value is the value of equipment or its components for recycling or other uses. Equipment's salvage value may be negative when removal, disposal, or decommissioning costs are considered.

2. OPERATING COSTS

Operating costs are those incurred by the actual operation of the system. They include costs of fuel and electricity, wages, supplies, water, material, and maintenance parts and services. Energy is a large part of total operating costs. Chapter 19 of the 2013 *ASHRAE Handbook—Fundamentals* outlines how fuel and electrical requirements are estimated. Because most energy management activities are dictated by economics, the facility manager must understand the utility rates that apply to each facility. Electric rates are usually more complex than gas or water rates. In addition to general commercial or institutional electric rates, special rates may exist such as time of day, interruptible service, on-peak/off-peak, summer/winter, and peak demand. Electric rate schedules vary widely in North America. The facility manager should work with local utility companies to identify the most favorable rates and to understand how to qualify for them. The local utility representative can help the facility manager develop the most cost-effective methods of metering and billing. The facility manager must understand the utility rates, including the distinction between marginal and average costs and, in the case of demand-based electric rates, how demand is computed.

Note that, in general, total energy consumption cannot be multiplied by a per-unit energy cost to arrive at a correct annual utility cost, because rate schedules (especially for electricity) often have a sliding scale of prices that vary with consumption, time of day, and other factors.

Future energy costs used in discounted payback analyses must be carefully evaluated. Energy costs have historically escalated at a different rate than the overall inflation rate as measured by the consumer price index. To assist in life-cycle cost analysis, fuel price escalation rate forecasts by end-use sector and fuel type are updated annually by the National Institute of Standards and Technology and published in the Annual Supplement to NIST *Handbook 135* (Rushing et al. 2010). There are no published projection rates for water prices for use in life-cycle cost analyses. Water escalation rates should be obtained from the local water utility when possible. Building designers should use energy price projections from their local utility in place of regional forecasts whenever possible, especially when evaluating alternative fuel types.

Deregulation in some areas may allow increased access to nontraditional energy providers and pricing structures; in other areas, traditional utility infrastructures and practices may prevail. The amount and profile of the energy used by the facility will also determine

energy cost. Unbundling energy services (having separate contracts for energy and for its transportation to point of use) may dictate separate agreements for each service component or may be packaged by a single provider. Contract length and price stability are factors in assessing nontraditional versus traditional energy suppliers when estimating operating costs. The degree of energy supply and system reliability and price stability considered necessary by the owner/occupants of a building may require considerable deliberation. The sensitivity of a building's functionality to energy-related variables should dictate the degree of attention allocated in evaluating these factors.

Electrical Energy

The total cost of electricity is determined by a rate schedule and is usually a combination of several components: consumption (kilowatt-hours), demand (kilowatts) fuel adjustment charges, special allowances or other adjustments, and applicable taxes. Of these, consumption and demand are the major cost components and the ones the owner or facility manager may be able to affect.

Electricity Consumption Charges. Most electric rates have step-rate schedules for consumption, and the cost of the last unit consumed may be substantially different from that of the first. The last unit is usually cheaper than the first because the fixed costs to the utility may already have been recovered from earlier consumption costs. Because of this, the energy analysis cannot use average costs to accurately predict savings from implementation of energy conservation measures. Average costs will overstate the savings possible between alternative equipment or systems; instead, marginal (or incremental) costs must be used.

To reflect time-varying operating costs or to encourage peak shifting, electric utilities may charge different rates for consumption according to the time of use and season, with higher costs occurring during the peak period of use.

Fuel Adjustment Charge. Because of substantial variations in fuel prices, electric utilities may apply a fuel adjustment charge to recover costs. This adjustment may not be reflected in the rate schedule. The fuel adjustment is usually a charge per unit of consumption and may be positive or negative, depending on how much of the actual fuel cost is recovered in the energy consumption rate. The charge may vary monthly or seasonally.

Allowances or Adjustments. Special discounts or rates may be available for customers who can receive power at higher voltages or for those who own transformers or similar equipment. Special rates or riders may be available for specific interruptible loads such as domestic water heaters.

Certain facility electrical systems may produce a low power factor [i.e., ratio of real (active) kilowatt power to apparent (reactive) kVA power], which means that the utility must supply more current on an intermittent basis, thus increasing their costs. These costs may be passed on as an adjustment to the utility bill if the power factor is below a level established by the utility.

When calculating power bills, utilities should be asked to provide detailed cost estimates for various consumption levels. The final calculation should include any applicable special rates, allowances, taxes, and fuel adjustment charges.

Demand Charges. Electric rates may also have demand charges based on the customer's peak kilowatt demand. Whereas consumption charges typically cover the utility's operating costs, demand charges typically cover the owning costs.

Demand charges may be formulated in a variety of ways:

- *Straight charge.* Cost per kilowatt per month, charged for the peak demand of the month.
- *Excess charge.* Cost per kilowatt above a base demand (e.g., 50 kW), which may be established each month.

- *Maximum demand (ratchet).* Cost per kilowatt for maximum annual demand, which may be reset only once a year. This established demand may either benefit or penalize the owner.
- *Combination demand.* Cost per hour of operation of demand. In addition to a basic demand charge, utilities may include further demand charges as demand-related consumption charges.

The actual demand represents the peak energy use averaged over a specific period, usually 15, 30, or 60 min. Accordingly, high electrical loads of only a few minutes' duration may never be recorded at the full instantaneous value. Alternatively, peak demand is recorded as the average of several consecutive short periods (i.e., 5 min out of each hour).

The particular method of demand metering and billing is important when load shedding or shifting devices are considered. The portion of the total bill attributed to demand may vary greatly, from 0% to as high as 70%.

- *Real-time or time-of-day rates.* Cost of electricity at time of use. An increasing number of utilities offer these rates. End users who can shift operations or install electric load-shifting equipment, such as thermal storage, can take advantage of such rates. Because these rates usually reflect a utility's overall load profile and possibly the availability of specific generating resources, contact with the supplying utility is essential to determine whether these rates are a reasonable option for a specific application.

Understanding Electric Rates. To illustrate a typical commercial electric rate with a ratchet, electricity consumption and demand data for an example building are presented in Table 5.

The example building in Table 5 is on a ratcheted rate, and bill demand is determined as a percentage of actual demand in the summer. How the ratchet operates is illustrated in Figure 2.

Table 5 Electricity Data Consumption and Demand for Atlanta Example Building, 2003 to 2004

	Billing Days	Consumption, kWh	Actual Demand, kW	Billing Demand, kW	Total Cost, US\$
Jan. 2003	29	57,120	178	185	4,118
Feb. 2003	31	61,920	145	185	4,251
Mar. 2003	29	60,060	140	185	4,199

Total 2004	339	685,680			45,240

Fig. 2 Bill Demand and Actual Demand for Atlanta Example Building, 2004

Table 5 shows that the actual demand in the first six months of 2004 had no effect on the billing demand, and therefore no effect on the dollar amount of the bill. The same is true for the last three months of the year. Because of the ratchet, the billing demand in the first half of 2004 was set the previous summer. Likewise, billing demand for the last half of 2004 and first half of 2005 was set by the peak actual demand of 180 kW in July 2003. This tells the facility manager to pay attention to demand in the summer months (June to September) and that demand is not a factor in the winter (October to May) months for this particular rate. (Note that Atlanta's climate is hot and humid; in other climates, winter electric demand is an important determinant of costs.) Consumption must be monitored all year long.

Understanding the electric rates is key when evaluating the economics of energy conservation projects. Some projects save electrical demand but not consumption; others save mostly consumption but have little effect on demand. Electric rates must be correctly applied for economic analyses to be accurate. Chapter 56 contains a thorough discussion of various electric rates.

Natural Gas

Rates. Conventional natural gas rates are usually a combination of two main components: (1) utility rate or base charges for gas consumption and (2) purchased gas adjustment (PGA) charges.

Although gas is usually metered by volume, it is often sold by energy content. The utility rate is the amount the local distribution company charges per unit of energy to deliver the gas to a particular location. This rate may be graduated in steps; the first 100 units of gas consumed may not be the same price as the last 100 units. The PGA is an adjustment for the cost of the gas per unit of energy to the local utility. It is similar to the electric fuel adjustment charge. The total cost per unit is then the sum of the appropriate utility rate and the PGA, plus taxes and other adjustments.

Interruptible Gas Rates and Contract/Transport Gas. Large industrial plants usually have the ability to burn alternative fuels and can qualify for special interruptible gas rates. During peak periods of severe cold weather, these customers' supply may be curtailed by the gas utility, and they may have to switch to propane, fuel oil, or some other back-up fuel. The utility rate and PGA are usually considerably cheaper for these interruptible customers than they are for firm-rate (noninterruptible) customers.

Deregulation of the natural gas industry allows end users to negotiate for gas supplies on the open market. The customer actually contracts with a gas producer or broker and pays for the gas at the source. Transport fees must be negotiated with the pipeline companies carrying the gas to the customer's local gas utility. This can be a very complicated administrative process and is usually economically feasible only for large gas users. Some local utilities have special rates for delivering contract gas volumes through their system; others simply charge a standard utility fee (PGA is not applied because the customer has already negotiated with the supplier for the cost of the fuel itself).

When calculating natural gas bills, be sure to determine which utility rate and PGA and/or contract gas price is appropriate for the particular interruptible or firm-rate customer. As with electric bills, the final calculation should include any taxes, prompt payment discounts, or other applicable adjustments.

Other Fossil Fuels

Propane, fuel oil, and diesel are examples of other fossil fuels in widespread use. Calculating the cost of these fuels is usually much simpler than calculating typical utility rates.

The cost of the fuel itself is usually a simple charge per unit volume or per unit mass. The customer is free to negotiate for the best price. However, trucking or delivery fees must also be included in final calculations. Some customers may have their own transport trucks, but most seek the best delivered price. If storage tanks are not customer-owned, rental fees must be considered. Periodic replacement of diesel-type fuels may be necessary because of storage or shelf-life limitations and must also be considered. The final fuel cost calculation should include any of these costs that are applicable, as well as appropriate taxes.

It is usually difficult, however, to relate usage of stored fossil fuels (e.g., fuel oil) with their operating costs. This is because propane or fuel oil is bought in bulk and stored until needed, and normally not metered or measured as it is consumed, whereas natural gas and power are metered and billed for as they are used.

Energy Source Choices

In planning for a new facility, the designer may undertake **energy master planning**. One component of energy master planning is choice of fuels. Typical necessary decisions include, for example, whether the building should be heated by electricity or natural gas, how service hot water should be produced, whether a hybrid heating plant (i.e., a combination of both electric and gas boilers) should be considered, and whether emergency generators should be fueled by diesel or natural gas.

Decision makers should consider histories or forecasts of price volatility when selecting energy sources. In addition to national trending, local energy price trends from energy suppliers can be informative. These evaluations are particularly important where relative operating costs parity exists between various fuel options, or where selecting more efficient equipment may help mitigate utility price concerns.

Many sources of historic and projected energy costs are available for reference. In addition to federal projections, utility and energy supplier annual reports and accompanying financial data may provide insight into future energy costs. Indicators such as constrained or declining energy supply or production may be key factors in projecting future energy pricing trends. Pricing patterns that suggest unusual levels of energy price volatility should be carefully analyzed and tested at extreme predicted price levels to assess potential effects on system operating costs.

Under conditions of rapidly evolving energy prices or new pricing options, imminent technological improvements, or pending environmental standards and mandates, the adaptability of design options must be carefully evaluated. Where appropriate, contingency

planning for accommodating foreseeable alterations to building systems may be prudent. Using diverse energy sources or suppliers in lieu of single sourcing may reduce cost of shifting energy use in the event that single-source pricing becomes volatile, and may even provide negotiating leverage for facility owners.

Water and Sewer Costs

Water and sewer costs have risen in many parts of the country and should not be overlooked in economic analyses. Fortunately, these rates are usually very simple and straightforward: commonly, a charge per hundred cubic feet (CCF) for water and a different charge per CCF for sewer. Because water consumption is metered and sewerage is not, most rates use the water consumption quantity to compute the sewer charge. If an owner uses water that is not returned to sewer, there may be an opportunity to receive a credit or refund. Owners frequently use irrigation meters for watering grounds when the water authority has a special irrigation rate with no sewer charge. Another opportunity that is sometimes overlooked is to separately meter makeup water for cooling towers. This can be done with an irrigation meter if the costs of setting the meter can be justified; alternatively, it may be done by installing an in-line water meter for the cooling tower, in which case the owner reports the usage annually and applies for a credit or refund.

Because of rising costs of water and sewer, water recycling and reclamation is becoming more cost effective. For example, it may now be cost effective in some circumstances to capture cooling coil condensate and pump it to a cooling tower for makeup water.

3. MAINTENANCE COSTS

The quality of maintenance and maintenance supervision can be a major factor in overall life-cycle cost of a mechanical system. The maintenance cost of mechanical systems varies widely depending upon configuration, equipment locations, accessibility, system complexity, service duty, geography, and system reliability requirements. Maintenance costs can be difficult to predict, because each system or facility is unique.

Dohrmann and Alereza (1986) obtained maintenance costs and HVAC system information from 342 buildings located in 35 states in the United States. In 1983 U.S. dollars, data collected showed a mean HVAC system maintenance cost of \$0.32/ft² per year, with a median cost of \$0.24/ft² per year. Building age has a statistically significant but minor effect on HVAC maintenance costs. Analysis also indicated that building size is not statistically significant in explaining cost variation. The type of maintenance program or service agency that building management chooses can also have a significant effect on total HVAC maintenance costs. Although extensive or thorough routine and preventive maintenance programs cost more to administer, they usually extend equipment life; improve reliability; and reduce system downtime, energy costs, and overall life-cycle costs.

Some maintenance cost data are available, both in the public domain and from proprietary sources used by various commercial service providers. These sources may include equipment manufacturers, independent service providers, insurers, government agencies (e.g., the U.S. General Services Administration), and industry-related organizations [e.g., the Building Owners and Managers Association (BOMA)] and service industry publications. More traditional, widely used products and components are likely to have statistically reliable records. However, design changes or modifications necessitated by industry changes, such as alternative refrigerants, may make historical data less relevant.

Newer HVAC products, components, system configurations, control systems and protocols, and upgraded or revised system applications present an additional challenge. Care is required when using data not drawn from broad experience or field reports. In

many cases, maintenance information is proprietary or was sponsored by a particular entity or group. Particular care should be taken when using such data. It is the user’s responsibility to obtain these data and to determine their appropriateness and suitability for the application being considered.

ASHRAE research project TRP-1237 (Abramson et al. 2005) developed a standardized Internet-based data collection tool and database on HVAC equipment service life and maintenance costs. The database was seeded with data on 163 buildings from around the country. Maintenance cost data were gathered for total HVAC system maintenance costs from 100 facilities. In 2004 dollars, the mean HVAC maintenance cost from these data was \$0.47/ft², and the median cost was \$0.44/ft². Table 6 compares these figures with estimates reported by Dohrmann and Alereza (1983), both in terms of contemporary dollars, and in 2004 dollars, and shows that the cost per square foot varies widely between studies.

Estimating Maintenance Costs

Total HVAC maintenance cost for new and existing buildings with various types of equipment may be estimated several ways, using several resources. Equipment maintenance requirements can be obtained from the equipment manufacturers for large or custom pieces of equipment. Estimating in-house labor requirements can be difficult; BOMA (2003) provides guidance on this topic. Many independent mechanical service companies provide preventative maintenance contracts. These firms typically have proprietary estimating programs developed through their experience, and often provide generalized maintenance costs to engineers and owners upon request, without obligation.

When evaluating various HVAC systems during design or retrofit, the absolute magnitude of maintenance costs may not be as important as the relative costs. Whichever estimating method or resource is selected, it should be used consistently throughout any evaluation. Mixing information from different resources in an evaluation may provide erroneous results.

Applying simple costs per unit of building floor area for maintenance is highly discouraged. Maintenance costs can be generalized by system types. When projecting maintenance costs for different HVAC systems, the major system components need to be identified with a required level of maintenance. The potential long-term costs of environmental issues on maintenance costs should also be considered.

Factors Affecting Maintenance Costs

Maintenance costs are primarily a measure of labor activity. System design, layout, and configuration can significantly affect the amount of time and effort required for maintenance and, therefore, the maintenance cost. Factors to consider when evaluating maintenance costs include the following:

- **Quantity and type of equipment.** Each piece of equipment requires a core amount of maintenance and time, regardless of its size or capacity. A greater number of similar pieces of equipment are generally more expensive to maintain than larger but fewer units. For example, one manufacturer suggests the annual maintenance for centrifugal chillers is 24 h for a nominal

Table 6 Comparison of Maintenance Costs Between Studies

Survey	Cost per ft ² , as Reported		Consumer Price Index	Cost per ft ² , 2004 Dollars	
	Mean	Median		Mean	Median
Dohrmann and Alereza (1983)	\$0.32	\$0.24	99.6	\$0.61	\$0.46
Abramson et al. (2005)	\$0.47	\$0.44	188.9	\$0.47	\$0.44

1000 ton chiller and 16 h for a nominal 500 ton chiller. Therefore, the total maintenance labor for a 1000 ton chiller plant with two 500 ton chillers would be 32 h, or 1/3 more than a single 1000 to chiller.

- **Equipment location and access.** The ability to maintain equipment in a repeatable and cost-effective manner is significantly affected by the equipment's location and accessibility. Equipment that is difficult to access increases the amount of time required to maintain it, and therefore increases maintenance cost. Equipment maintenance requiring erection of ladders and scaffolding or hydraulic lifts increases maintenance costs while likely reducing the quantity and quality of maintenance performed. Equipment location may also dictate an unusual working condition that could require more service personnel than normal. For example, maintenance performed in a confined space (per OSHA definitions) requires an additional person to be present, for safety reasons.
- **System run time.** The number of hours of operation for an HVAC system affects maintenance costs. Many maintenance tasks are dictated by equipment run time. The greater the run time, the more often these tasks need to be performed.
- **Critical systems.** High-reliability systems require more maintenance to ensure uninterrupted system operation. Critical system maintenance is also usually performed with stringent shutdown and failsafe procedures that tend to increase the amount of time required to service equipment. An office building system can be turned off for a short time with little effect on occupants, allowing maintenance almost any time. Shutdown of a hospital operating room or pharmaceutical manufacturing HVAC system, on the other hand, must be coordinated closely with the operation of the facility to eliminate risk to patients or product. Maintenance on critical systems may sometimes incur labor premiums because of unusual shutdown requirements.
- **System complexity.** More complex systems tend to involve more equipment and sophisticated controls. Highly sophisticated systems may require highly skilled service personnel, who tend to be more costly.
- **Service environment.** HVAC systems subjected to harsh operating conditions (e.g., coastal and marine environments) or environments like industrial operations may require more frequent and/or additional maintenance.
- **Local conditions.** The physical location of the facility may require additional maintenance. Equipment in dusty or dirty areas or exposed to seasonal conditions (e.g., high pollen, leaves) may require more frequent or more difficult cleaning of equipment and filters. Additional maintenance tasks may be needed.
- **Geographical location.** Maintenance costs for remote locations must consider the cost of getting to and from the locations. Labor costs for the number of anticipated trips and their duration for either in-house or outsourced service personnel to travel to and from the site must be added to the maintenance cost to properly estimate the total maintenance cost.
- **Equipment age.** The effect of age on equipment repair costs varies significantly by type of HVAC equipment. Technologies in equipment design and application have changed significantly, affecting maintenance costs.
- **Available infrastructure.** Maintenance costs are affected by the availability of an infrastructure that can maintain equipment, components, and systems. Available infrastructure varies on a national, regional, and local basis and is an important consideration in the HVAC system selection process.

4. REFRIGERANT PHASEOUTS

Production phaseout of many commonly used refrigerants has required building owners to decide between replacing existing

equipment or retrofitting for alternative refrigerants. Several factors must be considered, including

- **Initial Cost.** New equipment may have a significantly higher installed cost than retrofitting existing equipment. For example, retrofitting an existing centrifugal chiller to operate on R-123 may cost 50% of the cost for a new chiller, making the installation cost of a new chiller seem a prudent alternative. Conversely, the cost of rigging a new unit may significantly raise the installed cost, improving the first-cost advantage of refrigerant conversion.
- **Operating Costs.** The overall efficiency of new equipment is often substantially better than that of existing equipment, depending on age, usage, and level of maintenance performed over the life of the existing unit. In addition, conversion to alternative refrigerants may reduce capacity and/or efficiency of the existing equipment.
- **Maintenance Costs.** The maintenance cost for new equipment is generally lower than that for existing equipment. However, the level of retrofit required to attain compatibility between existing equipment and new refrigerant often includes replacement or remanufacture of major unit components, which can bring the maintenance and repair costs in line with those expected of new equipment.
- **Equipment Useful Life.** The effect of a retrofit on equipment useful life is determined by the extent of modification required. Complete remanufacture of a unit should extend the remaining useful life to a level comparable to that of new equipment.

Replacing existing equipment or converting to alternative refrigerants can improve overall system efficiency. Reduced capacity requirements and introduction of new technologies such as variable-speed drives and microprocessor-based controllers can substantially reduce annual operating costs and significantly improve a project's economic benefit.

Information should be gathered to complete Table 1 for each alternative. The techniques described in the section on Economic Analysis Techniques may then be applied to compare the relative values of each option.

Other Sources

The DOE's Federal Energy Management Program (FEMP) web site (energy.gov/eere/femp/find-product-categories-covered-efficiency-programs) has up-to-date information on energy-efficient federal procurement. Products that qualify for the EPA/DOE ENERGY STAR label are listed, as are efficiency recommendations, cost effectiveness examples, and purchasing guidance. FEMP also provides web-based cost-calculator tools that simplify the energy cost comparison between products with different efficiencies.

The General Services Administration (GSA) has a basic ordering agreement (BOA) that offers a streamlined procurement method for some HVAC products based on lowest life-cycle cost. For chillers purchased through commercial sources, the BOA can still be used as a guide in preparing specifications.

5. OTHER ISSUES

Financing Alternatives

Alternative financing is commonly used in third-party funding of projects, particularly retrofit projects, and is variously called privatization, third-party financing, energy services outsourcing, performance contracting, energy savings performance contracting (ESPC), or innovative financing. In these programs, an outside party performs an energy study to identify or quantify attractive energy-saving retrofit projects and then (to varying degrees) designs, builds, and finances the retrofit program on behalf of the owner or host facility. These contracts range in complexity from simple projects

such as lighting upgrades to more detailed projects involving all aspects of energy consumption and facility operation.

Alternative financing can be used to accomplish any or all of the following objectives:

- Upgrade capital equipment
- Provide for maintenance of existing facilities
- Speed project implementation
- Conserve or defer capital outlay
- Save energy
- Save money

The benefits of alternative financing are not free. In general terms, these financing agreements transfer the risk of attaining future savings from the owner to the contractor, for which the contractor is paid. In addition, these innovative owning and operating cost reduction approaches have important tax consequences that should be investigated on a case-by-case basis.

There are many variations of the basic arrangements and nearly as many terms to define them. Common nomenclature includes guaranteed savings (performance-based), shared savings, paid from savings, guaranteed savings loans, capital leases, municipal leases, and operating leases. For more information, refer to the U.S. Department of Energy's web site and to the DOE (2007). A few examples of alternative financing techniques follow.

Leasing. Among the most common methods of alternative financing is the lease arrangement. In a true lease or lease-purchase arrangement, outside financing provides capital for construction of a facility. The institution then leases the facility at a fixed monthly charge and assumes responsibility for fuel and personnel costs associated with its operation. Leasing is also commonly available for individual pieces of equipment or retrofit systems and often includes all design and installation costs. Equipment suppliers or independent third parties retain ownership of new equipment and lease it to the user.

Outsourcing. For a cogeneration, steam, or chilled-water plant, either a lease or an energy output contract can be used. An energy output contract enables a private company to provide all the capital and operating costs, such as personnel and fuel, while the host facility purchases energy from the operating company at a variable monthly charge.

Energy Savings. Retrofit projects that lower energy usage create an income stream that can be used to amortize the investment. In **paid-from-savings** programs, utility payments remain constant over a period of years while the contractor is paid out of savings until the project is amortized. In **shared savings** programs, the institution receives a percentage of savings over a longer period of years until the project becomes its property. In a **guaranteed savings** program, the owner retains all the savings and is guaranteed that a certain level of savings will be attained. A portion of the savings is used to amortize the project. In any type of energy savings project, building operation and use can strongly affect the amount of savings actually realized.

Low-Interest Financing. In this arrangement, the supplier offers equipment with special financing arrangements at below-market interest rates.

Cost Sharing. Several variations of cost-sharing programs exist. In some instances, two or more groups jointly purchase and share new equipment or facilities, thereby increasing use of the equipment and improving the economic benefits for both parties. In other cases, equipment suppliers or independent third parties (such as utilities) who receive an indirect benefit may share part of the equipment or project cost to establish a market foothold for the product.

District Energy Service

District energy service is increasingly available to building owners; district heating and cooling eliminates most on-site heating and cooling equipment. A third party produces treated water or steam and pipes it from a central plant directly to the building. The building owner then pays a metered rate for the energy that is used.

A cost comparison of district energy service versus on-site generation requires careful examination of numerous, often site-specific, factors extending beyond demand and energy charges for fuel. District heating and cooling eliminates or minimizes most costs associated with installation, maintenance, administration, repair, and operation of on-site heating and cooling equipment. Specifically, costs associated with providing water, water treatment, specialized maintenance services, insurance, staff time, space to house on-site equipment, and structural additions needed to support equipment should be considered. Costs associated with auxiliary equipment, which represent 20 to 30% of the total plant annual operating costs, should also be included.

Any analysis that fails to include all the associated costs does not give a clear picture of the building owner's heating and cooling alternatives. In addition to the tangible costs, there are a number of other factors that should be considered, such as convenience, risk, environmental issues, flexibility, and back-up.

On-Site Electrical Power Generation

On-site electrical power generation covers a broad range of applications, from emergency back-up to power for a single piece of equipment to an on-site power plant supplying 100% of the facility's electrical power needs. Various system types and fuel sources are available, but the economic principles described in this chapter apply equally to all of them. Other chapters (e.g., Chapters 7 and 37 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*) may be helpful in describing system details.

An economic study of on-site electrical power generation should include consideration of all owning, operating, and maintenance costs. Typically, on-site generation is capital intensive (i.e., high first cost) and therefore requires a high use rate to produce savings adequate to support the investment. High use rates mean high run time, which requires planned maintenance and careful operation.

Owning costs include any related systems required to adapt the building to on-site power generation. Additional equipment is required if the building will also use purchased power from a utility. Costs associated with shared equipment should also be considered. For example, if the power source for the generator is a steam turbine, and a hot-water boiler would otherwise be used to meet the HVAC demand, the boiler would need to be a larger, high-pressure steam boiler with a heat exchanger to meet the hot-water needs. Operation and maintenance costs for the boiler also are increased because of the increased operating hours.

Costs of an initial investment and ongoing inventory of spare parts must also be considered. Most equipment manufacturers provide a recommended spare parts list as well as recommended maintenance schedules, typically daily, weekly, and monthly routine maintenance and periodic major overhauls. Major overhaul frequency depends on equipment use and requires taking the equipment off-line. The cost of either lost building use or the provision of electricity from an alternative source during the shutdown should be considered.

6. ECONOMIC ANALYSIS TECHNIQUES

Analysis of overall owning and operating costs and comparisons of alternatives require an understanding of the cost of lost opportunities, inflation, and the time value of money. This process of economic analysis of alternatives falls into two general categories: simple payback analysis and detailed economic analyses (life-cycle cost analyses).

A simple payback analysis reveals options that have short versus long paybacks. Often, however, alternatives are similar and have similar paybacks. For a more accurate comparison, a more comprehensive economic analysis is warranted. Many times it is appropriate to have both a simple payback analysis and a detailed economic analysis. The simple payback analysis shows which options should not be considered further, and the detailed economic analysis determines which of the viable options are the strongest. The strongest options can be accepted or further analyzed if they include competing alternatives.

Simple Payback

In the simple payback technique, a projection of the revenue stream, cost savings, and other factors is estimated and compared to the initial capital outlay. This simple technique ignores the cost of borrowing money (interest) and lost opportunity costs. It also ignores inflation and the time value of money.

Example 1. Equipment item 1 costs \$10,000 and will save \$2000 per year in operating costs; equipment item 2 costs \$12,000 and saves \$3000 per year. Which item has the best simple payback?

Item 1	\$10,000/(\$2000/yr) = 5-year simple payback
Item 2	\$12,000/(\$3000/yr) = 4-year simple payback

Because analysis of equipment for the duration of its realistic life can produce a very different result, the simple payback technique should be used with caution.

More Sophisticated Economic Analysis Methods

Economic analysis should consider details of both positive and negative costs over the analysis period, such as varying inflation rates, capital and interest costs, salvage costs, replacement costs, interest deductions, depreciation allowances, taxes, tax credits, mortgage payments, and all other costs associated with a particular system. See the section on Symbols for definitions of variables.

Present-Value (Present Worth) Analysis. All sophisticated economic analysis methods use the basic principles of present value analysis to account for the time value of money. Therefore, a good understanding of these principles is important.

The total present value (present worth) for any analysis is determined by summing the present worths of all individual items under consideration, both future single-payment items and series of equal future payments. The scenario with the highest present value is the preferred alternative.

Single-Payment Present-Value Analysis. The cost or value of money is a function of the available interest rate and inflation rate. The future value F of a present sum of money P over n periods with compound interest rate i per period is

$$F = P(1 + i)^n \quad (1)$$

Conversely, the present value or present worth P of a future sum of money F is given by

$$P = F/(1 + i)^n \quad (2)$$

or

$$P = F \times \text{PWF}(i, n)_{\text{sgl}} \quad (3)$$

where the single-payment present-worth factor $\text{PWF}(i, n)_{\text{sgl}}$ is defined as

$$\text{PWF}(i, n)_{\text{sgl}} = 1/(1 + i)^n \quad (4)$$

Example 2. Calculate the value in 10 years at 10% per year interest of a system presently valued at \$10,000.

$$F = P(1 + i)^n = \$10,000(1 + 0.1)^{10} = \$25,937.42$$

Example 3. Using the present-worth factor for 10% per year interest and an analysis period of 10 years, calculate the present value of a future

sum of money valued at \$10,000. (Stated another way, determine what sum of money must be invested today at 10% per year interest to yield \$10,000 10 years from now.)

$$\begin{aligned} P &= F \times \text{PWF}(i, n)_{\text{sgl}} \\ P &= \$10,000 \times 1/(1 + 0.1)^{10} \\ &= \$3855.43 \end{aligned}$$

Series of Equal Payments. The present-worth factor for a series of future equal payments (e.g., operating costs) is given by

$$\text{PWF}(i, n)_{\text{ser}} = \frac{(1 + i)^n - 1}{i(1 + i)^n} \quad (5)$$

The present value P of those future equal payments (PMT) is then the product of the present-worth factor and the payment [i.e., $P = \text{PWF}(i, n)_{\text{ser}} \times \text{PMT}$].

The number of future equal payments to repay a present value of money is determined by the capital recovery factor (CRF), which is the reciprocal of the present-worth factor for a series of equal payments:

$$\text{CRF} = \text{PMT}/P \quad (6)$$

$$\text{CRF}(i, n)_r = \frac{i(1 + i)^n}{(1 + i)^n - 1} = \frac{i}{1 - (1 + i)^{-n}} \quad (7)$$

The CRF is often used to describe periodic uniform mortgage or loan payments.

Note that when payment periods other than annual are to be studied, the interest rate must be expressed per appropriate period. For example, if monthly payments or return on investment are being analyzed, then interest must be expressed per month, not per year, and n must be expressed in months.

Example 4. Determine the present value of an annual operating cost of \$1000 per year over 10 years, assuming 10% per year interest rate.

$$\begin{aligned} \text{PWF}(i, n)_{\text{ser}} &= [(1 + 0.1)^{10} - 1]/[0.1(1 + 0.1)^{10}] = 6.14 \\ P &= \$1000(6.14) = \$6140 \end{aligned}$$

Example 5. Determine the uniform monthly mortgage payments for a loan of \$100,000 to be repaid over 30 years at 10% per year interest. Because the payment period is monthly, the payback duration is $30(12) = 360$ monthly periods, and the interest rate per period is $0.1/12 = 0.00833$ per month.

$$\begin{aligned} \text{CRF}(i, n) &= 0.00833(1 + 0.00833)^{360}/[(1 + 0.00833)^{360} - 1] \\ &= 0.008773 \\ \text{PMT} &= P(\text{CRF}) \\ &= \$100,000(0.008773) \\ &= \$877.30 \text{ per month} \end{aligned}$$

Improved Payback Analysis. This somewhat more sophisticated payback approach is similar to the simple payback method, except that the cost of money (interest rate, discount rate, etc.) is considered. Solving Equation (7) for n yields the following:

$$n = \frac{\ln[\text{CRF}/(\text{CRF} - i)]}{\ln(1 + i)} \quad (8)$$

Given known investment amounts and earnings, CRFs can be calculated for the alternative investments. Subsequently, the number of periods until payback has been achieved can be calculated using Equation (8).

Example 6. Compare the years to payback of the same items described in Example 2 if the value of money is 10% per year.

Item 1
 cost = \$10,000
 savings = \$2000/year
 CRF = \$2000/\$10,000 = 0.2
 $n = \ln[0.2/(0.2 - 0.1)]/\ln(1 + 0.1) = 7.3$ years

Item 2
 cost = \$12,000
 savings = \$3000/year
 CRF = \$3000/\$12,000 = 0.25
 $n = \ln[0.25/(0.25 - 0.1)]/\ln(1 + 0.1) = 5.4$ years

If years to payback is the sole criteria for comparison, Item 2 is preferable because the investment is repaid in a shorter period of time.

Accounting for Inflation. Different economic goods may inflate at different rates. Inflation reflects the rise in the real cost of a commodity over time and is separate from the time value of money. Inflation must often be accounted for in an economic evaluation. One way to account for inflation is to substitute effective interest rates that account for inflation into the equations given in this chapter.

The effective interest rate i' , sometimes called the real rate, accounts for inflation rate j and interest rate i or discount rate i_d ; it can be expressed as follows (Kreider and Kreith 1982):

$$i' = \frac{1+i}{1+j} - 1 = \frac{i-j}{1+j} \quad (9)$$

Different effective interest rates can be applied to individual components of cost. Projections for future fuel and energy prices are available in the *Annual Supplement to NIST Handbook 135* (Rushing et al. 2010).

Example 7. Determine the present worth P of an annual operating cost of \$1000 over 10 years, given a discount rate of 10% per year and an inflation rate of 5% per year.

$$i' = (0.1 - 0.05)/(1 + 0.05) = 0.0476$$

$$PWF(i', n)_{ser} = \frac{(1 + 0.0476)^{10} - 1}{0.0476(1 + 0.0476)^{10}} = 7.813$$

$$P = \$1000(7.813) = \$7813$$

The following are three common methods of present-value analysis that include life-cycle cost factors (life of equipment, analysis period, discount rate, energy escalation rates, maintenance cost, etc., as shown in Table 1). These comparison techniques rely on the same assumptions and economic analysis theories but display the results in different forms. They also use the same definition of each term. All can be displayed as a single calculation or as a cash flow table using a series of calculations for each year of the analysis period.

Savings-to-Investment Ratio. Most large military-sponsored work and many other U.S. government entities require a savings-to-investment-ratio (SIR) method. Simply put, SIR is the ratio of an option's savings to its costs. This ratio defines the relative economic strength of each option. The higher the ratio, the better the economic strength. If the ratio is less than 1, the measure does not pay for itself within the analysis period. The escalated savings on an annual and a special (nonannual) basis is calculated and discounted. Costs are shown on an annual and special basis for each year over the life of the system or option. Savings and investments are both discounted separately on an annual basis, and then the discounted total cumulative savings is divided by the discounted total cumulative investments (costs). The analysis period is usually the life of the system or equipment being considered.

The SIR is the sum of a series of operation-related savings from a project alternative divided by the sum of its additional investment-related costs. Typically, this is over a period of years (5, 10, or 20 years, or the typical expected life span).

The general equation for the SIR simply rearranges these two terms as a ratio:

$$SIR_{A:BC} = \frac{\sum_{t=0}^N S_t/(1+d)^t}{\sum_{t=0}^N I_t/(1+d)^t} \quad (10)$$

where

- $SIR_{A:BC}$ = ratio of PV savings to additional PV investment costs of (mutually exclusive) alternative A to base case BC
- S_t = savings in year t in operational costs attributable to alternative
- I_t = investment-related costs in year t attributable to alternative
- t = year of occurrence (where 0 is base date)
- d = discount rate
- N = length of study

A more practical SIR base-case equation for buildings is as follows:

$$SIR_{A:BC} = \frac{E + W + OM\&R}{I_o + Repl - Res} \quad (11)$$

where

- $SIR_{A:BC}$ = ratio of operational savings to investment-related additional costs computed for alternative A to base case BC
- E = $(E_{BC} - E_A)$, savings in energy costs attributable to alternative relative to base case
- W = $(W_{BC} - W_A)$, savings in water costs attributable to alternative
- OM&R = difference in OM&R costs; $OM\&R_{BC} - OM\&R_A$
- I_o = additional initial investment cost required for alternative relative to base case; $(I_A - I_{BC})$
- Repl = difference in capital replacement costs; $(Repl_A - Repl_{BC})$
- Res = difference in residual value; $(Res_A - Res_{BC})$

where all amounts are in present values.

Example 8: SIR Computation. For this example, the numerator and denominator are defined as follows:

- Numerator:
 PV of operational savings attributable to the alternative = \$91,030
- Denominator:
 PV of additional investment costs required for the alternative = \$7,239
- Thus,

$$SIR_{A:BC} = \frac{\$91,030}{\$7,239} = 12.6$$

A ratio of 12.6 means that the energy-conserving design generates an average return of \$12.6 for every \$1 invested, over and above the minimum required rate of return imposed by the discount rate. The project alternative in this example is clearly cost effective. A ratio of 1.0 indicates that the cost of the investment equals its savings; a ratio of less than 1.0 indicates an uneconomic alternative that would cost more than it would save.

Summary of SIR Method

- An investment is cost effective if its SIR is greater than 1.0; this is equivalent to having net savings greater than zero.
- The SIR is a relative measure; it must be calculated with respect to a designated base case.
- When computing the SIR of an alternative relative to its base case, the same study period and the same discount rate must be used.

- The SIR is useful for evaluating a single project alternative against a base case or for ranking independent project alternatives; it is not useful for evaluating multiple mutually exclusive alternatives.

Internal Rate of Return. The internal rate of return (IRR) method calculates a return on investment over the defined analysis period. The annual savings and costs are not discounted, and a cash flow is established for each year of the analysis period, to be used with an initial cost (or value of the loan). Annual recurring and special (nonannual) savings and costs can be used. The cash flow is then discounted until a calculated discount rate is found that yields a net present value of zero. This method assumes savings are reinvested at the same calculated rate of return; therefore, the calculated rates of return can be overstated compared to the actual rates of return.

Another version of this is the **modified or adjusted internal rate of return (MIRR or AIRR)**. In this version, reinvested savings are assumed to have a given rate of return on investment, and the financed moneys a given interest rate. The cash flow is then discounted until a calculated discount rate is found that yields a net present value of zero. This method gives a more realistic indication of expected return on investment, but the difference between alternatives can be small.

The most straightforward method of calculating the AIRR requires that the SIR for a project (relative to its base case) be calculated first. Then the AIRR can be computed easily using the following equation:

$$\text{AIRR} = (1 + r)(\text{SIR})^{1/N} - 1 \tag{12}$$

where r is the reinvestment rate and N is the number of years in the study period. Using the SIR of 12.6 from Equation (10) and a reinvestment rate of 3% [the minimum acceptable rate of return (MARR)], the AIRR is found as follows:

$$\text{AIRR}_{\text{A:BC}} = (1 + 0.03)(12.6)^{1/20} - 1 = 0.1691$$

Because an AIRR of 16.9% for the alternative is greater than the MARR, which in this example is the FEMP discount rate of 3%, the project alternative is considered to be cost effective in this application.

Life-Cycle Costs. This method of analysis compares the cumulative total of implementation, operating, and maintenance costs. The total costs are discounted over the life of the system or over the

Table 7 Two Alternative LCC Examples

Alternative 1: Purchase Chilled Water from Utility											
	Year										
	0	1	2	3	4	5	6	7	8	9	10

20-year life-cycle cost	\$717,100										

loan repayment period. The costs and investments are both discounted and displayed as a total combined life-cycle cost at the end of the analysis period. The options are compared to determine which has the lowest total cost over the anticipated project life.

Example 9. A municipality is evaluating two different methods of providing chilled water for cooling a government office building: purchasing chilled water from a central chilled-water utility service in the area, or installing a conventional chiller plant. Because the municipality is not a tax-paying entity, the evaluation does not need to consider taxes, allowing for either a current or constant dollar analysis.

The first-year price of the chilled-water utility service contract is \$65,250 per year and is expected to increase at a rate of 2.5% per year.

The chiller and cooling tower would cost \$220,000, with an expected life of 20 years. A major overhaul (\$90,000) of the chiller is expected to occur in year ten. Annual costs for preventative maintenance (\$1400), labor (\$10,000), water (\$2000) and chemical treatments (\$1800) are all expected to keep pace with inflation, which is estimated to average 3% annually over the study period. The annual electric cost (\$18,750) is expected to increase at a rate of 5% per year. The municipality uses a discount rate of 8% to evaluate financial decisions.

Which option has the lowest life-cycle cost?

Solution. Table 7 compares the two alternatives. For the values provided, alternative 1 has a 20-year life cycle cost of \$769,283 and alternative 2 has a 20-year life cycle cost of \$717,100. If LCC is the only basis for the decision, alternative 2 is preferable because it has the lower life-cycle cost.

Computer Analysis

Many computer programs are available that incorporate economic analysis methods. These range from simple macros developed for popular spreadsheet applications to more comprehensive, menu-driven computer programs. Commonly used examples of the latter include Building Life-Cycle Cost (BLCC) and PC-ECONPACK.

BLCC was developed by the National Institute of Standards and Technology (NIST) for the U.S. Department of Energy (DOE). The program follows criteria established by the Federal Energy Management Program (FEMP) and the Office of Management and Budget (OMB). It is intended for evaluation of energy conservation investments in nonmilitary government buildings; however, it is also appropriate for similar evaluations of commercial facilities.

PC-ECONPACK, developed by the U.S. Army Corps of Engineers for use by the DOD, uses economic criteria established by the OMB. The program performs standardized life-cycle cost calculations such as net present value, equivalent uniform annual cost, SIR, and discounted payback period.

Macros developed for common spreadsheet programs generally contain preprogrammed functions for various life-cycle cost calculations. Although typically not as sophisticated as the menu-driven programs, the macros are easy to install and learn.

Reference Equations

Table 8 lists commonly used discount formulas as addressed by NIST. Refer to NIST *Handbook* 135 (Fuller and Petersen 1996) for detailed discussions.

7. SYMBOLS

- AIRR = modified or adjusted internal rate of return (MIRR or AIRR)
- c* = cooling system adjustment factor
- C* = total annual building HVAC maintenance cost
- C_e* = annual operating cost for energy
- C_{s,assess}* = assessed system value
- C_{s,init}* = initial system cost
- C_{s,salv}* = system salvage value at end of study period
- C_y* = uniform annualized mechanical system owning, operating, and maintenance costs
- CRF = capital recovery factor
- CRF(*i*, *n*) = capital recovery factor for interest rate *i* and analysis period *n*
- CRF(*i'*, *n*) = capital recovery factory for interest rate *i'* for items other than fuel and analysis period *n*
- CRF(*i''*, *n*) = capital recovery factor for fuel interest rate *i''* and analysis period *n*
- CRF(*i_m*, *n*) = capital recovery factor for loan or mortgage rate *i_m* and analysis period *n*
- d* = distribution system adjustment factor
- D_k* = depreciation during period *k*
- D_{k,SL}* = depreciation during period *k* from straight-line depreciation method
- D_{k,SD}* = depreciation during period *k* from sum-of-digits depreciation method
- F* = future value of sum of money
- h* = heating system adjustment factor
- i* = compound interest rate per period

Table 8 Commonly Used Discount Formulas

Name	Algebraic Form ^{a,b}	Name	Algebraic Form ^{a,b}
Single compound-amount (SCA) equation	$F = P \cdot [(1 + d)^n]$	Uniform compound-amount (UCA) equation	$F = A \cdot \left[\frac{(1 + d)^n - 1}{d} \right]$
Single present-value (SPV) equation	$P = F \cdot \left[\frac{1}{(1 + d)^n} \right]$	Uniform present-value (UPV) equation	$P = A \cdot \left[\frac{(1 + d)^n - 1}{d(1 + d)^n} \right]$
Uniform sinking-fund (USF) equation	$A = F \cdot \left[\frac{d}{(1 + d)^n - 1} \right]$	Modified uniform present-value (UPV*) equation	$P = A_0 \cdot \left(\frac{1 + e}{d - e} \right) \cdot \left[1 - \left(\frac{1 + e}{1 + d} \right)^n \right]$
Uniform capital recovery (UCR) equation	$A = P \cdot \left[\frac{d(1 + d)^n}{(1 + d)^n - 1} \right]$		

where

- A* = end-of-period payment (or receipt) in a uniform series of payments (or receipts) over *n* periods at *d* interest or discount rate
- A₀* = initial value of a periodic payment (receipt) evaluated at beginning of study period
- A_t* = *A₀(1 + e)^t*, where *t* = 1, . . . , *n*
- d* = interest or discount rate
- e* = price escalation rate per period

Source: NIST *Handbook* 135 (Fuller and Petersen 1996).

^aNote that the USF, UCR, UCA, and UPV equations yield undefined answers when *d* = 0. The correct algebraic forms for this special case would be as follows: USF formula, *A* = *F*/*N*; UCR formula, *A* = *P*/*N*; UCA formula, *F* = *A**n*. The UPV* equation also yields an undefined answer when *e* = *d*. In this case, *P* = *A₀* · *n*.

^bThe terms by which known values are multiplied are formulas for the factors found in discount factor tables. Using acronyms to represent the factor formulas, the discounting equations can also be written as *F* = *P* × SCA, *P* = *F* × SPV, *A* = *F* × USF, *A* = *P* × UCR, *F* = UCA, *P* = *A* × UPV, and *P* = *A₀* × UPV*.

i_d = discount rate per period
 i_m = market mortgage rate
 i' = effective interest rate for all but fuel
 i'' = effective interest rate for fuel
 I = insurance cost per period
 ITC = investment tax credit
 j = inflation rate per period
 j_e = fuel inflation rate per period
 k = end of period(s) during which replacement(s), repair(s), depreciation, or interest are calculated
 M = maintenance cost per period
 n = number of periods under analysis
 P = present value of a sum of money
 P_k = outstanding principle on loan at end of period k
 PMT = future equal payments
 PWF = present worth factor
 $PWF(i_d, k)$ = present worth factor for discount rate i_d at end of period k
 $PWF(i', k)$ = present worth factor for effective interest rate i' at end of period k
 $PWF(i, n)_{sgl}$ = single payment present worth factor
 $PWF(i, n)_{ser}$ = present worth factor for a series of future equal payments
 R_k = net replacement, repair, or disposal costs at end of period k
 SIR = savings-to-investment ratio
 T_{inc} = net income tax rate
 T_{prop} = property tax rate
 T_{salv} = tax rate applicable to salvage value of system

SYSTEMS that control the environment in a building change with time and use, and must be rebalanced accordingly. The designer must consider initial and supplementary testing and balancing requirements for commissioning. Complete and accurate operating and maintenance instructions that include intent of design and how to test, adjust, and balance the building systems are essential. Building operating personnel must be well-trained, or qualified operating service organizations must be employed to ensure optimum comfort, proper process operations, and economical operation.

This chapter does not suggest which groups or individuals should perform a complete testing, adjusting, and balancing procedure. However, the procedure must produce repeatable results that meet the design intent and the owner's requirements. Overall, one source must be responsible for testing, adjusting, and balancing all systems. As part of this responsibility, the testing organization should check all equipment under field conditions to ensure compliance.

Testing and balancing should be repeated as systems are renovated and changed. Testing boilers and other pressure vessels for compliance with safety codes is not the primary function of the testing and balancing firm; rather, it is to verify and adjust operating conditions in relation to design conditions for flow, temperature, pressure drop, noise, and vibration. ASHRAE *Standard* 111 details procedures not covered in this chapter.

1. TERMINOLOGY

Testing, adjusting, and balancing (TAB) is the process of checking and adjusting all environmental systems in a building to produce the design objectives. This process includes (1) balancing air and water distribution systems, (2) adjusting the total system to provide design quantities, (3) electrical measurement, (4) establishing quantitative performance of all equipment, (5) verifying automatic control system operation and sequences of operation, and (6) sound and vibration measurement. These procedures are accomplished by checking installations for conformity to design, measuring and establishing the fluid quantities of the system as required to meet design specifications, and recording and reporting the results.

The following definitions are used in this chapter. Refer to *ASHRAE Terminology* (<https://www.ashrae.org/resources--publications/rac-resources/ashrae-terminology>) for additional definitions.

Test. Determine quantitative performance of equipment.

Adjust. Regulate the specified fluid flow rate and air patterns at terminal equipment (e.g., reduce fan speed, adjust a damper).

Balance. Proportion flows in the distribution system (submains, branches, and terminals) according to specified design quantities.

Balanced System. A system designed to deliver heat transfer required for occupant comfort or process load at design conditions.

A minimum heat transfer of 97% should be provided to the space or load served at design flow. The flow required for minimum heat transfer establishes the system's flow tolerance. The fluid distribution system should be designed to allow flow to maintain the required tolerance and verify its performance.

Procedure. An approach to and execution of a sequence of work operations to yield repeatable results.

Report forms. Test data sheets arranged in logical order for submission and review. They should also form the permanent record to be used as the basis for any future TAB work.

Terminal. A point where the controlled medium (fluid or energy) enters or leaves the distribution system. In air systems, these may be variable- or constant-volume boxes, registers, grilles, diffusers, louvers, and hoods. In water systems, these may be heat transfer coils, fan-coil units, convectors, or finned-tube radiation or radiant panels.

2. GENERAL CRITERIA

Effective and efficient TAB requires a systematic, thoroughly planned procedure implemented by experienced and qualified staff. All activities, including organization, calibration of instruments, and execution of the work, should be scheduled. Air-side work must be coordinated with water-side and control work. Preparation includes planning and scheduling all procedures, collecting necessary data (including all change orders), reviewing data, studying the system to be worked on, preparing forms, and making preliminary field inspections.

Air leakage in a conduit (duct) system can significantly reduce performance, so conduits (ducts) must be designed, constructed, and installed to minimize and control leakage. During construction, all duct systems should be sealed and tested for air leakage. Water, steam, and pneumatic piping should be tested for leakage, which can harm people and equipment.

Design Considerations

TAB begins as design functions, with most of the devices required for adjustments being integral parts of the design and installation. To ensure that proper balance can be achieved, the engineer should show and specify a sufficient number of dampers, valves, flow measuring locations, and flow-balancing devices; these must be properly located in required straight lengths of pipe or duct for accurate measurement. Testing depends on system characteristics and layout. Interaction between individual terminals varies with pressures, flow requirements, and control devices.

The design engineer should specify balancing tolerances. Minimum flow tolerances are $\pm 10\%$ for individual terminals and branches in noncritical applications and $\pm 5\%$ for main air ducts. For critical water systems where differential pressures must be maintained, tolerances of $\pm 5\%$ are suggested. For critical air systems, recommendations are the following:

The preparation of this chapter is assigned to TC 7.7, Testing and Balancing.

Positive zones:	
Supply air	0 to +10%
Exhaust and return air	0 to -10%
Negative zones:	
Supply air	0 to -10%
Exhaust and return air	0 to +10%

Balancing Devices. Balancing devices should be used to provide maximum flow-limiting ability without causing excessive noise. Flow reduction should be uniform over the entire duct or pipe. Single-blade dampers or butterfly balancing valves are not good balancing valves because of the uneven flow pattern at high pressure drops. Pressure drop across equipment is not an accurate flow measurement but can be used to determine whether the manufacturer design pressure is within specified limits. Liberal use of pressure taps at critical points is recommended.

3. AIR VOLUMETRIC MEASUREMENT METHODS

General

The pitot-tube traverse is the generally accepted method of measuring airflow in ducts; ways to measure airflow at individual terminals are described by manufacturers. The primary objective is to establish repeatable measurement procedures that correlate with the pitot-tube traverse.

Laboratory tests, data, and techniques prescribed by equipment and air terminal manufacturers must be reviewed and checked for accuracy, applicability, and repeatability of results. Conversion factors that correlate field data with laboratory results must be developed to predict the equipment's actual field performance.

Air Devices

All flow-measuring instruments should be field verified by comparing to pitot-tube traverses to establish correction and/or density factors.

Generally, correction factors given by air diffuser manufacturers should be checked for accuracy by field measurement and by comparing actual flow measured by pitot-tube traverse to actual measured velocity. Air diffuser manufacturers usually base their volumetric test measurements on a deflecting vane anemometer. The velocity is multiplied by an empirical effective area to obtain the air diffuser's delivery. Accurate results are obtained by measuring at the vena contracta with the probe of the deflecting vane anemometer. Methods advocated for measuring airflow of troffer-type terminals are similar to those for air diffusers.

A capture hood is frequently used to measure device airflows, primarily of diffusers and slots. Loss coefficients should be established for hood measurements with varying flow and deflection settings. If the air does not fill the measurement grid, the readings will require a correction factor.

Rotating vane anemometers are commonly used to measure airflow from sidewall grilles. Effective areas (correction factors) should be established with the face dampers fully open and deflection set uniformly on all grilles. Correction factors are required when measuring airflow in open ducts [i.e., damper openings and fume hoods (Sauer and Howell 1990)].

Duct Flow

The preferred method of measuring duct volumetric flow is the pitot-tube traverse average. The maximum straight run should be obtained before and after the traverse station. To obtain the best duct velocity profile, measuring points should be located as shown in Chapter 36 of the 2013 *ASHRAE Handbook—Fundamentals* and *ASHRAE Standard 111*. When using factory-fabricated volume-measuring stations, the measurements should be checked against a pitot-tube traverse.

Power input to a fan's driver should be used as only a guide to indicate its delivery; it may also be used to verify performance determined by a reliable method (e.g., pitot-tube traverse of system's main) that considers possible system effects. For some fans, the flow rate is not proportional to the power needed to drive them. In some cases, as with forward-curved-blade fans, the same power is required for two or more flow rates. The backward-curved-blade centrifugal fan is the only type with a flow rate that varies directly with power input.

If an installation has an inadequate straight length of ductwork or no ductwork to allow a pitot-tube traverse, the procedure from Sauer and Howell (1990) can be followed: a vane anemometer reads air velocities at multiple points across the face of a coil to determine a loss coefficient.

Mixture Plenums

Approach conditions are often so unfavorable that the air quantities comprising a mixture (e.g., outdoor and return air) cannot be determined accurately by volumetric measurements. In such cases, the mixture's temperature indicates the balance (proportions) between the component airstreams. Temperatures must be measured carefully to account for stratification, and the difference between outdoor and return temperatures must be greater than 20°F. The temperature of the mixture can be calculated as follows:

$$Q_t t_m = Q_o t_o + Q_r t_r \quad (1)$$

where

Q_t = total measured air quantity, %

Q_o = outdoor air quantity, %

Q_r = return air quantity, %

t_m = temperature of outdoor and return mixture, °F

t_o = outdoor temperature, °F

t_r = return temperature, °F

Pressure Measurement

Air pressures measured include barometric, static, velocity, total, and differential. For field evaluation of air-handling performance, pressure should be measured per *ASHRAE Standard 111* and analyzed together with manufacturers' fan curves and system effect as predicted by *AMCA Standard 210*. When measured in the field, pressure readings, air quantity, and power input often do not correlate with manufacturers' certified performance curves unless proper correction is made.

Pressure drops through equipment such as coils, dampers, or filters should not be used to measure airflow. Pressure is an acceptable means of establishing flow volumes only where it is required by, and performed in accordance with, the manufacturer certifying the equipment.

Stratification

Normal design minimizes conditions causing air turbulence, to produce the least friction, resistance, and consequent pressure loss. Under some conditions, however, air turbulence is desirable and necessary. For example, two airstreams of different temperatures can stratify in smooth, uninterrupted flow conditions. In this situation, design should promote mixing. Return and outdoor airstreams at the inlet side of the air-handling unit tend to stratify where enlargement of the inlet plenum or casing size decreases air velocity. Without a deliberate effort to mix the two airstreams (e.g., in cold climates, placing the outdoor air entry at the top of the plenum and return air at the bottom of the plenum to allow natural mixing), stratification can be carried throughout the system (e.g., filter, coils, eliminators, fans, ducts). Stratification can freeze coils and rupture tubes, and can affect temperature control in plenums, spaces, or both.

Stratification can also be reduced by adding vanes to break up and mix the airstreams. No solution to stratification problems is

guaranteed; each condition must be evaluated by field measurements and experimentation.

4. BALANCING PROCEDURES FOR AIR DISTRIBUTION

No one established procedure is applicable to all systems. The bibliography lists sources of additional information.

Instruments for Testing and Balancing

The minimum instruments necessary for air balance are

- Manometer calibrated in 0.005 in. of water divisions
- Combination inclined/vertical manometer (0 to 10 in. of water)
- Pitot tubes in various lengths, as required
- Tachometer (direct-contact, self-timing) or strobe light
- Clamp-on ammeter with voltage scales [root-mean-square (RMS) type]
- Rotating vane anemometer
- Deflecting vane anemometer
- Thermal anemometer
- Capture hood
- Digital thermometers (0.1°F increments as a minimum) and glass stem thermometers (0.1°F graduations minimum)
- Sound level meter with octave band filter set, calibrator, and microphone
- Vibration analyzer capable of measuring displacement velocity and acceleration
- Water flowmeters (0 to 50 in. of water and 0 to 400 in. of water ranges)
- Compound gage
- Test gages (100 psi and 300 psi)
- Sling psychrometer
- Etched-stem thermometer (30 to 120°F in 0.1°F increments)
- Hygrometers
- Relative humidity and dew-point instruments

Instruments must be calibrated periodically to verify their accuracy and repeatability before use in the field.

Preliminary Procedure for Air Balancing

1. Before balancing, all pressure tests (duct leakage) of duct and piping systems must be complete and acceptable.
2. Obtain as-built design drawings and specifications, and become thoroughly acquainted with the design intent.
3. Obtain copies of approved shop drawings of all air-handling equipment, outlets (supply, return, and exhaust), and temperature control diagrams, including performance curves. Compare design requirements with shop drawing capacities.
4. Compare design to installed equipment and field installation.
5. Walk the system from air-handling equipment to terminal units to determine variations of installation from design.
6. Check dampers (both volume and fire) for correct and locked position and temperature control for completeness of installation before starting fans.
7. Prepare report test sheets for both fans and outlets. Obtain manufacturer's outlet factors and recommended test procedure. A summation of required outlet volumes allows cross-checking with required fan volumes.
8. Determine the best locations in the main and branch ductwork for the most accurate duct traverses.
9. Place all outlet dampers in full open position.
10. Prepare schematic diagrams of system as-built ductwork and piping layouts to facilitate reporting.
11. Check filters for cleanliness and proper installation (no air bypass). If specifications require, establish procedure to simulate dirty filters.

12. For variable-volume systems, develop a plan to simulate diversity (if required).

Equipment and System Check

1. All fans (supply, return, and exhaust) must be operating before checking the following items:
 - Motor amperage and voltage to guard against overload
 - Fan rotation
 - Operability of static pressure limit switch
 - Automatic dampers for proper position
 - Air and water controls operating to deliver required temperatures
 - Air leaks in the casing and around the coils and filter frames must be stopped. Note points where piping enters the casing to ensure that escutcheons are right. Do not rely on pipe insulation to seal these openings (insulation may shrink). In prefabricated units, check that all panel-fastening holes are filled.
2. Traverse the main supply ductwork whenever possible. All main branches should also be traversed where duct arrangement allows. Traverse points and method of traverse should be selected as follows:
 - Traverse each main or branch after the longest possible straight run for the duct involved.
 - For test hole spacing, refer to Chapter 36 of the 2013 *ASHRAE Handbook—Fundamentals*.
 - Traverse using a pitot tube and manometer where velocities are over 600 fpm. Below this velocity, use either a micromanometer and pitot tube or an electronic multimeter and a pitot tube.
 - Note temperature and barometric pressure and correct for standard air quantity if needed.
 - After establishing the total air being delivered, adjust fan speed to obtain design airflow, if necessary. Check power and speed to confirm motor power and/or critical fan speed are not exceeded.
 - Proportionally adjust branch dampers until each has the proper air volume.
 - With all dampers and registers in the system proportioned and with supply and return fans operating at or near design airflow, set the minimum outdoor and return air ratio. If duct traverse locations are not available, this can be done by measuring the mixture temperature in the return air, outdoor air louver, and filter section. The mixture temperature may be approximated from Equation (1).

The greater the temperature difference between outdoor and return air, the easier it is to get accurate damper settings. Take the temperature at many points in a uniform traverse to be sure there is no stratification.

After the minimum outdoor air damper has been set for the proper percentage of outdoor air, run another traverse of mixture temperatures and install baffling if variation from the average is more than 5%. Remember that stratified mixed-air temperatures vary greatly with outdoor temperature in cold weather, whereas return air temperature has only a minor effect.
3. Balance terminal outlets in each control zone in proportion to each other, as follows:
 - Once the preliminary fan quantity is set, proportion the terminal outlet balance from the outlets into the branches to the fan. Concentrate on proportioning the flow rather than the absolute quantity. As fan settings and branch dampers change, the outlet terminal quantities remain proportional. Branch dampers should be used for major adjusting and terminal dampers for trim or minor adjustment only. It may be necessary to install additional sub-branch dampers to decrease the use of terminal dampers that create objectionable noise.
 - Normally, several passes through the entire system are necessary to obtain proper outlet values.

- The total tested outlet air quantity compared to duct traverse air quantities may indicate duct leakage.
- With total design air established in the branches and at the outlets, (1) take new fan motor amperage readings, (2) find static pressure across the fan, (3) read and record static pressure across each component (intake, filters, coils, mixing dampers), and (4) take a final duct traverse.

Multizone Systems

Balancing should be accomplished as follows:

1. When adjusting multizone constant-volume systems, establish the ratio of the design volume through the cooling coil to total fan volume to achieve the desired diversity factor. Keep the proportion of cold to total air constant during the balance. However, check each zone on full cooling. If the design calls for full flow through the cooling coil, the entire system should be set to full flow through the cooling side while making tests. Perform the same procedure for the hot-air side.
2. Check leaving air temperature at each zone to verify that hot and cold damper inlet leakage is not greater than the established maximum allowable leakage.
3. Check apparatus and main trunks, as outlined in the section on Equipment and System Check.
4. Proportionately balance diffusers or grilles.
5. Change control settings to full heating, and ensure that controls function properly. Verify airflow at each diffuser. Check for stratification.
6. If the engineer included a diversity factor in selecting the main apparatus, it will not be possible to get full flow to all zones simultaneously, as outlined in item 3 under Equipment and System Check. Zones equaling the diversity should be set to heating.

Dual-Duct Systems

Balancing should be accomplished as follows:

1. When adjusting dual-duct constant-volume systems, establish the ratio of the design volume through the cooling coil to total fan volume to achieve the desired diversity factor. Keep the proportion of cold to total air constant during the balance. If the design calls for full flow through the cooling coil, the entire system should be set to full flow through the cooling side while making tests. Perform the same procedure for the hot-air side.
2. Check leaving air temperature at the nearest terminal to verify that hot and cold damper inlet leakage is not greater than the established maximum allowable leakage.
3. Check apparatus and main trunks, as outlined in the section on Equipment and System Check.
4. Determine whether static pressure at the end of the system (the longest duct run) is at or above the minimum required for mixing box operation. Proceed to extreme end of the system and check the static pressure with an inclined manometer. Pressure should exceed the minimum static pressure recommended by the mixing box manufacturer.
5. Proportionately balance diffusers or grilles on the low-pressure side of the box, as described for low-pressure systems in the previous section.
6. Change control settings to full heating, and ensure that the controls and dual-duct boxes function properly. Spot-check airflow at several diffusers. Check for stratification.
7. If the engineer has included a diversity factor in selecting the main apparatus, it will not be possible to get full flow from all boxes simultaneously, as outlined in item 3 under Equipment and System Check. Mixing boxes closest to the fan should be set to full heating to force the air to the end of the system.

5. VARIABLE-VOLUME SYSTEMS

Many types of variable-air-volume (VAV) systems have been developed to conserve energy. They can be categorized as pressure-dependent or pressure-independent.

Pressure-dependent systems incorporate air terminal boxes with a thermostat signal controlling a damper actuator. Air volume to the space varies to maintain space temperature; air temperature supplied to terminal boxes remains constant. The balance of this system constantly varies with loading changes; therefore, any balancing procedure will not produce repeatable data unless changes in system load are simulated by using the same configuration of thermostat settings each time the system is tested (i.e., the same terminal boxes are fixed in the minimum and maximum positions for the test). Each terminal box requires a balancing damper upstream of its inlet.

In a pressure-dependent system with pneumatic controls, setting minimum airflows to the space (other than at no flow) is not suggested unless the terminal box has a normally closed damper and the manufacturer of the damper actuator provides adjustable mechanical stops.

Pressure-independent systems incorporate air terminal boxes with a thermostat signal used as a master control to open or close the damper actuator, and a velocity controller used as a sub-master control to maintain the maximum and minimum amounts of air to be supplied to the space. Air volume to the space varies to maintain the space temperature; air temperature supplied to the terminal remains constant. Take care to verify the operating range of the damper actuator as it responds to the velocity controller to prevent dead bands or overlap of control in response to other system components (e.g., double-duct VAV, fan-powered boxes, retrofit systems). Care should also be taken to verify the action of the thermostat with regard to the damper position, as the velocity controller can change the control signal ratio or reverse the control signal.

The pressure-independent system requires verifying that the velocity controller is operating properly; it can be adversely affected by inlet duct configurations if a multipoint sensor is not used (Griggs et al. 1990). The primary difference between the two systems is that the pressure-dependent system supplies a different amount of air to the space as pressure upstream of the terminal box changes. If the thermostats are not calibrated properly to meet the space load, zones may overcool or overheat. When zones overcool and receive greater amounts of supply air than required, they decrease the amount of air that can be supplied to overheated zones. The pressure-independent system is not affected by improper thermostat calibration in the same way as a pressure-dependent system, because minimum and maximum airflow limits may be set for each zone.

Static Control

Static control saves energy and prevents overpressurizing the duct system. The following procedures and equipment are some of the means used to control static pressure.

Fan Control. Consult ASHRAE *Standard* 90.1.

Discharge Damper. Losses and noise should be considered.

Vortex Damper. Losses from inlet air conditions are a problem, and the vortex damper does not completely close. The minimum expected airflow should be evaluated.

Variable Inlet Cones. System loss can be a problem because the cone does not typically close completely. The minimum expected airflow should be evaluated.

Varying Fan Speed Mechanically. Slippage, loss of belts, cost of belt replacement, and the initial cost of components are concerns.

Variable Pitch-in-Motion Fans. Maintenance and preventing the fan from running in the stall condition must be evaluated.

Varying Fan Speed Electrically. Varying voltage or frequency to the fan motor is usually the most efficient method. Some motor drives may cause electrical noise and affect other devices.

In controlling VAV fan systems, location of the static pressure sensors is critical and should be field-verified to give the most representative point of operation. After the terminal boxes have been proportioned, static pressure control can be verified by observing static pressure changes at the fan discharge and the static pressure sensor as load is simulated from maximum to minimum airflow (i.e., set all terminal boxes to balanced airflow conditions and determine whether any changes in static pressure occur by placing one terminal box at a time to minimum airflow, until all terminals are placed at the minimal airflow setting). The maximum to minimum air volume changes should be within the fan curve performance (speed or total pressure).

Diversity

Diversity may be used on a VAV system, assuming that total airflow is lower by design and that all terminal boxes never fully open at the same time. Duct leakage should be avoided. All ductwork upstream of the terminal box should be considered medium-pressure, whether in a low- or medium-pressure system.

A procedure to test the total air on the system should be established by setting terminal boxes to the zero or minimum position nearest the fan. During peak load conditions, care should be taken to verify that adequate pressure is available upstream of all terminal boxes to achieve design airflow to the spaces.

Outdoor Air Requirements

Maintaining a space under a slight positive or neutral pressure to atmosphere is difficult with all variable-volume systems. In most systems, the exhaust requirement for the space is constant; thus, outdoor air used to equal the exhaust air and meet minimum outdoor air requirements for building codes must also remain constant. Because of the location of the outdoor air intake and pressure changes, this does not usually happen. Outdoor air should enter the fan at a point of constant pressure (i.e., supply fan volume can be controlled by proportional static pressure control, which can control the return air fan volume). Makeup air fans can also be used for outdoor air control.

Return Air Fans

If return air fans are required in series with a supply fan, control and sizing of the fans is most important. Serious over- and under-pressurization can occur, especially during economizer cycles.

Types of VAV Systems

Single-Duct VAV. This system uses a pressure-dependent or -independent terminal and usually has reheat at a minimal setting on the terminal unit, or a separate heating system. Consult ASHRAE *Standard* 90.1 when considering this system.

Bypass. This system uses a pressure-dependent damper, which, on demand for heating, closes the damper to the space and opens to the return air plenum. Bypass sometimes uses a constant bypass airflow or a reduced amount of airflow bypassed to the return plenum in relation to the amount supplied to the space. No economic value can be obtained by varying fan speed with this system. A control problem can exist if any return air sensing is done to control a warm-up or cool-down cycle. Consult ASHRAE *Standard* 90.1 when considering this system.

VAV Using Single-Duct VAV and Fan-Powered, Pressure-Dependent Terminals. This system has a primary source of air from the fan to the terminal and a secondary powered fan source that pulls air from the return air plenum before the additional heat source. In some fan-powered boxes, backdraft dampers allow duct leakage when the system calls for the damper to be fully closed. Typical applications include geographic areas where the ratio of heating hours to cooling hours is low.

Double-Duct VAV. This type of terminal uses two single-duct variable terminals. It is controlled by velocity controllers that operate in sequence so that both hot and cold ducts can be opened or closed. Some controls have a downstream flow sensor in the terminal unit. The total-airflow sensor is in the inlet and controlled by the thermostat. As this inlet damper closes, the downstream controller opens the other damper to maintain set airflow. Low pressure in the ducts controlled by the thermostat may cause unwanted mixing of air, which results in excess energy use or discomfort in the space.

Balancing the VAV System

The general procedure for balancing a VAV system is

1. Determine the required maximum air volume to be delivered by the supply and return air fans. Load diversity usually means that the volume will be somewhat less than the outlet total.
2. Obtain fan curves on these units, and request information on surge characteristics from the fan manufacturer.
3. If inlet vortex damper control is used, obtain the fan manufacturer's data on deaeration of the fan when used with the damper. If speed control is used, find the maximum and minimum speed that can be used on the project.
4. Obtain from the manufacturer the minimum and maximum operating pressures for terminal or variable-volume boxes to be used on the project.
5. Construct a theoretical system curve, including an approximate surge area. The system curve starts at the boxes' minimum inlet static pressure, plus system loss at minimum flow, and terminates at the design maximum flow. The operating range using an inlet vane damper is between the surge line intersection with the system curve and the maximum design flow. When variable-speed control is used, the operating range is between (1) the minimum speed that can produce the necessary minimum box static pressure at minimum flow still in the fan's stable range and (2) the maximum speed necessary to obtain maximum design flow.
6. Position the terminal boxes to the proportion of maximum fan air volume to total installed terminal maximum volume.
7. Proportion outlets, and verify design volume with the VAV box on maximum flow. Verify minimum flow setting.
8. Set the fan to operate at approximate design speed.
9. Verify flow at all terminal boxes. Identify which boxes are not in control and the inlet static pressures, if any. If all terminal boxes are in control, reduce the fan flow until the remote terminals are just in control and within the tolerances of filter loading.
10. Run a total air traverse with a pitot tube.
11. Run steps (8) through (10) with the return or exhaust fan set at design flow as measured by a pitot-tube traverse and with the system set on minimum outdoor air.
12. Set terminals to minimum, and adjust the inlet vane or speed controller until minimum static pressure and airflow are obtained.
13. Temperature control personnel, balancing personnel, and the design engineer should agree on final placement of the sensor for the static pressure controller. This sensor must be placed in a representative location in the supply duct to sense average maximum and minimum static pressures in the system.
14. Check return air fan speed or its inlet vane damper, which tracks or adjusts to the supply fan airflow, to ensure proper outdoor air volume.
15. Operate the system on 100% outdoor air (weather permitting), and check supply and return fans for proper power and static pressure.

Induction Systems

Most induction systems use high-velocity air distribution. Balancing should be accomplished as follows:

1. For apparatus and main trunk capacities, perform general VAV balancing procedures.
2. Determine primary airflow at each terminal unit by reading the unit plenum pressure with a manometer and locating the point on the charts (or curves) of air quantity versus static pressure supplied by the unit manufacturer.
3. Normally, about three complete passes around the entire system are required for proper adjustment. Make a final pass without adjustments to record the end result.
4. To provide the quietest possible operation, adjust the fan to run at the slowest speed that provides sufficient nozzle pressure to all units with minimum throttling of all unit and riser dampers.
5. After balancing each induction system with minimum outdoor air, reposition to allow maximum outdoor air and check power and static pressure readings.

Report Information

To be of value to the consulting engineer and owner's maintenance department, the air-handling report should consist of at least the following items:

1. *Design*
 - Air quantity to be delivered
 - Fan static pressure
 - Motor power installed or required
 - Percent of outdoor air under minimum conditions
 - Fan speed
 - Input power required to obtain this air quantity at design static pressure
2. *Installation*
 - Equipment manufacturer (indicate model and serial numbers)
 - Size of unit installed
 - Arrangement of air-handling unit
 - Nameplate power and voltage, phase, cycles, and full-load amperes of installed motor
3. *Field tests*
 - Fan speed
 - Power readings (voltage, amperes of all phases at motor terminals)
 - Total pressure differential across unit components
 - Fan suction and fan discharge static pressure (equals fan total pressure)
 - Plot of actual readings on manufacturer's fan performance curve to show the installed fan operating point
 - Measured airflow rate

It is important to establish initial static pressures accurately for the air treatment equipment and duct system so that the variation in air quantity caused by filter loading can be calculated. It enables the designer to ensure that the total air quantity never is less than the minimum requirements. Because the design air quantity for peak loading of the filters has already been calculated, it also serves as a check of dirt loading in coils.
4. *Terminal Outlets*
 - Outlet by room designation and position
 - Manufacture and type
 - Size (using manufacturer's designation to ensure proper factor)
 - Manufacturer's outlet factor [where no factors are available, or field tests indicate listed factors are incorrect, a factor must be determined in the field by traverse of a duct leading to a single

outlet); this also applies to capture hood readouts (see ASHRAE *Standard* 111)]

- Adjustment pattern for every air terminal
5. *Additional Information (if applicable)*
 - Air-handling units
 - Belt number and size
 - Drive and driven sheave size
 - Belt position on adjusted drive sheaves (bottom, middle, and top)
 - Motor speed under full load
 - Motor heater size
 - Filter type and static pressure at initial use and full load; time to replace
 - Variations of velocity at various points across face of coil
 - Existence of vortex or discharge dampers, or both
 - Distribution system
 - Unusual duct arrangements
 - Branch duct static readings in double-duct and induction system
 - Ceiling pressure readings where plenum ceiling distribution is used; tightness of ceiling
 - With wind conditions outdoors less than 5 mph, relationship of building to outdoor pressure under both minimum and maximum outdoor air
 - Induction unit manufacturer and size (including required air quantity and plenum pressures for each unit) and test plenum pressure and resulting primary air delivery from manufacturer's listed curves
 - All equipment nameplates visible and easily readable

Many independent firms have developed detailed procedures suitable to their own operations and the area in which they function. These procedures are often available for information and evaluation on request.

6. PRINCIPLES AND PROCEDURES FOR BALANCING HYDRONIC SYSTEMS

Heat Transfer at Reduced Flow Rate

The typical heating-only hydronic terminal (200°F, 20°F Δt) gradually reduces heat output as flow is reduced (Figure 1). Decreasing water flow to 20% of design reduces heat transfer to 65% of that at full design flow. The control valve must reduce water flow to 10% to reduce heat output to 50%. This relative insensitivity to changing flow rates is because the governing coefficient for heat transfer is the air-side coefficient; a change in internal or water-side coefficient with flow rate does not materially affect the overall heat transfer coefficient. This means (1) heat transfer for water-to-air terminals is established by the mean air-to-water temperature difference, (2) heat transfer is measurably changed, and (3) a change in mean water temperature requires a greater change in water flow rate.

Tests of hydronic coil performance show that when flow is throttled to the coil, the water-side differential temperature of the coil increases with respect to design selection. This applies to both constant-volume and variable-volume air-handling units. In constantly circulated coils that control temperature by changing coil entering water temperature, decreasing source flow to the circuit decreases the water-side differential temperature.

A secondary concern applies to heating terminals. Unlike chilled water, hot water can be supplied at a wide range of temperatures. Inadequate terminal heating capacity caused by insufficient flow can sometimes be overcome by raising supply water temperature. Design below the 250°F limit (ASME low-pressure boiler code) must be considered.

Figure 2 shows the flow variation when 90% terminal capacity is acceptable. Note that heating tolerance decreases with temperature

Fig. 1 Effects of Flow Variation on Heat Transfer from a Hydronic Terminal

Fig. 2 Percent of Design Flow Versus Design Δt to Maintain 90% Terminal Heat Transfer for Various Supply Water Temperatures

and flow rates and that chilled-water terminals are much less tolerant of flow variation than hot-water terminals.

Dual-temperature heating/cooling hydronic systems are sometimes first started during the heating season. Adequate heating ability in the terminals may suggest that the system is balanced. Figure 2 shows that 40% of design flow through the terminal provides 90% of design heating with 140°F supply water and a 10°F temperature drop. Increased supply water temperature establishes the same heat transfer at terminal flow rates of less than 40% design.

Sometimes, dual-temperature water systems have decreased flow during the cooling season because of chiller pressure drop; this could cause a flow reduction of 25%. For example, during the cooling season, a terminal that heated satisfactorily would only receive 30% of the design flow rate.

Although the example of reduced flow rate at $\Delta t = 20^\circ\text{F}$ only affects heat transfer by 10%, this reduced heat transfer rate may have the following negative effects:

- Object of the system is to deliver (or remove) heat where required. When flow is reduced from design rate, the system must supply

Fig. 3 Typical Heating-Coil Heat Transfer Versus Water Flow

heating or cooling for a longer period to maintain room temperature.

- As load reaches design conditions, the reduced flow rate is unable to maintain room design conditions.
- Control valves with average range ability (30:1) and reasonable authority ($\beta = 0.5$) may act as on/off controllers instead of throttling flows to the terminal. The resultant change in riser friction loss may cause overflow or underflow in other system terminals. Attempting to throttle may cause wear on the valve plug or seat because of higher velocities at the vena contracta of the valve. In extreme situations, cavitations may occur.

Terminals with lower water temperature drops have greater tolerance for unbalanced conditions. However, larger water flows are necessary, requiring larger pipes, pumps, and pumping cost.

System balance becomes more important in terminals with a large temperature difference. Less water flow is required, which reduces the size of pipes, valves, and pumps, as well as pumping costs. A more linear emission curve gives better system control. If flow varies by more than 5% at design flow conditions, heat transfer can fall off rapidly, ultimately causing poorer control of the wet-bulb temperature and potentially decreasing system air quality.

Heat Transfer at Excessive Flow

Increasing the flow rate above design in an effort to increase heat transfer requires careful consideration. Figure 3 shows that increasing the flow to 200% of design only increases heat transfer by 6% but increases resistance or pressure drop four times and power by the cube of the original power (pump laws) for a lower design Δt . In coils with larger water-side design Δt , heat transfer can increase.

Generalized Chilled-Water Terminal: Heat Transfer Versus Flow

Heat transfer for a typical chilled-water coil in an air duct versus water flow rate is shown in Figure 4. The curves are based on ARI rating points: 45°F inlet water at a 10°F rise with entering air at 80°F db and 67°F wb. The basic curve applies to catalog ratings for lower dry-bulb temperatures providing a consistent entering-air moisture content (e.g., 75°F db, 65°F wb). Changes in inlet water temperature, temperature rise, air velocity, and dry- and wet-bulb temperatures cause terminal performance to deviate from the curves.

Fig. 4 Chilled-Water Terminal Heat Transfer Versus Flow

Table 1 Load Flow Variation

Load Type	% Design Flow at 90% Load	Other Load, Order of %		
		Sensible	Total	Latent
Sensible	65	90	84	58
Total	75	95	90	65
Latent	90	98	95	90

Note: Dual-temperature systems are designed to chilled flow requirements and often operate on a 10°F temperature drop at full-load heating.

Figure 4 is only a general representation and does not apply to all chilled-water terminals. Comparing Figure 4 with Figure 1 indicates the similarity of nonlinear heat transfer and flow for both the heating and cooling terminals.

Table 1 shows that if the coil is selected for the load and flow is reduced to 90% of load, three flow variations can satisfy the reduced load at various sensible and latent combinations. Note that the reduction in flow will not maintain a chilled-water design differential when coil velocity drops below 1.5 fps. This affects chiller loading and unloading.

Flow Tolerance and Balance Procedure

The design procedure rests on a design flow rate and an allowable flow tolerance. The designer must define both the terminal's flow rates and feasible flow tolerance, remembering that the cost of balancing rises with tightened flow tolerance. Any overflow increases pumping cost, and any flow decrease reduces the maximum heating or cooling at design conditions.

7. WATER-SIDE BALANCING

Water-side balancing adjustments should be made with a thorough understanding of piping friction loss calculations and measured system pressure losses. It is good practice to show expected losses of pipes, fittings, and terminals and expected pressures in operation on schematic system drawings.

The water side should be tested by direct flow measurement. This method is accurate because it deals with system flow as a function of differential pressures, and avoids compounding errors introduced by temperature difference procedures. Measuring flow at each terminal enables proportional balancing and, ultimately, matching pump head and flow to actual system requirements by trimming the pump impeller or reducing pump motor power. Often, reducing pump operating cost pays for the cost of water-side balancing.

Equipment

Proper equipment selection and preplanning are needed to successfully balance hydronic systems. Circumstances sometimes dictate that flow, temperature, and pressure be measured. The designer should specify the water flow balancing devices for installation during construction and testing during hydronic system balancing. The devices may consist of all or some of the following:

- Flowmeters (ultrasonic stations, turbines, venturi, orifice plate, multiported pitot tubes, and flow indicators)
- Manometers, ultrasonic digital meters, and differential pressure gages (analog or digital)
- Portable digital meter to measure flow and pressure drop
- Portable pyrometers to measure temperature differentials when test wells are not provided
- Test pressure taps, pressure gages, thermometers, and wells.
- Balancing valve with a factory-rated flow coefficient C_v , a flow versus handle position and pressure drop table, or a slide rule flow calculator
- Dynamic balancing valves or flow-limiting valves (for prebalanced systems only); field adjustment of these devices is not normally required or possible (see Chapter 46)
- Pumps with factory-certified pump curves
- Components used as flowmeters (terminal coils, chillers, heat exchangers, or control valves if using manufacturer's factory-certified flow versus pressure drop curves)

Record Keeping

Balancing requires accurate record keeping while making field measurements. Dated and signed field test reports help the designer or customer in work approval, and the owner has a valuable reference when documenting future changes.

Sizing Balancing Valves

A balancing valve is placed in the system to adjust water flow to a terminal, branch, zone, riser, or main. It should be located on the leaving side of the hydronic branch. General branch layout is from takeoff to entering service valve, then to the coil, control valve, and balancing/service valve. Pressure is thereby left on the coil, helping keep dissolved air in solution and preventing false balance problems resulting from air bind.

A common valve sizing method is to select for line size; however, balancing valves should be selected to pass design flows when near or at their fully open position with 12 in. of water minimum pressure drop. Larger Δp is recommended for accurate pressure readings. Many balancing valves and measuring meters give an accuracy of $\pm 5\%$ of range down to a pressure drop of 12 in. of water with the balancing valve wide open. Too large a balancing valve pressure drop affects the performance and flow characteristic of the control valve. Too small a pressure drop affects its flow measurement accuracy as it is closed to balance the system. Equation (2) may be used to determine the flow coefficient C_v for a balancing valve or to size a control valve.

The flow coefficient C_v is defined as the number of gallons of water per minute that flows through a wide-open valve with a pressure drop of 1 psi at 60°F. This is shown as

$$C_v = Q \sqrt{s_f / \Delta p} \quad (2)$$

where

- Q = design flow for terminal or valve, gpm
- s_f = specific gravity of fluid
- Δp = pressure drop, psi
- Δh = pressure drop, ft of water

If pressure drop is determined in feet of water Δh , Equation (2) can be shown as

$$C_v = 1.5Q \sqrt{s_f / \Delta h} \quad (3)$$

8. HYDRONIC BALANCING METHODS

Various techniques are used to balance hydronic systems. Balance by temperature difference and water balance by proportional method are the most common.

Preparation. Minimally, preparation before balancing should include collecting the following:

1. Pump submittal data; pump curves, motor data, etc.
2. Starter sizes and overload protection information
3. Control valve C_v , ratings and temperature control diagrams
4. Chiller, boiler, and heat exchanger information; flow and head loss
5. Terminal unit information; flow and head loss data
6. Pressure relief and reducing valve setting
7. Flowmeter calibration curves
8. Other pertinent data

System Preparation for Static System

1. Examine piping system: Identify main pipes, risers, branches and terminals on as-built drawings. Check that flows for all balancing devices are indicated on drawings before beginning work. Check that design flows for each riser equal the sum of the design flows through the terminals.
2. Examine reducing valve
3. Examine pressure relief valves
4. Examine expansion tank
5. For pumps, confirm
 - Location and size
 - Vented volute
 - Alignment
 - Grouting
 - Motor and lubrication
 - Nameplate data
 - Pump rotational direction
6. For strainers, confirm
 - Location and size
 - Mesh size and cleanliness
7. Confirm location and size of terminal units
8. Control valves:
 - Confirm location and size
 - Confirm port locations and flow direction
 - Set all valves open to coil
 - Confirm actuator has required force to close valve under loaded conditions
9. Ensure calibration of all measuring instruments, and that all calibration data are known for balancing devices
10. Remove all air from piping; all high points should have air vents

Pump Start-Up

1. Start pump and confirm rotational direction; if rotation is incorrect, have corrected.
2. Read differential head and apply to pump curve to observe flow approximates design.

3. Slowly close pump (if pump is under 25 hp) throttle valve to shutoff. Read pump differential head from gages.
 - If shutoff head corresponds with published curve, the previously prepared velocity head correction curve can be used as a pump flow calibration curve.
 - A significant difference between observed and published shutoff head can be caused by an unvented volute, a partially plugged impeller, or by an impeller size different from that specified.

Confirmation of System Venting

1. Confirm tank location and size.
2. Shut off pump; record shutoff gauge pressure at tank junction.
3. Start pump and record operating pressure at tank junction.
4. Compare operating to shutoff pressures at tank junction. If there is no pressure change, the system is air-free.
5. Eliminate free air.
 - No air separation: Shut off pump and revert. Retest and revert until tank junction pressure is stable.
 - Air separation: Operate system until free air has been separated out, indicated by stable tank junction pressure.

Balancing

For single-, multiple-, and parallel pump systems, after pump start-up and confirmation of system venting,

1. Adjust pump throttle until pump head differential corresponds to design.
2. Record pump motor voltage and amperage, and pump strainer head, at design flow.
3. Balance equipment room piping circuit so that pumped flow remains constant over alternative flow paths.
4. Record chiller and boiler circuits (for multiple-pump systems, requires a flowmeter installed between header piping).

For multiple-pump systems only,

5. Check for variable flow in source circuits when control valves are operated.
6. Confirm
 - Pump suction pressure remains above cavitations range for all operating conditions.
 - Pump flow rates remain constant.
 - Source working pressures are unaffected.

For parallel-pump systems, follow steps (1) to (4), then shut off pumps alternately and

5. Record head differential and flow rate through operating pump, and operating pump motor voltage and current.
6. Confirm that operational point is satisfactory (no overload, cavitation potential, etc.).

Balance by Temperature Difference

This common balancing procedure is based on measuring the water temperature difference between supply and return at the terminal. The designer selects the cooling and/or heating terminal for a calculated design load at full-load conditions. At less than full load, which is true for most operating hours, the temperature drop is proportionately less. Figure 5 demonstrates this relationship for a heating system at a design Δt of 20°F for outdoor design of 10°F and room design of 70°F.

For every outdoor temperature other than design, the balancing technician should construct a similar chart and read off the Δt for balancing. For example, at 50% load, or 30°F outdoor air, the Δt required is 10°F, or 50% of the design drop.

Fig. 5 Water Temperature Versus Outdoor Temperature Showing Approximate Temperature Difference

This method is a rough approximation and should not be used where great accuracy is required. It is not accurate enough for cooling systems.

Water Balance by Proportional Method

Preset Method. A thorough understanding of the pressure drops in the system riser piping, branches, coils, control valves, and balancing valves is needed. Generally, several pipe and valve sizes are available for designing systems with high or low pressure drops. A flow-limiting or trim device will be required. Knowing system pressure losses in design allows the designer to select a balancing device to absorb excess system pressures in the branch, and to shift pressure drop (which might be absorbed by a balancing device nearly close to achieve balance) to the pipes, coils, and valves so the balancing device merely trims these components' performance at design flow. It may also indicate where high-head-loss circuits can exist for either relocation in the piping network, or hydraulic isolation through hybrid piping techniques. The installed balancing device should never be closed more than 40 to 50%; below this point flow reading accuracy falls to ± 20 to 30%. Knowing a starting point for setting the valve (preset) allows the designer to iterate system piping design. This may not always be practical in large systems, but minimizing head and flow saves energy over the life of the facility and allows for proper temperature control. In this method,

1. Analyze the piping network for the largest hydraulic loss based on design flow and pipe friction loss. The pump should be selected to provide the total of all terminal flows, and the head required to move water through the hydraulically greatest circuit. Balance devices in this circuit should be sized only for the loss required for flow measurement accuracy. Trimming is not required.
2. Analyze differences in pressure drop in the pumping circuit for each terminal without using a balancing device. The difference between each circuit and the pump head (which represents the drop in the farthest circuit) is the required drop for the balancing device.
3. Select a balancing device that will achieve this drop with minimum valve throttling. If greater than two pipe sizes smaller, shift design drop into control valve or coil (or both), equalizing pressure drop across the devices.
4. Monitor system elevations and pressure drops to ensure air management, minimizing pocket collections and false pressure references that could lead to phantom balancing problems.
5. Use proportional balancing methods as outlined for field testing and adjustment.

Proportional Balancing

Proportional water-side balancing may use design data, but relies most on as-built conditions and measurements and adapts well to design diversity factors. This method works well with multiple-riser systems. When several terminals are connected to the same circuit, any variation of differential pressure at the circuit inlet affects flows in all other units in the same proportion. Circuits are proportionally balanced to each other by a flow quotient:

$$\text{Flow quotient} = \frac{\text{Actual flow rate}}{\text{Design flow rate}} \quad (4)$$

To balance a branch system proportionally,

1. Fully open the balancing and control valves in that circuit.
2. Adjust the main balancing valve for total pump flow of 100 to 110% of design flow.
3. Calculate each riser valve's quotient based on actual measurements. Record these values on the test form, and note the circuit with the lowest flow quotient.

Note: When all balancing devices are open, flow will be higher in some circuits than others. In some, flow may be so low that it cannot be accurately measured. The situation is complicated because an initial pressure drop in series with the pump is necessary to limit total flow to 100 to 110% of design; this decreases the available differential pressure for the distribution system. After all other risers are balanced, restart analysis of risers with unmeasurable flow at step (2).
4. Identify the riser with the highest flow ratio. Begin balancing with this riser, then continue to the next highest flow ratio, and so on. When selecting the branch with the highest flow ratio,
 - Measure flow in all branches of the selected riser.
 - In branches with flow higher than 150% of design, close the balancing valves to reduce flow to about 110% of design.
 - Readjust total pump flow using the main valve.
 - Start balancing in branches with a flow ratio greater than or equal to 1. Start with the branch with the highest flow ratio.

The reference circuit has the lowest quotient and the greatest pressure loss. Adjust all other balancing valves in that branch until they have the same quotient as the reference circuit (at least one valve in the branch should be fully open).

When a second valve is adjusted, the flow quotient in the reference valve also changes; continued adjustment is required to make their flow quotients equal. Once they are equal, they will remain equal or in proportional balance to each other while other valves in the branch are adjusted or until there is a change in pressure or flow.

When all balancing valves are adjusted to their branches' respective flow quotients, total system water flow is adjusted to the design by setting the balancing valve at the pump discharge to a flow quotient of 1.

Pressure drop across the balancing valve at pump discharge is produced by the pump that is not required to provide design flow. This excess pressure can be removed by trimming the pump impeller or reducing pump speed. The pump discharge balancing valve must then be reopened fully to provide the design flow.

As in variable-speed pumping, diversity and flow changes are well accommodated by a system that has been proportionately balanced. Because the balancing valves have been balanced to each other at a particular flow (design), any changes in flow are proportionately distributed.

Balancing the water side in a system that uses diversity must be done at full flow. Because components are selected based on heat transfer at full flow, they must be balanced to this point. To accomplish full-flow proportional balance, shut off part of the system while balancing the remaining sections. When a section has been balanced, shut it off and open the section that was open originally to

complete full balance of the system. When balancing, care should be taken if the building is occupied or if load is nearly full.

Variable-Speed Pumping. To achieve hydronic balance, full flow through the system is required during balancing, after which the system can be placed on automatic control and the pump speed allowed to change. After the full-flow condition is balanced and the system differential pressure set point is established, to control the variable-speed pumps, observe the flow on the circuit with the greatest resistance as the other circuits are closed one at a time. The flow in the observed circuit should remain equal to, or more than, the previously set flow. Water flow may become laminar at less than 2 fps, which may alter the heat transfer characteristics of the system.

Other Balancing Techniques

Flow Balancing by Rated Differential Procedure. This procedure depends on deriving a performance curve for the test coil, comparing water temperature difference Δt_w to entering water temperature t_{ew} minus entering air temperature t_{ea} . One point of the desired curve can be determined from manufacturer’s ratings, which are published as $(t_{ew} - t_{ea})$. A second point is established by observing that the heat transfer from air to water is zero when $(t_{ew} - t_{ea})$ is zero (consequently, $\Delta t_w = 0$). With these two points, an approximate performance curve can be drawn (Figure 6). Then, for any other $(t_{ew} - t_{ea})$, this curve is used to determine the appropriate Δt_w . The basic curve applies to catalog ratings for lower dry-bulb temperatures, providing a consistent entering air moisture content (e.g., 75°F db, 65°F wb). Changes in inlet water temperature, temperature rise, air velocity, and dry- and wet-bulb temperatures cause terminal performance to deviate from the curves. The curve may also be used for cooling coils for sensible transfer (dry coil).

Flow Balancing by Total Heat Transfer. This procedure determines water flow by running an energy balance around the coil. From field measurements of airflow, wet- and dry-bulb temperatures up- and downstream of the coil, and the difference Δt_w between entering and leaving water temperatures, water flow can be determined by the following equations:

$$Q_w = q/500\Delta t_w \tag{5}$$

$$q_{cooling} = 4.5Q_a(h_1 - h_2) \tag{6}$$

$$q_{heating} = 1.08Q_a(t_1 - t_2) \tag{7}$$

where

Q_w = water flow rate, gpm

Fig. 6 Coil Performance Curve

- q = load, Btu/h
- $q_{cooling}$ = cooling load, Btu/h
- $q_{heating}$ = heating load, Btu/h
- Q_a = airflow rate, cfm
- h = enthalpy, Btu/lb
- t = temperature, °F

Example 1. Find the water flow for a cooling system with the following characteristics:

Test data

- t_{ewb} = entering wet-bulb temperature = 68.5°F
- t_{lwb} = leaving wet-bulb temperature = 53.5°F
- Q_a = airflow rate = 22,000 cfm
- t_{lw} = leaving water temperature = 59.0°F
- t_{ew} = entering water temperature = 47.5°F

From psychrometric chart

- h_1 = 32.84 Btu/lb
- h_2 = 22.32 Btu/lb

Solution: From Equations (5) and (6),

$$Q_w = \frac{4.5 \times 22,000(32.84 - 22.32)}{500(59.0 - 47.5)} = 181 \text{ gpm}$$

The desired water flow is achieved by successive manual adjustments and recalculations. Note that these temperatures can be greatly influenced by the heat of compression, stratification, bypassing, and duct leakage.

General Balance Procedures

All the variations of balancing hydronic systems cannot be listed; however, the general method should balance the system and minimize operating cost. Excess pump pressure (operating power) can be eliminated by trimming the pump impeller. Allowing excess pressure to be absorbed by throttle valves adds a lifelong operating-cost penalty to the operation.

The following is a general procedure based on setting the balance valves on the site:

1. Develop a flow diagram if one is not included in the design drawings. Illustrate all balance instrumentation, and include any additional instrument requirements.
2. Compare pumps, primary heat exchangers, and specified terminal units, and determine whether a design diversity factor can be achieved.
3. Examine the control diagram and determine the control adjustments needed to obtain design flow conditions.

Balance Procedure: Primary and Secondary Circuits

1. Inspect the system completely to ensure that (1) it has been flushed out, it is clean, and all air is removed; (2) all manual valves are open or in operating position; (3) all automatic valves are in their proper positions and operative; and (4) the expansion tank is properly charged.
2. Place controls in position for design flow.
3. Examine flow diagram and piping for obvious short circuits; check flow and adjust the balance valve.
4. Take pump suction, discharge, and differential pressure readings at both full and no flow. For larger pumps, a no-flow condition may not be safe. In any event, valves should be closed slowly.
5. Read pump motor amperage and voltage, and determine approximate power.
6. Establish a pump curve, and determine approximate flow rate.
7. If a total flow station exists, determine the flow and compare with pump curve flow.
8. If possible, set total flow about 10% high using the total flow station first and the pump differential pressure second; then

maintain pumped flow at a constant value as balance proceeds by adjusting the pump throttle valve.

9. Any branch main flow stations should be tested and set, starting by setting the shortest runs low as balancing proceeds to the longer branch runs.
10. With primary and secondary pumping circuits, a reasonable balance must be obtained in the primary loop before the secondary loop can be considered. The secondary pumps must be running and terminal units must be open to flow when the primary loop is being balanced, unless the secondary loop is decoupled.

9. FLUID FLOW MEASUREMENT

Flow Measurement Based on Manufacturer's Data

Any component (terminal, control valve, or chiller) that has an accurate, factory-certified flow/pressure drop relationship can be used as a flow-indicating device. The flow and pressure drop may be used to establish an equivalent flow coefficient as shown in Equation (3). According to the Bernoulli equation, pressure drop varies as the square of the velocity or flow rate, assuming density is constant:

$$Q_1^2/Q_2^2 = \Delta h_1/\Delta h_2 \tag{8}$$

For example, a chiller has a certified pressure drop of 25 ft of water at 100 gpm. The calculated flow with a field-measured pressure drop of 30 ft is

$$Q_2 = 100 \sqrt{30/25} = 109.5 \text{ gpm}$$

Flow calculated in this manner is only an estimate. The accuracy of components used as flow indicators depends on the accuracy of (1) cataloged information concerning flow/pressure drop relationships and (2) pressure differential readings. As a rule, the component should be factory-certified flow tested if it is to be used as a flow indicator.

Pressure Differential Readout by Gage

Gages are used to read differential pressures. Gages are usually used for high differential pressures and manometers for lower differentials. Accurate gage readout is diminished when two gages are used, especially when the gages are permanently mounted and, as such, subject to malfunction.

A single high-quality gage should be used for differential readout (Figure 7). This gage should be alternately valved to the high- and low-pressure side to establish the differential. A single gage needs no static height correction, and errors caused by gage calibration are eliminated.

Differential pressure can also be read from differential gages, thus eliminating the need to subtract outlet from inlet pressures to establish differential pressure. Differential pressure gages are usually dual gages mechanically linked to read differential pressure.

Fig. 7 Single Gage for Reading Differential Pressure

The differential pressure gage readout can be stated in terms of psi or in feet of head of 60°F water.

Conversion of Differential Pressure to Head

Pressure gage readings can be restated to fluid head, which is a function of fluid density. The common hydronic system conversion factor is related to water density at about 60°F; 1 psi equals 2.31 ft. Pressure gages can be calibrated to feet of water head using this conversion. Because the calibration only applies to water at 60°F, the readout may require correction when the gage is applied to water at a significantly higher temperature.

Pressure gage conversion and correction factors for various fluid specific gravities (in relation to water at 60°F) are shown in Table 2. The differential gage readout should only be defined in terms of the head of the fluid actually causing the flow pressure differential. When this is done, the resultant fluid head can be applied to the C_v to determine actual flow through any flow device, provided the manufacturer has correctly stated the flow to fluid head relationship.

For example, a manufacturer may test a boiler or control valve with 100°F water. If the test differential pressure is converted to head at 100°F, a C_v independent of test temperature and density may be calculated. Differential pressures from another test made in the field at 250°F may be converted to head at 250°F. The C_v calculated with this head is also independent of temperature. The manufacturer's data can then be directly correlated with the field test to establish flow rate at 250°F.

A density correction must be made to the gage reading when differential heads are used to estimate pump flows as in Figure 8. This is because of the shape of the pump curve. An incorrect head difference entry into the curve caused by an uncorrected gage reading can cause a major error in the estimated pumped flow. In this case, the gage reading for a pumped liquid that has a specific gravity of 0.9 (2.57 ft liquid/psi) was not corrected; the gage conversion is assumed to be 2.31 ft liquid/psi. A 50% error in flow estimation is shown.

Differential Head Readout with Manometers

Manometers are used for differential pressure readout, especially when very low differentials, great precision, or both, are required. But manometers must be handled with care; they should not be used for field testing because fluid could blow out into the water and rapidly deteriorate the components. A proposed manometer arrangement is shown in Figure 9.

Figure 9 and the following instructions provide accurate manometer readings with minimum risk of blowout.

1. Make sure that both legs of manometer are filled with water.

Fig. 8 Fluid Density Correction Chart for Pump Curves

0.70		3.30	
0.60		3.85	
0.50		4.63	

^aDifferential psi readout is multiplied by this number to obtain feet fluid head when gage is calibrated in psi.

^bDifferential feet water head readout is multiplied by this number to obtain feet fluid head when gage calibration is stated to feet head of 60°F water.

- Open purge bypass valve.
- Open valved connections to high and low pressure.
- Open bypass vent valve slowly and purge air here.
- Open manometer block vents and purge air at each point.
- Close needle valves. The columns should zero in if the manometer is free of air. If not, vent again.
- Open needle valves and begin throttling purge bypass valve slowly, watching the fluid columns. If the manometer has an adequate available fluid column, the valve can be closed and the differential reading taken. However, if the fluid column reaches the top of the manometer before the valve is completely closed, insufficient manometer height is indicated and further throttling will blow fluid into the blowout collector. A longer manometer or the single gage readout method should then be used.

An error is often introduced when converting inches of gage fluid to feet of test fluid. The conversion factor changes with test fluid temperature, density, or both. Conversion factors shown in Table 2 are to a water base, and the counterbalancing water height *H* (Figure 9) is at room temperature.

Orifice Plates, Venturi, and Flow Indicators

Manufacturers provide flow information for several devices used in hydronic system balance. In general, the devices can be classified as (1) orifice flowmeters, (2) venturi flowmeters, (3) velocity impact meters, (4) pitot-tube flowmeters, (5) bypass spring impact flowmeters, (6) calibrated balance valves, (7) turbine flowmeters, and (8) ultrasonic flowmeters.

The **orifice flowmeter** is widely used and is extremely accurate. The meter is calibrated and shows differential pressure versus flow. Accuracy generally increases as the pressure differential across the meter increases. The differential pressure readout instrument may be a manometer, differential gage, or single gage (see Figure 7).

The **venturi flowmeter** has lower pressure loss than the orifice plate meter because a carefully formed flow path increases velocity head recovery. The venturi flowmeter is placed in a main flow line where it can be read continuously.

Velocity impact meters have precise construction and calibration. The meters are generally made of specially contoured glass or plastic, which allows observation of a flow float. As flow increases, the flow float rises in the calibrated tube to indicate flow rate. Velocity impact meters generally have high accuracy.

A special version of the velocity impact meter is applied to hydronic systems. This version operates on the velocity head difference between the pipe side wall and the pipe center, which causes fluid to flow through a small flowmeter. Accuracy depends on the location of the impact tube and on a velocity profile that corresponds to theory and the laboratory test calibration base. Generally, the accuracy of this **bypass flow impact** or differential velocity head flowmeter is less than a flow-through meter, which can operate without creating a pressure loss in the hydronic system.

The **pitot-tube flowmeter** is also used for pipe flow measurement. Manometers are generally used to measure velocity head differences because these differences are low.

The **bypass spring impact flowmeter** uses a defined piping pressure drop to cause a correlated bypass side branch flow. The side branch flow pushes against a spring that increases in length with increased flow. Each individual flowmeter is calibrated to relate extended spring length position to main flow. The bypass spring impact flowmeter has, as its principal merit, a direct readout. However, dirt on the spring reduces accuracy. The bypass is opened only when a reading is made. Flow readings can be taken at any time.

The **calibrated balance valve** is an adjustable orifice flowmeter. Balance valves can be calibrated so that a flow/pressure drop relationship can be obtained for each incremental setting of the valve. A ball, rotating plug, or butterfly valve may have its setting expressed in percent open or degree open; a globe valve, in percent open or number of turns. The calibrated balance valve must be manufactured with precision and care to ensure that each valve of a particular size has the same calibration characteristics.

The **turbine flowmeter** is a mechanical device. The velocity of the liquid spins a wheel in the meter, which generates a 4 to 20 mA output that may be calibrated in units of flow. The meter must be well maintained, because wear or water impurities on the bearing may slow the wheel, and debris may clog or break the wheel.

The **ultrasonic flowmeter** senses sound signals, which are calibrated in units of flow. The ultrasonic metering station may be installed as part of the piping, or it may be a strap-on meter. In either case, the meter has no moving parts to maintain, nor does it intrude into the pipe and cause a pressure drop. Two distinct types of ultrasonic meter are available: (1) the transit time meter for HVAC or clear-water systems and (2) the Doppler meter for systems handling sewage or large amounts of particulate matter.

If any of the above meters are to be useful, the minimum distance of straight pipe upstream and downstream, as recommended

Fig. 10 Minimum Installation Dimensions for Flowmeter

Fig. 11 Single Gage for Differential Readout Across Pump and Strainer

by the meter manufacturer and flow measurement handbooks, must be adhered to. Figure 10 presents minimum installation suggestions.

Using a Pump as an Indicator

Although the pump is not a meter, it can be used as an indicator of flow together with the other system components. Differential pressure readings across a pump can be correlated with the pump curve to establish the pump flow rate. Accuracy depends on (1) accuracy of readout, (2) pump curve shape, (3) actual conformance of the pump to its published curve, (4) pump operation without cavitation, (5) air-free operation, and (6) velocity head correction.

When a differential pressure reading must be taken, a single gage with manifold provides the greatest accuracy (Figure 11). The pump suction to discharge differential can be used to establish pump differential pressure and, consequently, pump flow rate. The single gage and manifold may also be used to check for strainer clogging by measuring the pressure differential across the strainer.

If the pump curve is based on fluid head, pressure differential, as obtained from the gage reading, needs to be converted to head, which is pressure divided by the fluid weight per cubic foot. The pump differential head is then used to determine pump flow rate (Figure 12). As long as the differential head used to enter the pump curve is expressed as head of the fluid being pumped, the pump curve shown by the manufacturer should be used as described. The pump curve may state that it was defined by test with 85°F water. This is unimportant, because the same curve applies from 60 to 250°F water, or to any fluid within a broad viscosity range.

Generally, pump-derived flow information, as established by the performance curve, is questionable unless the following precautions are observed:

1. The installed pump should be factory calibrated by a test to establish the actual flow/pressure relationship for that particular pump. Production pumps can vary from the cataloged curve because of minor changes in impeller diameter, interior casting tolerances, and machine fits.
2. When a calibration curve is not available for a centrifugal pump being tested, the discharge valve can be closed briefly to establish the no-flow shutoff pressure, which can be compared to the published curve. If the shutoff pressure differs from that

Fig. 12 Differential Pressure Used to Determine Pump Flow

published, draw a new curve parallel to the published curve. Though not exact, the new curve usually fits the actual pumping circumstance more accurately. Clearance between the impeller and casing minimizes the danger of damage to the pump during a no-flow test, but manufacturer verification is necessary.

3. Differential head should be determined as accurately as possible, especially for pumps with flat flow curves.
4. The pump should be operating air-free and without cavitation. A cavitating pump will not operate to its curve, and differential readings will provide false results.
5. Ensure that the pump is operating above the minimum net positive suction head.
6. Power readings can be used (1) as a check for the operating point when the pump curve is flat or (2) as a reference check when there is suspicion that the pump is cavitating or providing false readings because of air.
7. The flow determined by the pump curve should be compared to the flow measured at the flowmeters, flow measured by pressure drops through circuits, and flow measured by pressure drops through exchangers.
8. The pump flow derived from the pressure differential at the suction and discharge connections is only an indicator of the actual flow; it cannot be used to verify the test and balance measurements. If pump flow is to be used for balancing verification, it needs to be determined using the Hydraulic Institute procedure or by measuring the flow through a properly installed metering station 15 to 20 straight pipe diameters downstream from the pump discharge.

Power draw should be measured in watts. Ampere readings cannot be trusted because of voltage and power factor problems. If motor efficiency is known, the wattage drawn can be related to pump brake power (as described on the pump curve) and the operating point determined.

Central Plant Chilled-Water Systems

For existing installations, establishing accurate thermal load profiles is of prime importance because it establishes proper primary chilled-water supply temperature and flow. In new installations, actual load profiles can be compared with design load profiles to obtain valid operating data.

To perform proper testing and balancing, all interconnecting points between the primary and secondary systems must be designed with sufficient temperature, pressure, and flow connections so that adequate data may be indicated and/or recorded.

Water Flow Instruments

As indicated previously, proper location and use of instruments is vital to accurate balancing. Instruments for testing temperature

and pressure at various locations are listed in Table 3. Flow-indicating devices should be placed in water systems as follows:

- At each major heating coil bank (10 gpm or more)
- At each major cooling coil bank (10 gpm or more)
- At each bridge in primary-secondary systems
- At each main pumping station
- At each water chiller evaporator
- At each water chiller condenser
- At each water boiler outlet
- At each floor takeoff to booster reheat coils, fan coil units, induction units, ceiling panels, and radiation (do not exceed 25 terminals off of any one zone meter probe)
- At each vertical riser to fan coil units, induction units, and radiation
- At the point of tie-in to existing systems

10. STEAM DISTRIBUTION

Procedures for Steam Balancing Variable Flow Systems

Steam distribution cannot be balanced by adjustable flow-regulating devices. Instead, fixed restrictions built into the piping in accordance with carefully designed pipe and orifice sizes are used to regulate flow.

It is important to have a balanced distribution of steam to all portions of the steam piping at all loads. This is best accomplished by properly designing the steam distribution piping, which includes carefully considering steam pressure, steam quantities required by each branch circuit, pressure drops, steam velocities, and pipe sizes. Just as other flow systems are balanced, steam distribution systems are balanced by ensuring that the pressure drops are equalized at design flow rates for all portions of the piping. Only marginal balancing can be done by pipe sizing. Therefore, additional steps must be taken to achieve a balanced performance.

Steam flow balance can be improved by using spring-type packless supply valves equipped with precalibrated orifices. The valves should have a tight shutoff between 25 in. of Hg and 60 psig. These valves have a nonrising stem, are available with a lockshield, and have a replaceable disk. Orifice flanges can also be used to regulate

and measure steam flow at appropriate locations throughout the system. The orifice sizes are determined by the pressure drop required for a given flow rate at a given location. A schedule should be prepared showing (1) orifice sizes, (2) valve or pipe sizes, (3) required flow rates, and (4) corresponding pressure differentials for each flow rate. It may be useful to calculate pressure differentials for several flow rates for each orifice size. Such a schedule should be maintained for future reference.

After the appropriate regulating orifices are installed in the proper locations, the system should be tested for tightness by sealing all openings in the system and applying a vacuum of 20 in. of Hg, held for 2 hours. Next, the system should be readied for warm-up and pressurizing with steam following the procedures outlined in Section VI of the ASME *Boiler and Pressure Vessel Code*. After the initial warm-up and system pressurization, evaluate system steam flow, and compare it to system requirements. The orifice schedule calculated earlier will now be of value should any of the orifices need to be changed.

Steam Flow Measuring Devices

Many devices are available for measuring flow in steam piping: (1) steam meters, (2) condensate meters, (3) orifice plates, (4) venturi fittings, (5) steam recorders, and (6) manometers for reading differential pressures across orifice plates and venturi fittings. Some of these devices are permanently affixed to the piping system to facilitate taking instantaneous readings that may be necessary for proper operation and control. A surface pyrometer used in conjunction with a pressure gage is a convenient way to determine steam saturation temperature and the degree of superheat at various locations in the system. This information can be used to evaluate performance characteristics.

11. COOLING TOWERS

Field-testing cooling towers is demanding and difficult. ASME *Standard PTC 23* and CTI *Standard Specification ATC-105* establish procedures for these tests. Certain general guidelines for testing cooling towers are as follows:

Conditions at Time of Test

- Water flow within 15% of design
- Heat load within 30% of design and stabilized
- Entering wet bulb within 12°F of design

Using these limitations and field readings that are as accurate as possible, a projection to design conditions produces an accuracy of ±5% of tower performance.

Conditions for Performing Test

- Water-circulating systems serving tower should be thoroughly cleaned of all dirt and foreign matter. Samples of water should be clear and indicate clear passage of water through pumps, piping, screens, and strainers.
- Fans serving cooling tower should operate in proper rotation. Foreign obstructions should be removed. Permanent obstruction should be noted.
- Interior filling of cooling tower should be clean and free of foreign materials such as scale, algae, or tar.
- Water level in tower basin should be maintained at proper level. Visually check basin sump during full flow to verify that centrifugal action of the water is not causing entrainment of air, which could cause pump cavitation.
- Water-circulating pumps should be tested with full flow through tower. If flow exceeds design, it should be valved down until design is reached. The flow that is finally set should be maintained throughout the test period. All valves, except necessary balancing valves, should be fully open.

- If makeup and blowdown have facilities to determine flow, set them to design flow at full flow through the tower. If flow cannot be determined, shut off both.

Instruments

Testing and balancing agencies provide instruments to perform the required tests. Mechanical contractors provide and install all components such as orifice plates, venturis, balancing valves, thermometer wells, gage cocks, and corporation cocks. Designers specify measuring point locations.

Instruments used should be recently calibrated as follows:

Temperature

- Thermometer with divisions of 0.2°F in a proper well for water should be used.
- Thermometer with solar shield and 0.2°F divisions or thermocouple with 0.2°F readings having mechanical aspiration for wet-bulb readings should be used.
- Sling psychrometer may be used for rough checks.
- Thermometer with 0.2°F divisions should be used for dry-bulb readings.

Water Flow

- Orifice, venturi, and balancing valve pressure drops can be read using a manometer or recently calibrated differential pressure gage.
- Where corporation cocks are installed, a pitot tube and manometer traverse can be made by trained technicians.

Test Method

1. Conduct water flow tests to determine volume of water in tower, and of makeup and blowdown water.
2. Conduct water temperature tests, if possible, in suitable wells as close to tower as possible. Temperature readings at pumps or condensing element are not acceptable in tower evaluation. If there are no wells, surface pyrometer readings are acceptable.
3. Take makeup water volume and temperature readings at point of entry into tower.
4. Take blowdown volume and temperature readings at point of discharge from tower.
5. Take inlet and outlet dry- and wet-bulb temperature readings using prescribed instruments.
 - Use wet-bulb entering and leaving temperatures to determine tower actual performance against design.
 - Use wet- and dry-bulb entering and leaving temperatures to determine evaporation involved.
6. If tower has a ducted inlet or outlet where a reasonable duct traverse can be made, use this air volume as a cross-check of tower performance.
7. Take wet- and dry-bulb temperature readings 3 to 5 ft from the tower on all inlet sides, halfway between the base and the top of inlet louvers at no more than 5 ft spacing horizontally the readings. Note any unusual inlet conditions.
8. Note wind velocity and direction at time of test.
9. Take test readings continually with a minimum time lapse between readings.
10. If the first test indicates a tower deficiency, perform two additional tests to verify the original readings.

12. TEMPERATURE CONTROL VERIFICATION

The test and balance technician should work closely with the temperature control installer to ensure that the project is completed correctly. The balancing technician needs to verify proper operation of the control and communicate findings back to the agency responsible for ensuring that the controls have been installed correctly. This is usually the HVAC system designer, although others may be involved. Generally, the balancing technician does not adjust, relocate, or

calibrate the controls. However, this is not always the case, and differences do occur with VAV terminal unit controllers. The balancing technician should be familiar with the specifications and design intent of the project so that all responsibilities are understood.

During the design and specification phase of the project, the designer should specify verification procedures for the controls and responsibilities for the contractor who installs the temperature controls. It is important that the designer specify the (1) degree of coordination between the installer of the control and the balancing technician and (2) testing responsibilities of each.

Verification of control operation starts with the balancing technician reviewing the submitted documents and shop drawings of the control system. In some cases, the controls technician should instruct the balancing technician in the operation of certain control elements, such as digital terminal unit controllers. This is followed by schedule coordination between the control and balancing technicians. In addition, the balancing and controls technicians need to work together when reviewing the operation of some sections of the HVAC system, particularly with VAV systems and the setting of the flow measurement parameters in digital terminal unit controllers.

Major mechanical systems should be verified after testing, adjusting, and balancing is completed. The control system should be operated in stages to prove it can match system capacity to varying load conditions. Mechanical subsystem controllers should be verified when balancing data are collected, considering that the entire system may not be completely functional at the time of verification. Testing and verification should account for seasonal variations; tests should be performed under varying outdoor loads to ensure operational performance. Retesting a random sample of terminal units may be desirable to verify the control technician's work.

Suggested Procedures

The following verification procedures may be used with either pneumatic or electrical controls:

1. Obtain design drawings and documentation, and become well acquainted with the design intent and specified responsibilities.
2. Obtain copies of approved control shop drawings.
3. Compare design to installed field equipment.
4. Obtain recommended operating and test procedures from manufacturers.
5. Verify with the control contractor that all controllers are calibrated and commissioned.
6. Check location of transmitters and controllers. Note adverse conditions that would affect control, and suggest relocation as necessary.
7. Note settings on controllers. Note discrepancies between set point for controller and actual measured variable.
8. Verify operation of all limiting controllers, positioners, and relays (e.g., high- and low-temperature thermostats, high- and low-differential pressure switches, etc.).
9. Activate controlled devices, checking for free travel and proper operation of stroke for both dampers and valves. Verify normally open (NO) or normally closed (NC) operation.
10. Verify sequence of operation of controlled devices. Note line pressures and controlled device positions. Correlate to air or water flow measurements. Note speed of response to step change.
11. Confirm interaction of electrically operated switch transducers.
12. Confirm interaction of interlock and lockout systems.
13. Coordinate balancing and control technicians' schedules to avoid duplication of work and testing errors.

Pneumatic System Modifications

1. Verify main control supply air pressure and observe compressor and dryer operation.

- For hybrid systems using electronic transducers for pneumatic actuation, modify procedures accordingly.

Electronic Systems Modifications

- Monitor voltages of power supply and controller output. Determine whether the system operates on a grounded or nongrounded power supply, and check condition. Although electronic controls now have more robust electronic circuits, improper grounding can cause functional variation in controller and actuator performance from system to system.
- Note operation of electric actuators using spring return. Generally, actuators should be under control and use springs only upon power failure to return to a fail-safe position.

Direct Digital Controllers

Direct digital control (DDC) offers nontraditional challenges to the balancing technician. Many control devices, such as sensors and actuators, are the same as those in electronic and pneumatic systems. Currently DDC is dominated by two types of controllers: fully programmable or application-specific. Fully programmable controllers offer a group of functions linked together in an applications program to control a system such as an air-handling unit. Application-specific controllers are functionally defined with the programming necessary to carry out the functions required for a system, but not all adjustments and settings are defined. Both types of controllers and their functions have some variations. One of the functions is adaptive control, which includes control algorithms that automatically adjust settings of various controller functions.

The balancing technician must understand controller functions so that they do not interfere with the test and balance functions. Literacy in computer programming is not necessary, although it does help. When testing the DDC,

- Obtain controller application program. Discuss application of the designer's sequence with the control programmer.
- Coordinate testing and adjustment of controlled systems with mechanical systems testing. Avoid duplication of efforts between technicians.
- Coordinate storage (e.g., saving to central DDC database and controller memory) of all required system adjustments with control technician.

In cases where the balancing agency is required to test discrete points in the control system,

- Establish criteria for test with the designer.
- Use reference standards that test the end device through the entire controller chain (e.g., device, wiring, controller, communications, and operator monitoring device). An example would be using a dry block temperature calibrator (a testing device that allows a temperature to be set, monitored, and maintained in a small chamber) to test a space temperature sensor. The sensor is installed with extra wire so that it may be removed from the wall and placed in the calibrator chamber. After the system is thermally stabilized, the temperature is read at the controller and the central monitor, if installed.
- Report findings of reference and all points of reading.

13. FIELD SURVEY FOR ENERGY AUDIT

An energy audit is an organized survey of a specific building to identify and measure all energy uses, determine probable sources of energy losses, and list energy conservation opportunities. This is usually performed as a team effort under the direction of a qualified energy engineer. The field data can be gathered by firms employing technicians trained in testing, adjusting, and balancing.

Instruments

To determine a building's energy use characteristics, existing conditions must be accurately measured with proper instruments. Accurate measurements point out opportunities to reduce waste and provide a record of the actual conditions in the building before energy conservation measures were taken. They provide a compilation of installed equipment data and a record of equipment performance before changes. Judgments will be made based on the information gathered during the field survey; that which is not accurately measured cannot be properly evaluated.

Generally, instruments used for testing, adjusting, and balancing are sufficient for energy conservation surveying. Possible additional instruments include a power factor meter, light meter, combustion testing equipment, refrigeration gages, and equipment for recording temperatures, fluid flow rates, and energy use over time. Only high-quality instruments should be used.

Observation of system operation and any information the technician can obtain from the operating personnel pertaining to the operation should be included in the report.

Data Recording

Organized record keeping is extremely important. A camera is also helpful. Photographs of building components and mechanical and electrical equipment can be reviewed later when the data are analyzed.

Data sheets for energy conservation field surveys contain different and, in some cases, more comprehensive information than those used for testing, adjusting, and balancing. Generally, the energy engineer determines the degree of fieldwork to be performed; data sheets should be compatible with the instructions received.

Building Systems

The most effective way to reduce building energy waste is to identify, define, and tabulate the energy load by building system. For this purpose, load is defined as the quantity of energy used in a building, or by one of its subsystems, for a given period. By following this procedure, the most effective energy conservation opportunities can be achieved more quickly because high priorities can be assigned to systems that consume the most energy.

A building can be divided into nonenergized and energized systems. Nonenergized systems do not require outside energy sources such as electricity and fuel. Energized systems (e.g., mechanical and electrical systems) require outside energy. Energized and nonenergized systems can be divided into subsystems defined by function. Nonenergized subsystems are (1) building site, envelope, and interior; (2) building use; and (3) building operation.

Building Site, Envelope, and Interior. These subsystems should be surveyed to determine how they can be modified to reduce the building load that the mechanical and electrical systems must meet without adversely affecting the building's appearance. It is important to compare actual conditions with conditions assumed by the designer, so that mechanical and electrical systems can be adjusted to balance their capacities to satisfy actual needs.

Building Use. These loads can be classified as people occupancy or operation loads. People occupancy loads are related to schedule, density, and mixing of occupancy types (e.g., process and office). People operation loads are varied and include (1) operation of manual window shading devices; (2) setting of room thermostats; and (3) conservation-related habits such as turning off lights, closing doors and windows, turning off energized equipment when not in use, and not wasting domestic hot or chilled water.

Building Operation. This subsystem consists of the operation and maintenance of all the building subsystems. The load on the building operation subsystem is affected by factors such as (1) the time at which janitorial services are performed, (2) janitorial crew

size and time required to clean, (3) amount of lighting used to perform janitorial functions, (4) quality of equipment maintenance program, (5) system operational practices, and (6) equipment efficiencies.

Building Energized Systems

The energized subsystems of the building are generally plumbing, heating, ventilating, cooling, space conditioning, control, electrical, and food service. Although these systems are interrelated and often use common components, logical organization of data requires evaluating the energy use of each subsystem as independently as possible. In this way, proper energy conservation measures for each subsystem can be developed.

Process Loads

In addition to building subsystem loads, the process load in most buildings must be evaluated by the energy field auditor. Most tasks not only require energy for performance, but also affect the energy consumption of other building subsystems. For example, if a process releases large amounts of heat to the space, the process consumes energy and also imposes a large load on the cooling system.

Guidelines for Developing a Field Study Form

A brief checklist follows that outlines requirements for a field study form needed to conduct an energy audit.

Inspection and Observation of All Systems. Record physical and mechanical condition of the following:

- Fan blades, fan scroll, drives, belt tightness, and alignment
- Filters, coils, and housing tightness
- Ductwork (equipment room and space, where possible)
- Strainers
- Insulation ducts and piping
- Makeup water treatment and cooling tower

Interview of Physical Plant Supervisor. Record answers to the following survey questions:

- Is the system operating as designed? If not, what changes have been made to ensure its performance?
- Have there been modifications or additions to the system?
- If the system has had a problem, list problems by frequency of occurrence.
- Are any systems cycled? If so, which systems and when, and would building load allow cycling systems?

Recording System Information. Record the following system/equipment identification:

- Type of system: single-zone, multizone, double-duct, low- or high-velocity, reheat, variable-volume, or other
- System arrangement: fixed minimum outdoor air, no relief, gravity or power relief, economizer gravity relief, exhaust return, or other
- Air-handling equipment: fans (supply, return, and exhaust) manufacturer, model, size, type, and class; dampers (vortex, scroll, or discharge); motors manufacturer, power requirement, full load amperes, voltage, phase, and service factor
- Chilled- and hot-water coils: area, tubes on face, fin spacing, and number of rows (coil data necessary when shop drawings are not available)
- Terminals: high-pressure mixing box manufacturer, model, and type (reheat, constant-volume, variable-volume, induction); grilles, registers, and diffusers manufacturer, model, style, and loss coefficient to convert field-measured velocity to flow rate
- Main heating and cooling pumps, over 5 hp: manufacturer, pump service and identification, model, size, impeller diameter, speed, flow rate, head at full flow, and head at no flow; motor data (power, speed, voltage, amperes, and service factor)

- Refrigeration equipment: chiller manufacturer, type, model, serial number, nominal tons, brake horsepower, total heat rejection, motor (horsepower, amperes, volts), chiller pressure drop, entering and leaving chilled water temperatures, condenser pressure drop, condenser entering and leaving water temperatures, running amperes and volts, no-load running amperes and volts
- Cooling tower: manufacturer, size, type, nominal tons, range, flow rate, and entering wet-bulb temperature
- Heating equipment: boiler (small through medium) manufacturer, fuel, energy input (rated), and heat output (rated)

Recording Test Data. Record the following test data:

- Systems in normal mode of operation (if possible): fan motor running amperes and volts and power factor (over 5 hp); fan speed, total air (pitot-tube traverse where possible), and static pressure (discharge static minus inlet total); static profile drawing (static pressure across filters, heating coil, cooling coil, and dampers); static pressure at ends of runs of the system (identifying locations)
- Cooling coils: entering and leaving dry- and wet-bulb temperatures, entering and leaving water temperatures, coil pressure drop (where pressure taps permit and manufacturer's ratings can be obtained), flow rate of coil (when other than fan), outdoor wet and dry bulb, time of day, and conditions (sunny or cloudy)
- Heating coils: entering and leaving dry-bulb temperatures, entering and leaving water temperatures, coil pressure drop (where pressure taps permit and manufacturer's ratings can be obtained), and flow rate through coil (when other than fan)
- Pumps: no-flow head, full-flow discharge pressure, full-flow suction pressure, full-flow differential pressure, motor running amperes and volts, and power factor (over 5 hp)
- Chiller (under cooling load conditions): chiller pressure drop, entering and leaving chilled water temperatures, condenser pressure drop, entering and leaving condenser water temperatures, running amperes and volts, no-load running amperes and volts, chilled water on and off, and condenser water on and off
- Cooling tower: water flow rate in tower, entering and leaving water temperatures, entering and leaving wet bulb, fan motor [amperes, volts, power factor (over 5 hp), and ambient wet bulb]
- Boiler (full fire): input energy (if possible), percent CO₂, stack temperature, efficiency, and complete Orsat test on large boilers
- Boiler controls: description of operation
- Temperature controls: operating and set point temperatures for mixed air controller, leaving air controller, hot-deck controller, cold-deck controller, outdoor reset, interlock controls, and damper controls; description of complete control system and any malfunctions
- Outdoor air intake versus exhaust air: total airflow measured by pitot-tube traverses of both outdoor air intake and exhaust air systems, where possible. Determine whether an imbalance in the exhaust system causes infiltration. Observe exterior walls to determine whether outdoor air can infiltrate return air (record outdoor air, return air, and return air plenum dry- and wet-bulb temperatures). The greater the differential between outdoor and return air, the more evident the problem will be.

14. REPORTS

The report is a record of the HVAC system balancing and must be accurate in all respects. If the data are incomplete, it must be listed as a deficiency for correction by the installing contractor.

Reports should comply with ASHRAE *Standard* 111, be complete, and include the location of test drawings. An instrument list including serial numbers and current and future calibration dates should also be provided.

15. TESTING FOR SOUND AND VIBRATION

Testing for sound and vibration ensures that equipment is operating satisfactorily and that no objectionable noise and vibration are transmitted to the building structure and occupied space. Although sound and vibration are specialized fields that require expertise not normally developed by the HVAC engineer, the procedures to test HVAC are relatively simple and can be performed with a minimum of equipment by following the steps outlined in this section. Although this section provides useful information for resolving common noise and vibration problems, Chapter 48 should be consulted for information on problem solving or the design of HVAC.

Testing for Sound

Present technology does not test whether equipment is operating with desired sound levels; field tests can only determine sound pressure levels, and equipment ratings are almost always in terms of sound power levels. Until new techniques are developed, the testing engineer can only determine (1) whether sound pressure levels are within desired limits and (2) which equipment, systems, or components are the source of excessive or disturbing transmission.

Sound-Measuring Instruments. Although an experienced listener can often determine whether systems are operating in an acceptably quiet manner, sound-measuring instruments are necessary to determine whether system noise levels are in compliance with specified criteria, and if not, to obtain and report detailed information to evaluate the cause of noncompliance. Instruments normally used in field testing are as follows.

The **precision sound level meter** is used to measure sound pressure level. The most basic sound level meters measure overall sound pressure level and have up to three weighted scales that provide limited filtering capability. The instrument is useful in assessing outdoor noise levels in certain situations and can provide limited information on the low-frequency content of overall noise levels, but it provides insufficient information for problem diagnosis and solution. Its usefulness in evaluating indoor HVAC sound sources is thus limited.

Proper evaluation of HVAC sound sources requires a sound level meter capable of filtering overall sound levels into frequency increments of one octave or less.

Sound analyzers provide detailed information about sound pressure levels at various frequencies through filtering networks. The most popular sound analyzers are the octave band and center frequency, which break the sound into the eight octave bands of audible sound. Instruments are also available for 0.33, 0.1, and narrower spectrum analysis; however, these are primarily for laboratory and research applications. Sound analyzers (octave mid-band or center frequency) are required where specifications are based on noise criteria (NC) and room criteria (RC) curves or similar frequency criteria and for problem jobs where a knowledge of frequency is necessary to determine proper corrective action.

Personal computers are a versatile sound-measuring tool. Software used on portable computers has all the functional capabilities described previously, plus many that previously required a fully equipped acoustical laboratory. This type of sound-measuring system is many times faster and much more versatile than conventional sound level meters. With suitable accessories, it can also be used to evaluate vibration levels. Accuracy and calibration to applicable standards are of concern for software.

Regardless of which sound-measuring system is used, it should be calibrated before each use. Some systems have built-in calibration, while others use external calibrators. Much information is available on the proper application and use of sound-measuring instruments.

Air noise, caused by air flowing at a velocity of over 1000 fpm or by winds over 12 mph, can cause substantial error in sound measurements because of wind effect on the microphone. For outdoor

measurements or in drafty places, either a wind screen for the microphone or a special microphone is required. When in doubt, use a wind screen on standard microphones.

Sound Level Criteria. Without specified values, the testing engineer must determine whether sound levels are within acceptable limits (Chapter 47). Note that complete absence of noise is seldom a design criterion, except for certain critical locations such as sound and recording studios. In most locations, a certain amount of noise is desirable to mask other noises and provide speech privacy; it also provides an acoustically pleasing environment, because few people can function effectively in extreme quiet. Table 1 in Chapter 8 of the 2013 *ASHRAE Handbook—Fundamentals* lists typical sound pressure levels. In determining allowable HVAC equipment noise, it is as inappropriate to demand 30 dB for a factory where the normal noise level is 75 dB as it is to specify 60 dB for a private office where the normal noise level might be 35 dB.

Most field sound-measuring instruments and techniques yield an accuracy of ± 3 dB, the smallest difference in sound pressure level that the average person can discern. A reasonable tolerance for sound criteria is 5 dB; if 35 dBA is considered the maximum allowable noise, the design engineer should specify 30 dBA.

The measured sound level of any location is a combination of all sound sources present, including sound generated by HVAC equipment as well as sound from other sources such as plumbing systems and fixtures, elevators, light ballasts, and outdoor noises. In testing for sound, all sources from other than HVAC equipment are considered background or ambient noise.

Background sound measurements generally have to be made (1) when the specification requires that the sound levels from HVAC equipment only, as opposed to the sound level in a space, not exceed a certain specified level; (2) when the sound level in the space exceeds a desirable level, in which case the noise contributed by the HVAC system must be determined; and (3) in residential locations where little significant background noise is generated during the evening hours and where generally low allowable noise levels are specified or desired. Because background noise from outdoor sources such as vehicular traffic can fluctuate widely, sound measurements for residential locations are best made in the normally quiet evening hours. Procedures for residential sound measurements can be found in ASTM *Standard E1574*, Measurement of Sound in Residential Spaces.

Sound Testing. Ideally, a building should be completed and ready for occupancy before sound level tests are taken. All spaces in which readings will be taken should be furnished with whatever drapes, carpeting, and furniture are typical because these affect the room absorption, which can affect sound levels and the subjective quality of the sound. In actual practice, because most tests must be conducted before the space is completely finished and furnished for final occupancy, the testing engineer must make some allowances. Because furnishings increase the absorption coefficient and reduce by about 4 dB the sound pressure level that can be expected between most live and dead spaces, the following guidelines should suffice for measurements made in unfurnished spaces. If the sound pressure level is 5 dB or more over the specified or desired criterion, it can be assumed that the criterion will not be met, even with the increased absorption provided by furnishings. If the sound pressure level is 0 to 4 dB greater than the specified or desired criterion, recheck when the room is furnished to determine compliance.

Follow this general procedure:

1. Obtain a complete set of accurate, as-built drawings and specifications, including duct and piping details. Review specifications to determine sound and vibration criteria and any special instructions for testing.
2. Visually check for noncompliance with plans and specifications, obvious errors, and poor workmanship. Turn system on for aural

check. Listen for noise and vibration, especially duct leaks and loose fittings.

3. Adjust and balance equipment, as described in other sections, so that final acoustical tests are made with the HVAC as it will be operating. It is desirable to perform acoustical tests for both summer and winter operation, but where this is not practical, make tests for the summer operating mode, as it usually has the potential for higher sound levels. Tests must be made for all mechanical equipment and systems, including standby.
4. Check calibration of instruments.
5. Measure sound levels in all areas as required, combining measurements as indicated in step 3 if equipment or systems must be operated separately. Before final measurements are made in any particular area, survey the area using an A-weighted scale reading (dBA) to determine the location of the highest sound pressure level. Indicate this location on a testing form, and use it for test measurements. Restrict the preliminary survey to determine location of test measurements to areas that can be occupied by standing or sitting personnel. For example, measurements would not be made directly in front of a diffuser located in the ceiling, but would be made as close to the diffuser as standing or sitting personnel might be situated. In the absence of specified sound criteria, the testing engineer should measure sound pressure levels in all occupied spaces to determine compliance with criteria indicated in Chapter 48 and to locate any sources of excessive or disturbing noise. With octave band sound level measurements, overall NC and RC values can be determined. Measurements of 63 to 8000 Hz should be considered the minimum when sound levels in the 16 and 31.5 Hz octave band are desired, from completeness and evaluation of the possibility of noise-induced vibration as evaluated by RC and NCB methods.
6. Determine whether background noise measurements must be made.
 - If specification requires determining sound level from HVAC equipment only, background noise readings must be taken with HVAC equipment turned off.
 - If specification requires compliance with a specific noise level or criterion (e.g., sound levels in office areas not to exceed 35 dBA), ambient noise measurements must be made only if the noise level in any area exceeds the specified value.
 - For residential locations and areas requiring very low noise, such as sound recording studios and locations used during the normally quieter evening hours, it is usually desirable to take sound measurements in the evening and/or take ambient noise measurements.
7. For outdoor noise measurements to determine noise radiated by outdoor or roof-mounted equipment such as cooling towers and condensing units, the section on Sound Control for Outdoor Equipment in Chapter 48, which presents proper procedure and necessary calculations, should be consulted.

Noise Transmission Problems. Regardless of precautions taken by the specifying engineer and installing contractors, situations can occur where the sound level exceeds specified or desired levels, and there will be occasional complaints of noise in completed installations. A thorough understanding of Chapter 48 and the section on Testing for Vibration in this chapter is desirable before attempting to resolve any noise and vibration transmission problems. The following is intended as an overall guide rather than a detailed problem-solving procedure.

All noise transmission problems can be evaluated in terms of the source-path-receiver concept. Objectionable transmission can be resolved by (1) reducing noise at the source by replacing defective equipment, repairing improper operation, proper balancing and adjusting, and replacing with quieter equipment; (2) attenuating paths of transmission with silencers, vibration isolators, and wall

treatment to increase transmission loss; and (3) reducing or masking objectionable noise at the receiver by increasing room absorption or introducing a nonobjectionable masking sound. The following discussion includes ways to identify actual noise sources using simple instruments or no instruments and possible corrections.

When troubleshooting in the field, the engineer should listen to the offending sound. The best instruments are no substitute for careful listening, because the human ear has the remarkable ability to identify certain familiar sounds such as bearing squeak or duct leaks and can discern small changes in frequency or sound character that might not be apparent from meter readings only. The ear is also a good direction and range finder; noise generally gets louder as one approaches the source, and direction can often be determined by turning the head. Hands can also identify noise sources. Air jets from duct leaks can often be felt, and the sound of rattling or vibrating panels or parts often changes or stops when these parts are touched.

In trying to locate noise sources and transmission paths, the engineer should consider the location of the affected area. In areas remote from equipment rooms containing significant noise producers but adjacent to shafts, noise is usually the result of structure-borne transmission through pipe and duct supports and anchors. In areas adjoining, above, or below equipment rooms, noise is usually caused by openings (acoustical leaks) in the separating floor or wall or by improper, ineffective, or maladjusted vibration isolation systems.

Unless the noise source or path of transmission is quite obvious, the best way to identify it is by eliminating all sources systematically as follows:

1. Turn off all equipment to make sure that the objectionable noise is caused by the HVAC. If the noise stops, the HVAC components (compressors, fans, and pumps) must be operated separately to determine which are contributing to the objectionable noise. Where one source of disturbing noise predominates, the test can be performed starting with all equipment in operation and turning off components or systems until the disturbing noise is eliminated. Tests can also be performed starting with all equipment turned off and operating various component equipment singularly, which permits evaluation of noise from each individual component.

Any equipment can be termed a predominant noise source if, when the equipment is shut off, the sound level drops 3 dBA or if, when measurements are taken with equipment operating individually, the sound level is within 3 dBA of the overall objectionable measurement.

When a sound level meter is not used, it is best to start with all equipment operating and shut off components one at a time because the ear can reliably detect differences and changes in noise but not absolute levels.
2. When some part of the HVAC system is established as the source of objectionable noise, try to further isolate the source. By walking around the room, determine whether the noise is coming through air outlets or returns, hung ceiling, or floors or walls.
3. If the noise is coming through the hung ceiling, check that ducts and pipes are isolated properly and not touching the hung ceiling supports or electrical fixtures, which would provide large noise radiating surfaces. If ducts and pipes are the source of noise and are isolated properly, possible remedies to reduce noise include changing flow conditions, installing silencers, and/or wrapping the duct or pipe with an acoustical barrier or lagging such as a lead blanket or other materials suitable for the location (see Chapter 48).
4. If noise is coming through the walls, ceiling, or floor, check for any openings to adjoining shafts or equipment rooms, and check vibration isolation systems to ensure that there is no structure-borne transmission from nearby equipment rooms or shafts.

5. Noise traced to air outlets or returns usually requires careful evaluation by an engineer or acoustical consultant to determine the source and proper corrective action (see Chapter 48). In general, air outlets can be selected to meet any acoustical design goal by keeping the velocity sufficiently low. For any given outlet, the sound level increases about 2 dB for each 10% increase in airflow velocity over the vanes, and doubling the velocity increases the sound level by about 12 to 15 dB. Approach conditions caused by improperly located control dampers or improperly sized diffuser necks can increase sound levels by 10 to 20 dB. Using variable-frequency drive (VFD) speed controllers on air-handling units can help evaluate air velocity concerns. Dampers used to limit airflow often influence overall sound levels.

A simple, effective instrument that aids in locating noise sources is a microphone mounted on a pole. It can be used to localize noises in hard-to-reach places, such as hung ceilings and behind heavy furniture.

6. If noise is traced to an air outlet, measure the A-weighted sound level close to it but with no air blowing against the microphone. Then, remove the inner assembly or core of the air outlet and repeat the reading with the meter and the observer in exactly the same position as before. If the second reading is more than 3 dB below the first, a significant amount of noise is caused by airflow over the vanes of the diffuser or grille. In this case, check whether the system is balanced properly. As little as 10% too much air increases the sound generated by an air outlet by 2.5 dB. As a last resort, a larger air outlet could be substituted to obtain lower air velocities and hence less turbulence for the same air quality. Before this is considered, however, the air approach to the outlet should be checked.

Noise far exceeding the normal rating of a diffuser or grille is generated when a throttled damper is installed close to it. Air jets impinge on the vanes or cones of the outlet and produce **edge tones** similar to the hiss heard when blowing against the edge of a ruler. The material of the vanes has no effect on this noise, although loose vanes may cause additional noise from vibration.

When balancing air outlets with integral volume dampers, consider the static pressure drop across the damper, as well as the air quantity. Separate volume dampers should be installed sufficiently upstream from the outlet that there is no jet impingement. Plenum inlets should be brought in from the side, so that jets do not impinge on the outlet vanes.

7. If air outlets are eliminated as sources of excessive noise, inspect the fan room. If possible, change fan speed by about 10%. If resonance is involved, this small change can make a significant difference.
8. Sometimes fans are poorly matched to the system. If a belt-driven fan delivers air at a higher static pressure than is needed to move the design air quantity through the system, reduce fan speed by changing sheaves. If the fan does not deliver enough air, consider increasing fan speed only after checking the duct system for unavoidable losses. Turbulence in the air approach to the fan inlet increases fan sound generation and decreases its air capacity. Other parts that may cause excessive turbulence are dampers, duct bends, and sudden enlargements or contractions of the duct. When investigating fan noise, seek assistance from the fan supplier or manufacturer.
9. If additional acoustical treatment is to be installed in the ductwork, obtain a frequency analysis. This involves the use of an octave-band analyzer and should generally be left to a trained engineer or acoustic analysis consultant.

Testing for Vibration

Vibration testing is necessary to ensure that (1) equipment is operating within satisfactory vibration levels and (2) objectionable

vibration and noise are not transmitted to the building structure. Although these two factors are interrelated, they are not necessarily interdependent. A different solution is required for each, and it is essential to test both the isolation and vibration levels of equipment.

General Procedure.

1. Make a visual check of all equipment for obvious errors that must be corrected immediately.
2. Make sure all isolation is free-floating and not short-circuited by obstruction between equipment or equipment base and building structure.
3. Turn on the system for an aural check of any obviously rough operation. Checking bearings with vibration measurement instrumentation is especially important because bearings can become defective in transit and/or if equipment was not properly stored, installed, or maintained. Defective bearings should be replaced immediately to avoid damage to the shaft and other components.
4. Adjust and balance equipment and systems so that final vibration tests are made on equipment as it will actually be operating.
5. Test equipment vibration.

Instruments. Although instruments are not required to test vibration isolation systems, they are essential to test equipment vibration properly.

Sound-level meters and computer-driven sound-measuring systems are the most useful instruments for measuring and evaluating vibration. Usually, they are fitted with accelerometers or vibration pickups for a full range of vibration measurement and analysis. Other instruments used for testing vibration in the field are described as follows.

Reed vibrometers are relatively inexpensive and are often used for testing vibration, but their relative inaccuracy limits their usefulness.

Vibrometers are moderately priced and measure vibration amplitude by means of a light beam projected on a graduated scale.

Vibrographs are moderately priced mechanical instruments that measure both amplitude and frequency. They provide a chart recording amplitude, frequency, and actual wave form of vibration. They can be used for simple, accurate determination of the natural frequency of shafts, components, and systems by a **bump test**.

Reed vibrometers, vibrometers, and vibrographs have largely been supplanted by electronic meters that are more accurate and have become much more affordable.

Vibration meters are moderately priced, relatively simple-to-use modern electronic instruments that measure the vibration amplitude. They provide a single broadband (summation of all frequencies) number identifying the magnitude of the vibration level. Both analog and digital readouts are common.

Vibration analyzers are relatively expensive electronic instruments that measure amplitude and frequency, usually incorporating a variable filter.

Strobe lights are often used with many of the other instruments for analyzing and balancing rotating equipment.

Stethoscopes are available as inexpensive mechanic's type (basically, a standard stethoscope with a probe attachment), relatively inexpensive models incorporating a tunable filter, and moderately priced powered types that electronically amplify sound and provide some type of meter and/or chart recording.

The choice of instruments depends on the test. Vibrometers and vibration meters can be used to measure vibration amplitude as an acceptance check. Because they cannot measure frequency, they cannot be used for analysis and primarily function as a go/no-go instrument. The best acceptance criteria consider both amplitude and frequency. Anyone seriously concerned with vibration testing should use an instrument that can determine frequency as well as amplitude, such as a vibrograph or vibration analyzer.

Vibration measurement instruments (both meters and analyzers) made specifically for measuring machinery vibration typically use **moving coil velocity transducers**, which are sizable and rugged. These are typically limited to a lower frequency of 500 cycles per minute (cpm) [8.33 Hz] with normal calibration. If measuring very-low-speed machinery such as large fans, cooling towers, or compressors operating below this limit, use an adjustment factor provided by the instrument manufacturer or use an instrument with a lower low-frequency limit, which typically uses a smaller accelerometer as the vibration pickup transducer.

Testing Vibration Isolation.

1. Ensure that equipment is **free-floating** by applying an unbalanced load, which should cause the equipment to move freely and easily. On floor-mounted equipment, check that there are no obstructions between the base or foundation and the building structure that would cause transmission while still permitting equipment to rock relatively free because of the application of an unbalanced force (Figure 13). On suspended equipment, check that hanger rods are not touching the hanger. Rigid connections such as pipes and ducts can prohibit mounts from functioning properly and from providing a transmission path. Note that the fact that the equipment is free floating does not mean that the isolators are functioning properly. For example, a 500 rpm fan on isolators with a natural frequency of 500 cpm (8.33 Hz) could be free-floating but would actually be in resonance, resulting in transmission to the building and excessive movement.
2. Determine whether isolators are adjusted properly and providing desired isolation efficiency. All isolators supporting a piece of equipment should have approximately the same deflection (i.e., they should be compressed the same under the equipment). If not, they have been improperly adjusted, installed, or selected; this should be corrected immediately. Note that isolation efficiency cannot be checked by comparing vibration amplitude on equipment to amplitude on the structure (Figure 14).

Fig. 13 Obstructed Isolation Systems

Fig. 14 Testing Isolation Efficiency

The only accurate check of isolation efficiencies is to compare vibration measurements of equipment operating with isolators to measurements of equipment operating without isolators. Because this is usually impractical, it is better to check whether the isolator's deflection is as specified and whether the specified or desired isolation efficiency is being provided. Figure 15 shows natural frequency of isolators as a function of deflection and indicates the theoretical isolation efficiencies for various frequencies at which the equipment operates.

Although it is easy to determine the deflection of spring mounts by measuring the difference between the free heights with a ruler (information as shown on submittal drawings or available from a manufacturer), these measurements are difficult with most pad or rubber mounts. Further, most pad and rubber mounts do not lend themselves to accurate determination of natural frequency as a function of deflection. For these mounts, the most practical approach is to check that there is no excessive vibration of the base and no noticeable or objectionable vibration transmission to the building structure.

If isolators are in the 90% efficiency range and there is transmission to the building structure, either the equipment is operating roughly or there is a flanking path of transmission, such as connecting piping or obstruction, under the base.

Testing Equipment Vibration. Testing equipment vibration is necessary as an acceptance check to determine whether equipment is functioning properly and to ensure that objectionable vibration and noise are not transmitted. Although a person familiar with equipment can determine when it is operating roughly, instruments are usually required to determine accurately whether vibration levels are satisfactory.

Vibration Tolerances. Vibration tolerance criteria are listed in Table 45 of Chapter 48. These criteria are based on equipment installed on vibration isolators and can be met by any reasonably smoothly running equipment. Note that values in Chapter 48 are based on root-mean-square (RMS) values; other sources often use peak-to-peak or peak values, especially for displacements. For sinusoid responses, it is simple to obtain peak from RMS values, but in application the relationship may not be so straightforward. The main advantage of RMS is that the same instrumentation can be used for both sound and vibration measurements by simply changing the transducer. Also, there is only one recognized reference level

Fig. 15 Isolator Natural Frequencies and Efficiencies

for the decibel used for sound-pressure levels, but for vibration levels there are several recognized ones but no single standard. A common mistake in interpreting vibration data is misunderstanding the reference level and whether the vibration data are RMS, peak-to-peak, or peak values. Use great care in publishing and interpreting vibration data and converting to and from linear absolute values and levels in decibels.

Procedure for Testing Equipment Vibration.

1. Determine operating speeds of equipment from nameplates, drawings, or a speed-measuring device such as a tachometer or strobe, and indicate them on the test form. For any equipment where the driving speed (motor) is different from the driven speed (fan wheel, rotor, impeller) because of belt drive or gear reducers, indicate both driving and driven speeds.
2. Determine acceptance criteria from specifications, and indicate them on the test form. If specifications do not provide criteria, use those shown in Chapter 48.
3. Ensure that the vibration isolation system is functioning properly (see the section on Testing Vibration Isolation).
4. Operate equipment and make visual and aural checks for any apparent rough operation. Any defective bearings, misalignment, or obvious rough operation should be corrected before proceeding further. If not corrected, equipment should be considered unacceptable.
5. Measure and record vibration at bearings of driving and driven components in horizontal, vertical, and, if possible, axial directions. At least one axial measurement should be made for each rotating component (fan motor, pump motor).
6. Evaluate measurements.

Evaluating Vibration Measurements.

Amplitude Measurement. When specification for acceptable equipment vibration is based on amplitude measurements only, and measurements are made with an instrument that measures only amplitude (e.g., a vibration meter or vibrometer),

- No measurement should exceed specified values or values shown in Tables 45 or 46 of Chapter 48, taking into consideration reduced values for equipment installed on inertia blocks
- No measurement should exceed values shown in Tables 45 or 46 of Chapter 48 for driving and driven speeds, taking into consideration reduced values for equipment installed on inertia blocks. For example, with a belt-driven fan operating at 800 rpm and having an 1800 rpm driving motor, amplitude measurements at fan bearings must be in accordance with values shown for 800 cpm (13.3 Hz), and measurements at motor bearings must be in accordance with values shown for 1800 cpm (30 Hz). If measurements at motor bearings exceed specified values, take measurements of the motor only with belts removed to determine whether there is feedback vibration from the fan.
- No axial vibration measurement should exceed maximum radial (vertical or horizontal) vibration at the same location.

Amplitude and Frequency Measurement. When specification for acceptable equipment vibration is based on both amplitude and frequency measurements, and measurements are made with instruments that measure both amplitude and frequency (e.g., a vibrograph or vibration analyzer),

- Amplitude measurements at driving and driven speeds should not exceed specified values or values shown in Tables 45 or 46 of Chapter 48, taking into consideration reduced values for equipment installed on inertia blocks. Measurements that exceed acceptable amounts may be evaluated as explained in the section on Vibration Analysis.
- Axial vibration measurements should not exceed maximum radial (vertical or horizontal) vibration at the same location.

- The presence of any vibration at frequencies other than driving or driven speeds is generally reason to rate operation unacceptable; this vibration should be analyzed as explained in the section on Vibration Analysis.

Vibration Analysis. The following guide covers most vibration problems that may be encountered.

Axial Vibration Exceeds Radial Vibration. When the amplitude of axial vibration (parallel with shaft) at any bearing exceeds radial vibration (perpendicular to shaft, vertical or horizontal), it usually indicates misalignment, most common on direct-driven equipment because flexible couplings accommodate parallel and angular misalignment of shafts. This misalignment can generate forces that cause axial vibration, which can cause premature bearing failure, so misalignment should be checked carefully and corrected promptly. Other possible causes of large-amplitude axial vibration are resonance, defective bearings, insufficient rigidity of bearing supports or equipment, and loose hold-down bolts.

Vibration Amplitude Exceeds Allowable Tolerance at Rotational Speed. The allowable vibration limits established by Table 46 of Chapter 48 are based on vibration caused by rotor imbalance, which results in vibration at rotational frequency. Although vibration caused by imbalance must be at the frequency at which the part is rotating, a vibration at rotational frequency does not have to be caused by imbalance. An unbalanced rotating part develops centrifugal force, which causes it to vibrate at rotational frequency. Vibration at rotational frequency can also result from other conditions such as a bent shaft, an eccentric sheave, misalignment, and resonance. If vibration amplitude exceeds allowable tolerance at rotational frequency, the following steps should be taken before performing field balancing of rotating parts:

1. Check vibration amplitude as equipment goes up to operating speed and as it coasts to a stop. Any significant peaks at or near operating speed, as shown in Figure 16, indicate probable resonance (i.e., some part having a natural frequency close to the operating speed, resulting in greatly amplified levels of vibration).

A bent shaft or eccentricity usually causes imbalance that results in significantly higher vibration amplitude at lower speeds, as shown in Figure 17, whereas vibration caused by imbalance generally increases as speed increases.

If a bent shaft or eccentricity is suspected, check the dial indicator. A bent shaft or eccentricity between bearings as shown in Figure 18A can usually be compensated for by field balancing, although some axial vibration might remain. Field balancing cannot correct vibration caused by a bent shaft on direct-connected equipment, on belt-driven equipment where the shaft is bent at the location of sheave, or if the sheave is eccentric

Fig. 16 Vibration from Resonant Condition

Table 4 Common Causes of Vibration Other than Unbalance at Rotation Frequency

Frequency	Source
0.5 × rpm	Vibration at approximately 0.5 rpm can result from improperly loaded sleeve bearings. This vibration will usually disappear suddenly as equipment coasts down from operating speed.
2 × rpm	Equipment is not tightly secured or bolted down.
2 × rpm	Misalignment of couplings or shafts usually results in vibration at twice rotational frequency and generally a relatively high axial vibration.
Many × rpm	Defective antifriction (ball, roller) bearings usually result in low-amplitude, high-frequency, erratic vibration. Because defective bearings usually produce noise rather than any significantly measurable vibration, it is best to check all bearings with a listening device.

Fig. 17 Vibration Caused by Eccentricity

Fig. 18 Bent Shafts

(Figure 18B). This is because the center-to-center distance of the sheaves fluctuates, each revolution resulting in vibration.

- For belt- or gear-driven equipment where vibration is at motor driving frequency rather than driven speed, it is best to disconnect the drive to perform tests. If the vibration amplitude of the motor operating by itself does not exceed specified or allowable values, excessive vibration (when the drive is connected) is probably a function of bent shaft, misalignment, eccentricity, resonance, or loose holddown bolts.
- Vibration caused by imbalance can be corrected in the field by firms specializing in this service or by testing personnel if they have appropriate equipment and experience.

Vibration at Other than Rotational Frequency. Vibration at frequencies other than driving and driven speeds is generally considered unacceptable. Table 4 shows some common conditions that can cause vibration at other than rotational frequency.

Resonance. If resonance is suspected, determine which part of the system is in resonance.

Isolation Mounts. The natural frequency of the most commonly used spring mounts is a function of spring deflection, as shown in Figure 19, and it is relatively easy to calculate by determining the difference between the free and operating height of the mount, as explained in the section on Testing Vibration Isolation. This technique cannot be applied to rubber, pad, or fiberglass mounts, which have a natural frequency in the 300 to 3000 cpm (5 to 50 Hz) range. Natural frequency for such mounts is determined by a bump test. Any resonance with isolators should be immediately corrected

Fig. 19 Natural Frequency of Vibration Isolators

Fig. 20 Typical Tie Rod Assembly

because it results in excessive movement of equipment and more transmission to the building structure than if equipment were attached solidly to the building (installed without isolators).

Components. Resonance can occur with any shaft, structural base, casing, and connected piping. The easiest way to determine natural frequency is to perform a bump test with a vibration spectrum analyzer. This test consists of bumping the part and measuring; the part will vibrate at its natural frequency, which will show up as a response peak on the analyzer. However, most of these instruments are restricted to frequencies above 500 cpm (8.3 Hz). They therefore cannot be used to determine natural frequencies of most isolation systems, which usually have natural frequencies lower than 500 cpm (8.3 Hz). **Checking for Vibration Transmission.** The source of vibration transmission can be checked by determining frequency with a vibration analyzer and tracing back to equipment operating at this speed. However, the easiest and usually best method (even if test equipment is being used) is to shut off components one at a time until the source of transmission is located. Most transmission problems cause disturbing noise; listening is the most practical approach to determine a noise source because the ear is usually better than instruments at distinguishing small differences and changes in character and amount of noise. Where disturbing transmission consists solely of vibration, an instrument will probably be helpful, unless vibration is significantly above the sensory level of perception. Vibration below sensory perception is generally not objectionable.

If equipment is located near the affected area, check isolation mounts and equipment vibration. If vibration is not being transmitted through the base, or if the area is remote from equipment, the probable cause is transmission through connected piping and/or ducts. Ducts can usually be isolated by isolation hangers. However, transmission through connected piping is very common and presents many problems that should be understood before attempting to correct them (see the following section).

Vibration and Noise Transmission in Piping. Vibration and noise in connected piping can be generated by either equipment (e.g., pump or compressor) or flow (velocity). Mechanical vibration from equipment can be transmitted through the walls of pipes or by a water column. Flexible pipe connectors, which provide system flexibility to permit isolators to function properly and protect equipment from stress caused by misalignment and thermal expansion, can be useful in attenuating mechanical vibration transmitted through a pipe wall. However, they rarely suppress flow vibration and noise and only slightly attenuate mechanical vibration as transmitted through a water column.

Tie rods are often used with flexible rubber hose and rubber expansion joints (Figure 20). Although they accommodate thermal movements, they hinder vibration and noise isolation. This is because pressure in the system causes the hose or joint to expand until resilient washers under tie rods are virtually rigid. To isolate noise adequately with a flexible rubber connector, tie rods and anchor piping should not be used. However, this technique generally cannot be used with pumps on spring mounts, which would still permit the hose to elongate. Flexible metal hose can be used with spring-isolated pumps because wire braid serves as tie rods; metal hose controls vibration but not noise.

Problems of transmission through connected piping are best resolved by changes in the system to reduce noise (improve flow characteristics, reduce impeller size) or by completely isolating piping from the building structure. Note, however, that it is almost impossible to isolate piping completely from the structure, because the required resiliency is inconsistent with rigidity requirements of pipe anchors and guides. Chapter 48 contains information on flexible pipe connectors and resilient pipe supports, anchors, and guides, which should help resolve any piping noise transmission problems.

CHAPTER 39

OPERATION AND MAINTENANCE MANAGEMENT

<i>Operation and Maintenance as Part of Building Life-Cycle Costs</i>	39.1
<i>Elements of Successful Programs</i>	39.2
<i>Automated Fault Detection and Diagnosis (AFDD)</i>	39.5
<i>Documentation</i>	39.7
<i>Staffing</i>	39.8
<i>Managing Changes in Buildings</i>	39.9

EFFECTIVE operation and maintenance is essential for cost-effective provision of the built environment that humankind enjoys today. To derive the greatest return on existing building stock, and to ensure future generations will continue to enjoy these benefits, the built environment must be sustainable. A significant component of the sustainable facility is the way the structure and its systems are operated and preserved for the long term. This chapter presents several strategies, methods, procedures, and techniques for operation and maintenance management programs that minimize asset failure and preserve system function to deliver their intended purpose.

Evolving building system complexity and increasing operating costs demand that equipment and systems providing thermal comfort and beneficial indoor air quality be properly maintained to achieve energy efficiency and building owners' reliability requirements. These factors clearly imply that a highly organized, systematic approach for properly and effectively functioning building assets is necessary to achieve a successful maintenance program. Maintenance management is the formal effort required to plan, design, and implement a maintenance program tailored to the specific needs of the facility.

Traditionally, considerable focus has been devoted to minimizing first costs (i.e., capital investment) of construction. However, choices made regarding operation and maintenance (O&M) can have a greater effect on costs of ownership over a facility's entire life (NIBS 1998; Yates 2001).

1. OPERATION AND MAINTENANCE AS PART OF BUILDING LIFE-CYCLE COSTS

Operation and maintenance are major contributors to the total cost of ownership over the life of a facility. It is useful to compare maintenance costs to the total costs of facility ownership. The major categories of the life-cycle cost of facility ownership include design and construction; operations and maintenance; acquisition, renewal, and disposal; and employee salaries and benefits. Figure 1 represents the major categories of facility life-cycle costs as pillars supporting a building. Within each category, examples of the typical elements that make up the foundation of the category are shown.

Several studies [e.g., Romm (1994); Yates (2001)] state that the costs of operations and maintenance exceed the costs of design and construction. For example, Yates finds that "operational resource costs account for approximately five times construction costs over the 60 year life of a building." Accurately quantifying the life-cycle cost of building components through a statistically significant sample is difficult [see, e.g., Whitestone (2012)], given the availability of data, the timeline required to collect the data, and the varying lives of buildings.

Figure 2 (NIBS 1998) categorizes life-cycle costs to include design and construction, operations and maintenance, and employee salaries and benefits. Other studies find similar values: over a 30-year period, design and construction costs account for about 2% of the life-cycle cost, whereas operations and maintenance costs are about 6% and personnel salaries are 92% (Romm 1994). Figure 3 (BOMA 2008) further defines operations and maintenance costs for a typical office building and shows that operations and maintenance costs most directly related to HVAC (i.e., maintenance and repair and utilities) make up over 50% of the operations costs for a building.

Fig. 1 Three Pillars of Typical Life-Cycle Cost with Cost Elements

Fig. 2 Life-Cycle Cost Elements: Business Costs for Nonresidential Buildings, Including Salaries and Benefits to Occupants
 (Adapted from NIBS 1998)

The preparation of this chapter is assigned to TC 7.3, Operation and Maintenance Management. Significant content on fault detection and diagnostics was provided by TC 7.5, Smart Building Systems.

Fig. 3 Operations and Maintenance Cost Elements for Typical Office Building
(Adapted from BOMA 2008)

An alternative approach comparing the cost of design and construction to the cost of operation and maintenance over the building life cycle is to consider the **current replacement value (CRV)** as a percentage of the cost of construction of the building. CRV is calculated considering the cost of maintenance and repair (M&R). M&R includes routine maintenance, repairs, replacement, and the correction of deferred deficiencies, but not operations costs (which include custodial, grounds, and utilities costs). CRV is the estimated cost to construct a replacement building containing an equal amount of space that is designed and equipped for the same use as the original building, and meets current commonly accepted construction standards and environmental and regulatory requirements (Kaiser 2009). CRV does not include costs for routine maintenance, repairs, component or equipment replacements, or the correction of deferred deficiencies. It is calculated as

$$\text{Current replacement value} = (\text{Gross building area}) \times \left(\frac{\text{Construction cost}}{\text{Unit area}} \right)$$

A study by the National Research Council (NRC 1990) suggests that a range of 2 to 4% of CRV (excluding cost of land and major associated infrastructure) is an appropriate budget allocation for annual M&R, with the higher end of the range necessary when a backlog of maintenance and repair exists. If only operations costs are of interest, use 1.55% of the CRV for budget allocation (IFMA 2009a).

For buildings built using green design principles, a 2% investment can result in an average of a 20% life-cycle cost savings (Katz 2003). Given the life-cycle cost of a facility, the operations and maintenance staff should be involved with the predesign, design, and construction phases of the facility. During each phase, life-cycle costs, occupant comfort, energy efficiency, and maintenance strategies should be considered as key factors in the decision-making process. For example, any first-cost compromises made during the construction phase must consider the long-term effects on both life-cycle cost and ability to satisfy occupant thermal comfort while maintaining indoor air quality with efficient energy use. For a detailed discussion of life-cycle costs specific to operating and maintaining buildings, see Chapter 37.

2. ELEMENTS OF SUCCESSFUL PROGRAMS

A successful O&M management program preserves the performance of building assets and enables them to be used effectively to meet owner and occupant requirements for thermal comfort, indoor air quality, and energy efficiency. Success requires

- Understanding and appreciation of the quantitative and qualitative benefits of O&M management

- A written program with clear goals and objectives that are directly tied to owner and occupant requirements
- Proper budget and resources, including people, training, and tools
- Regular evaluation of the program, including adjustments when necessary

O&M management is a team effort. It requires the participation of the building owner, occupant, facility manager, and various staff. For the team to be successful, values must be shared. When each team member recognizes and values the advantages of well-functioning building systems, each will work toward fulfilling the goals of the O&M program.

For goals and objectives to be shared, they must first be communicated through documentation. The level of detail should allow each team member to comprehend his/her individual role, responsibilities, and objectives, as well as how his/her contributions complement others. This helps ensure that everyone is working toward a common goal, and facilitates continuity when members leave or join the team. An essential aspect of the written program is that the proper functioning of building assets be specifically tied to building productivity. This makes it easier for management to make budget and resource allocation decisions that support O&M objectives.

The O&M management program should be considered a living document. Over the life of a building, performance objectives are likely to change (e.g., when building tenants change or building systems are upgraded). At regular intervals, and especially during significant changes, the O&M management program should be reevaluated to ensure that it is still aligned with and meeting building owner and occupant objectives.

Creating and Implementing an Effective O&M Program

Effective maintenance provides the required reliability and availability at the lowest cost by identifying and implementing actions that reduce the probability of failure to an acceptable level. This strategy involves identifying and implementing actions that cost-effectively reduce the probability of significant performance degradation and failure. In general, businesses preferentially invest in assets that contribute directly to their mission. However, buildings they occupy may not be considered mission critical, and investments in buildings are often a lower priority.

Appropriate levels of maintainability seldom occur by chance. They require up-front planning, setting objectives, disciplined design implementation, and feedback from prior projects. If adequate measures for cost-effective maintainability are not integrated into the design and construction phases of a project, reliability and/or uptime are likely to be adversely affected and total life-cycle costs increased significantly. It is vital to identify critical maintainability and production reliability issues and integrate solutions to them into facility project designs to achieve long-term facility owning and operating benefits.

The frequency of maintenance depends in part on system run time and type of operation in the facility. ASHRAE *Standard* 180 provides maintenance frequencies for air distribution systems, chillers, boilers, condensing units, cooling towers, dehumidification and humidification, engines, microturbines, fan coils, pumps, rooftop units, and other HVAC systems.

A maintenance plan should include an inventory of maintained assets, the program goals and objectives, and implementation procedures of the maintenance program. The maintenance plan should be written for the size, scope, age, and complexity of the specific systems and equipment serving the facility. The plan describes all required tasks, their frequency, salient condition indicators, and the parties responsible for performing the work, documentation, and program monitoring tasks. Important concepts to consider when developing a maintenance plan include the following:

Maintenance management is the planning, implementation, and review of maintenance activities. Specific levels of maintenance rigor should be established, ideally determined by cost-effectiveness, health, and safety concerns. Cost-effectiveness is the balance among system effectiveness, including maintenance levels, equipment and system availability, reliability, maintainability, performance, and life-cycle costs.

Performance objectives are stated as desired outcomes, which can be measured in terms of equipment and system deliverables such as thermal comfort, energy efficiency, and indoor air quality. Other measures of performance include uptime, mean time between failures, mean time to repair, and normalized cost data. The program should include the source of the objectives.

Condition indicators rely on descriptions of unacceptable equipment and system conditions, which can be based on physical condition and/or performance output. In general, condition indicators are measurements and observations of conditions known to lead to equipment and system failure or performance degradation. Presence of these conditions is a signal that remedial actions should be expedited to avoid failures or larger repair costs later on.

Inspection and maintenance tasks are developed to minimize the risk of equipment and system failure to achieve operating performance goals for the facility. When abnormal conditions are found, the cause must be investigated and remedied. In general, maintenance tasks comprise a series of activities such as cleaning, adjustment, service, or replacement as conditions warrant. Arguably, unacceptable conditions require more significant repair work.

Task frequency for inspection and maintenance of new equipment and systems is initially established based on the manufacturer's recommendations. Based on the rate of asset condition or performance degradation, the task frequency can be adjusted to provide cost-effective assurance that the asset is in acceptable condition. The monitoring and review elements of a maintenance program are important for keeping maintenance costs in control. For maintenance programs established for equipment and systems in service past the warranty period, task frequencies based on O&M staff experience or advice from a maintenance engineer may be used.

Documentation is a critical element of any maintenance program and includes identifying the asset's capacity, its location, the list of inspection and maintenance tasks and their frequencies, results of inspections and maintenance, and verification that inspection and maintenance tasks have been carried out. Archived results of prior conditions and maintenance are key factors in determining whether task frequencies can be adjusted.

A facility's operating plan dictates when equipment and systems can be shut down for inspection and maintenance. For systems in which continuous operation is a critical requirement, outages must be scheduled in advance or workarounds must be developed to enable maintenance to be performed. In some cases, redundant capacity may be needed to allow off-line maintenance without interrupting operation of the equipment or system. This is demonstrated through task intervals or procedures that are developed to eliminate or minimize asset downtime.

Setting Clearly Defined Maintenance Goals

Maintenance management goals are interdependent with facility operating goals and objectives. The maintenance program must account for building operating plans, procedures, and the criticality of equipment and systems. In general, the maintenance program is established to mitigate asset degradation and failure while enabling assets to deliver the required performance. In other words, maintenance goals focus on equipment performance, reliability, and uptime. These goals must consider expected funding and human capital resources, age of equipment and systems, and capital projects planned for the near term.

Clearly defined goals should be measurable to allow adequate management of the maintenance program. These goals serve to align the facility maintenance and maintenance management staff with the facility operating strategy, required resources, and acceptable levels of risk. When defining goals for any situation, it is helpful to understand the interrelationship between several terms that are related to asset performance. Common descriptors of desired operational outcomes include the following:

Availability is the amount of time that machinery or equipment is operable when needed. Often referred to as *uptime*, availability improvements lead to increased production for manufacturing and industrial companies. Availability is often confused with reliability, which is a component of availability.

Capability is the ability of a system to satisfactorily provide required service. It is the probability of meeting functional requirements when operating under a designated set of conditions. An example of capability is the ability of a heating system to meet the heating load at the winter design temperature. Capability must be verified by commissioning, recommissioning, or retrocommissioning periodically and whenever functional requirements changes are made.

Deliverability is the total amount of production delivered to users per unit of time. High deliverability is clearly supported by levels of the other concepts.

Dependability is the measure of a system's condition. Assuming the system was operative at the beginning of its service life, dependability is the probability of it operating at any given time until the end of its life. For systems that cannot be repaired during use, dependability is the probability that there will not be a failure during use. For systems that can be repaired during use, dependability is governed by how easily and quickly repairs can be made.

Durability is the average expected service life of a system or facility. Table 3 of Chapter 37 lists median years of equipment service life. Individual manufacturers quantify durability as design life, which is the average number of hours of operation before failure, extrapolated from accelerated life tests and from stressing critical components to economic destruction.

Maintainability is the ease, accuracy, safety, and economy of performing maintenance. The purpose of maintainability is to improve the effectiveness and efficiency of maintenance to maximize uptime. Maintainability is an important design consideration and contributes to availability.

For some industries, maintainability is quantitative, corresponding to the probability of performing a maintenance action or repair in a specified period of time using prescribed procedures in a specified environment. For others, maintainability is simply the ease with which maintenance actions can be performed.

Operability is the efficient conversion of labor, raw materials, and energy into product for which the value of the ratio of output to input is optimal. Maintainability and reliability contribute to availability. High levels of availability minimize the input required for a given output, thereby contributing to high levels of operability.

Reliability is the probability that a system or facility will perform its intended function for a specified period of time when used under specific conditions and environment. Issues affecting reliability include operating practices, equipment and system design, installation, and maintenance practices. Reliability contributes to availability.

Sustainability is "providing for the needs of the present without detracting from the ability to fulfill the needs of the future" (ASHRAE 2010). Sustainable maintenance management includes identifying and reducing a building's detrimental environmental impacts during its operating life. Sustainability in buildings cannot be achieved simply through sustainable design practices, but also requires sustainable operation and maintenance.

Fig. 4 General Interrelationship of Concepts

There are multiple perspectives of the interrelationship among maintainability, reliability, and availability. Maintainability and reliability are often grouped together, because they deal with essentially the same design concepts from different perspectives. Reliability analyses often serve as input to maintainability analyses. In this chapter, maintainability and reliability are considered independent concepts, both of which contribute to availability. Increased availability and operability can significantly improve profitability. Figure 4 shows these relationships: reliability and maintainability combine to yield availability, which then combines with operability to yield deliverability. Improvements in any area (all else being equal) ultimately lead to improved results or profitability, because these concepts are interrelated. For example, good reliability and availability may minimize or eliminate the need for installed spare capacity, reducing a facility's footprint and resource consumption. Good operability increases efficiency and reduces energy use. As shown, all these concepts contribute to sustaining the facility.

The facility operating plan should stem from a strategy that incorporates the preceding concepts, which can be described in measurable outcomes that support achieving the goals of the maintenance program. The effectiveness of a maintenance program can be measured by its influence on profitability. Cost-effective improvements to any of the concepts shown in Figure 4 contribute to the maintenance program's profitability and effectiveness. In addition, goals may be established to indicate how efficiently the maintenance program is implemented. Good maintenance management monitors progress toward achieving goals over time. As progress is monitored, trends are more important than the incremental values. Comparing recent with historical data on condition and performance provides valuable input for an effective maintenance program. Clearly defined maintenance goals align the maintenance program with the business strategy of the enterprise and the resulting operation systems of plant and equipment. Clear definitions help develop goals that are measurable, and therefore manageable, and contribute to improving facility performance.

Choosing the Best Combination of O&M Strategies

Operation is the processes and methods used when the building is working correctly, in contrast to maintenance, which is the processes and methods necessary to repair and replace equipment. Operation of a building includes a set of procedures and standards to keep systems and equipment operating as designed. Daily or weekly walkthroughs of mechanical rooms, roofs with mechanical equipment, and other locations with mechanical equipment should be performed to help identify equipment conditions that adversely affect equipment operation.

A **building automation system (BAS)** is an important tool to measure, benchmark, and analyze energy consumption and other operational data over the building life. To use a BAS to track whole-building, system, and equipment performance, it is important to make sure the BAS has been properly commissioned, has an appropriate number of alarms set, and has properly set-up logs to collect necessary data. For more information about benchmarking and analyzing energy use, see Chapter 36.

There are three basic maintenance strategies. In **run-to-failure maintenance**, minimal or no resources are invested in maintenance until equipment or systems break down (i.e., fail). **Preventive maintenance** is scheduled, either by run time or by the calendar. **Condition-based and predictive maintenance** uses predictions of future equipment condition to optimize maintenance actions. Other maintenance strategies include corrective, planned, and unplanned maintenance. Within each strategy, the skills and management tools required can vary from simple to complex. Maintenance programs may incorporate features of all three approaches into a single program. Many arguments can be made about the cost-effectiveness of each of these programs. Operation and maintenance costs represent a significant portion of a facility's total life-cycle cost (see Figure 2). Therefore, the cost effectiveness of maintenance management is paramount.

Run-to-Failure and Repair. Failure is the inability of a system or equipment to perform its intended function at an acceptable level. Run-to-failure is applied when the cost of maintenance or repair exceeds the cost of replacement or losses in the event of failure. Only minimum maintenance, such as cleaning or changing filters, is performed. The equipment may or may not be monitored for proper operation, depending on the consequences of failure. This is a highly reactive approach to deal with abnormal conditions. For example, a window air conditioner may be operated although it is vibrating and making noise, then be replaced rather than repaired (a failure-triggered response in which operation is fully restored).

Preventive Maintenance. Preventive maintenance classifies available resources to ensure proper operation of a system or equipment under the maintenance program. Durability, reliability, efficiency, and safety are the principal objectives. Preventive maintenance is scheduled based on run time or by the calendar.

Condition-Based and Predictive Maintenance. Condition-based maintenance uses measurements of the performance of equipment and systems to guide maintenance activities. As performance degradation or operational faults are identified through measurements, they are addressed through corrective actions or deferred for correction until future condition measurements indicate sufficient degradation to warrant maintenance action. In essence, condition-based maintenance uses condition and performance indices based on measurements to optimize maintenance intervals. Maintenance is then performed on the basis of the actual conditions monitored and the interpretation of them. By basing maintenance actions on measurements of conditions, both excessive and too-infrequent maintenance can be avoided, thereby optimizing plant reliability and maximizing maintenance personnel productivity.

The supplemental training and instrumentation required to implement condition-based and predictive maintenance have costs. These costs must be included in an evaluation of the cost effectiveness of these approaches to compare them to the current maintenance approach used in a building and other methods under consideration, such as preventive or run-to-failure and replace.

Measurements can be taken continuously or periodically (e.g., weekly, monthly). Continuous monitoring provides continual information, enabling identification of catastrophic failures (e.g., failure of a motor or compressor) as they occur. Faults and performance degradation are detected by comparing the monitored indicator of performance with expected values, based on benchmarks (e.g., manufacturer specifications, historical performance, values from models). In some cases, alarms based on measured values of conditions exceeding known threshold values (e.g., maximum acceptable temperature, tabulated values of acceptable vibration) are used to notify operations and maintenance staff that action may be warranted to correct conditions. For complex systems, it may be necessary to monitor several conditions (e.g., temperatures, vibration, load) to assess the overall system condition. Trending over a period of time, using measurements of conditions either at intervals or

continuously, can be used to track gradual deterioration, and remedial work can be performed when deterioration reaches a critical level or planned in advance based on the rate of deterioration using a predictive approach.

In the case of air filters in a variable-air-volume (VAV) system where the supply fan draws air through the filter and is controlled to a fixed static pressure, the criterion for replacing the filter is a function of the maximum differential pressure the fully loaded filter can withstand without bursting and the energy consumption of the fan as the filter loading increases. It may be more economical to change the filter before the bursting pressure is reached if the rate of loading is slow. Continuous monitoring with a building automation system rather than changing filters on a fixed time schedule makes it possible to detect rapidly accelerated dust loading (e.g., by nearby construction work), so that the system alerts building staff before filters are overloaded and could potentially burst.

In a constant-volume system, assuming the main fan draws air through the filter, the filter change criterion is a function of the maximum differential pressure the filter can withstand without bursting and the drop in flow rate that can be tolerated by the system. As the filter becomes dirty, energy consumption increases and filter efficiency decreases. A fixed time interval for filter bank changing or cleaning may not be optimum. Changing the filter based on a monitored condition optimizes filter life and minimizes labor costs.

Routine operating plant inspection conducted by the technician during regularly scheduled plant tours can be an effective condition-monitoring practice. A technician's knowledge, experience, and familiarity with the plant are valuable for plant diagnostics. Plant familiarity, however, is valuable only when based on a solid knowledge of the underlying physical principles, and is lost with frequent technician staff changes.

Many physical parameters or conditions can be measured objectively using both special equipment and conventional building automation system sensors. One such condition is vibration on rolling element bearings. Vibration data are captured by computers. Special software is used to analyze the data to determine whether shaft alignment is correct, whether there are excessively unbalanced forces in the rotating mass, the state of bearing lubrication, and/or faults with the fixed or moving bearing surfaces or rolling elements. Not only can this technique be used to diagnose faults and determine repair requirements at an early stage, but it can also be used after completing a repair to ensure that the underlying cause of fault has been removed.

Other techniques include (1) using thermal infrared images of electrical connections to determine whether mechanical joints are tight, (2) analyzing oil and grease for contamination (e.g., water in fuel oil on diesel engines), (3) analyzing electrical current to diagnose motor winding faults, (4) measuring differential pressure across filter banks and heat exchangers to determine optimum change or cleaning frequency, and (5) measuring temperature differences, such as correct control valve response, chiller operation, and air handling.

In some cases, multiple parameters are required. For example, to determine the degree of contamination of an air filter bank in a VAV system, it is necessary to measure the differential pressure across the filter and interpret it in terms of the actual flow rate through the filter. This can be done either by forcing the fan on to high speed and then measuring the differential pressure, or by combining a flow rate signal with a differential pressure signal.

With predictive maintenance, indicators of performance degradation are extrapolated into the future to predict when an unacceptable degree of degradation will be reached and repair or maintenance should be performed. The extrapolation is based on a statistically valid approach that accounts for uncertainty of future projections. The resulting projections of the time to failure (or unacceptable performance) can be used to plan maintenance in advance. Predictions

can be based on nearly any indicator of performance degradation (e.g., pressure drop across a filter) that changes gradually over time. Several techniques are frequently associated with predictive maintenance, including nondestructive testing, chemical analysis, vibration and noise monitoring, and routine visual inspection and logging.

Additional Maintenance Strategies

Corrective maintenance classifies resources (expended or reserved) for predicting and correcting conditions of impending failure. Corrective action is strictly remedial and always performed before failure occurs. An identical procedure performed in response to failure is classified as a repair. Corrective action may be taken during a shutdown caused by failure, if the action is optional and unrelated.

Planned maintenance classifies resources invested in selected functions at specified intervals. All functions and resources in this classification must be planned, budgeted, and scheduled. Planned maintenance includes preventive and corrective maintenance.

Unplanned maintenance classifies resources expended or reserved to handle interruptions in the operation or function of systems or equipment covered by the maintenance program. This classification is defined by a repair response.

3. AUTOMATED FAULT DETECTION AND DIAGNOSIS (AFDD)

An emerging set of tools known as **automated fault detection and diagnosis (AFDD)** software can keep O&M staff more informed on the condition of HVAC&R equipment and systems and assist in performing system- and building-level maintenance management. AFDD can automatically and continuously monitor system performance and detect faults as they occur, enhancing the ability of O&M staff to remain informed on the condition of equipment and systems they manage. This section describes what AFDD is, types of AFDD tools, characteristics of AFDD systems, AFDD in practice, and the benefits of detecting and diagnosing system and equipment faults. For further information about AFDD, see Chapter 62.

The primary purpose of an AFDD system is early detection of faults and diagnosis of their causes, enabling correction before additional damage to the system, loss of service, or significant energy waste and increased costs occur. AFDD interprets values and trends in measured parameters to automatically reach conclusions about the presence of faults or degree of performance degradation. This enables performance monitoring to be performed continuously for a large inventory of equipment, which is not possible manually.

In AFDD, software automatically compares measured and expected system performance and determines the causes of discrepancies (i.e., symptoms or indicators of faults, caused by the faults themselves). **Fault detection** is the process of determining whether the monitored system deviates from normal operation, and **fault diagnosis** is the process of isolating the detected fault(s) from other possible faults. These processes are based on a thorough knowledge of the physical principles underlying the operation of HVAC systems, equipment, and components. Measurements provide data on actual performance at the time they are taken, and models that capture normal operational behavior are generally used to provide values of the same variables when the system is operating properly. Models used include engineering models based on first principles, purely empirical models based on past performance, gray-box models that combine some engineering modeling with empirical data, and various statistical approaches. These methods differ primarily by the type of model used, the methods used for detecting differences between measured and expected performance, and methods used to distinguish among diagnostic outcomes. These methods are

then coded in software to automate execution on measured data as they become available.

The ability to detect unacceptable conditions in HVAC&R systems has existed for some time and has been used primarily in safety devices intended to protect expensive equipment from catastrophic failure and for alarms tied to occupant comfort. These techniques were generally based on the value of a parameter exceeding a pre-defined threshold (e.g., a maximum acceptable pressure, above which a relief valve opens or equipment shuts down). They have also been used for alarms in building automation systems to alert operators to unacceptable conditions (e.g., a chilled-water temperature that is too high). In recent years, motivations for AFDD include increasing energy efficiency, improving indoor air quality, and reducing unscheduled equipment downtime (Braun 1999). At the same time, AFDD capabilities have expanded to detecting and diagnosing faults based on many different variables.

The benefits of AFDD capabilities have been validated in part by studies that documented a wide variety of operating faults in common HVAC equipment (Breuker and Braun 1998; Breuker et al. 2000; Comstock et al. 2002; House et al. 2001a, 2003; Jacobs et al. 2003; Katipamula et al. 1999; Proctor 2004; Rossi 2004; Seem et al. 1999). Faults included economizers in packaged air conditioners and heat pumps not operating properly; low (and high) refrigerant charges; condenser and filter fouling; faulty sensors; electrical problems; chillers with faulty controls, condensers, compressors, lubrication, piping, and evaporators; and air-handling units with too little or too much outdoor-air ventilation, poor economizer control, stuck outdoor-air dampers and other problems.

Types of AFDD Tools. **Portable service tools** can evaluate the performance of packaged and unitary vapor-compression systems and guide servicing to address problems. Self-contained, micro-processor-based portable hardware is used during a service visit for data acquisition and analysis. The sensors for making measurements and evaluating system performance may be installed temporarily or permanently. Data are usually collected for a relatively short period of time (minutes) while the equipment operates at steady-state conditions.

Local controllers with embedded AFDD include fault detection and diagnostic algorithms as part of the control software code. Embedded AFDD software can access data at the controller's short sampling interval; because they perform analysis locally on controllers, embedded AFDD tools can also reduce control network traffic. Computational and memory limits, however, may place practical restrictions on the complexity of algorithms embedded in local controllers.

Central workstation AFDD tools use dedicated software to detect and diagnose HVAC system faults using data from a building automation system or dedicated sensors or sensor networks. This software usually resides on a computer that is part of a building automation system, or has access to stored data from a BAS. A key strength of workstation AFDD software is its ability to detect system-level faults arising from interactions among components.

Workstation AFDD software may require extensive effort for configuration. In particular, mapping points from the building automation system to the AFDD tool can be labor intensive and costly, depending on the number of measurement and control points used by the AFDD tool.

Web-based AFDD software may obtain data from a BAS, independent data acquisition system, or controller-embedded AFDD software. In this case, wired and/or wireless Internet connections using the Internet for data acquisition allows gathering data from many buildings and supports enterprise-wide reporting. Because AFDD processing is done by software on the web, updating of software is simplified, and all users have access to the latest version. Web-based systems are emerging for detecting and diagnosing faults in individual equipment and whole-building energy

consumption (Brambley et al. 2005). A significant challenge for web-based AFDD is Internet security, which may require additional hardware and software administration.

Characteristics of AFDD Systems. Inherent characteristics of AFDD systems can be adjusted to suit a variety of applications and users.

Sensitivity is the lowest fault severity level required to trigger the correct detection and diagnosis of a fault. This characteristic is vital for monitoring safety-critical systems. For non-safety-critical applications (which cover most HVAC equipment), the sensitivity threshold can be higher so that faults have significant performance or cost impacts before operators are alerted.

False alarm rate is the rate at which an AFDD system reports faults when they do not actually exist (i.e., when operation is normal). A high false alarm rate could result in excessive costs from unnecessary service inspections or stoppage of equipment operation.

The challenge is to establish a balance between adequate AFDD system sensitivity and minimizing false alarms. Take care to achieve the right balance, because false alarms can defeat the purpose of installing AFDD. One technique used for critical systems, installing redundant sensors, mitigates excessive false alarms while maintaining desired fault sensitivity. Redundant sensors, however, are unusual in HVAC systems because of their additional cost.

Additional characteristics that affect the performance and usability that should be considered when selecting an AFDD tool (House et al. 2001b) include

- Number of sensors and control signals used
- Amount of design data used
- Training data required
- User-selected parameters

Users should seek a balance among these considerations that is appropriate for the intended application.

AFDD in Practice. Figure 5 shows an example of an operation and maintenance process using AFDD comprising four distinct functional processes. The first two steps in this process are fault detection and, if a fault is detected, fault diagnosis. After diagnosis, the software can analyze the various consequences of the faults detected. Human operators can then evaluate the results from the automated fault impact analysis to arrive at an integrated assessment of overall fault significance (based on operational requirements for safety, availability, cost, energy use, comfort, health, environmental impacts, or effects on other performance indicators). Once fault evaluation is completed, the operators determine how to respond (e.g., by taking a corrective action). Together, these four steps can alert operations and maintenance staff to problems, help identify the root causes of problems so that they can be properly corrected, and help prioritize maintenance activities to ensure that the most important problems are attended to first. This forms the basis for condition-based maintenance.

Benefits of Detecting and Diagnosing SYSTEM and Equipment Faults

Since 1995, many studies of the effects of O&M show that maintenance intended to preserve equipment performance and condition also accrues beneficial energy and operating cost savings. Operational savings exceed the cost of AFDD and servicing, particularly when considering optimizing service task scheduling, reducing unnecessary on-site inspections, and decreasing the peaks and valleys of seasonal work (Li and Braun 2007a, 2007b, 2007c; Rossi 2004). Building owners and operators should carefully evaluate the cost and benefits of implementing and using AFDD technology in their specific situations.

Fig. 5 Generic Application of AFDD to Operation and Maintenance of Engineered Systems [Adapted from Katipamula and Brambley (2005)]

4. DOCUMENTATION

Information on the facilities, equipment, and intended operation procedures is essential for planning and performing maintenance efficiently, documenting maintenance histories, following up on maintenance performance, energy reporting, and management reporting. For these reasons, documentation is a critical element in a successful maintenance program. Prepare operation and maintenance documentation as outlined in ASHRAE *Guideline 4*.

For new construction, establish operation and maintenance documentation requirements as part of the project requirements. Deliverables should support the expected maintenance strategy, skills of the maintenance and operations staff, and anticipated resources to be committed to performing operations and maintenance. The requirements for maintenance programs developed for existing facilities are the same; however, the operations and maintenance staff may be more involved with developing the documents.

Operation and Maintenance Documents

Information should be compiled into a manual as soon as it becomes available. This information can be used to support design and construction activities, commissioning, training of operation and maintenance staff, start-up, and troubleshooting. In addition to providing the operation and maintenance manual to the construction team, set aside an appropriate number of manuals for the building owner’s staff after construction turnover. It is critical that all information required to operate and maintain the systems and equipment be compiled before project turnover to the owner’s staff and be available to the entire facilities department.

A complete operation and maintenance documentation package includes an operation and maintenance document directory, emergency information, an operating manual, maintenance manual test reports, and construction documents. These documents should be available to the entire facilities department.

The **operation and maintenance document directory** provides easy access to the various sections within the document. The O&M manual will serve the facility for the entire use life. During this time, staff turnover will occur many times. A directory that is well organized and clearly organized facilitates quick reference by new technicians and operators.

Emergency information must be directly distributed to emergency response personnel. Including emergency information in the O&M documents that are kept in a single location ensures that this critical information is immediately available when needed. Emergency information should include emergency and staff and/or agency notification procedures.

The **operating manual** should contain the following information:

- I. General information
 - A. Building function
 - B. Basis of design
 - C. Building description
 - D. Operating standards and logs
- II. Technical information
 - A. System description
 - B. Operating routines and procedures
 - C. Seasonal start-up and shutdown
 - D. Special procedures

E. Basic troubleshooting

The **maintenance operating manual** should contain the following information:

- I. Equipment data sheets specific to installed equipment
 - A. Operating and nameplate data
 - B. Warranty information
- II. Maintenance program and procedure information
 - A. Manufacturer installation, operation, and maintenance instructions
 - B. Spare parts information
 - C. Corrective and planned maintenance actions, as applicable
 - D. Schedule of actions, including frequency
 - E. Action descriptions
 - F. History
- III. **Test reports** provide a record of observed performance during start-up and commissioning. The records should be compiled throughout the service life of the facility.
- IV. Copies of **construction documents**, also called record drawings

These documents should be available to the entire facilities department.

Initial system maintenance procedures should be detailed in the maintenance manual, with individual equipment maintenance frequency detailed in manufacturers' literature that was furnished during the initial installation or developed after installation. The maintenance program should be tailored to each specific facility and system type.

Documentation Methods

There are two basic methods for collecting and archiving operation and maintenance documents: (1) a bound written document that is executed and updated by hand, and (2) an electronic, computer-based database management system. The chosen method should be congruent with facility and maintenance program complexity and scope, and with the skill level of maintenance staff. The objective is to enter, archive, update, and evaluate information on building systems and assets efficiently and effectively. Regardless of which method is used, it is important that operations and maintenance staff be provided adequate time to collect and document the required information. Otherwise, the data collected may not be of the quality or accuracy needed to support effective decision making.

A **computerized maintenance management system (CMMS)** is a database software tool to plan, schedule, and track maintenance activities; store maintenance histories and asset inventory information; communicate building operation and maintenance information; and generate reports to quantify maintenance productivity. A CMMS is used by facility managers, maintenance technicians, third-party maintenance service providers, and asset managers to track the status, asset condition, and cost of day-to-day maintenance activities. The number and type of modules used within a CMMS is specified by the facility management team, depending on the facility's needs and the management team's goals. Typical CMMS modules include work order generator and tracking, work order requests, inventory control, planned maintenance, equipment histories, maintenance contracts, and key performance indicator (KPI) reporting.

Although a CMMS is not required to manage maintenance activities, they are becoming more commonly used (Sapp 2008). When implementing a CMMS in a new or existing facility, or upgrading an existing one, the needs of the CMMS and the planning process must be carefully determined. Although using a CMMS has the potential to increase the facility management team's efficiency and serve as a historical maintenance archive, more than 50% of implementations

fail (Berger 2009). One reason for failure is inadequate data population. To overcome this challenge, especially when new buildings and major renovations are designed and constructed using building information modeling (BIM), open information exchanges can be used. A supplement in the ASHRAE Handbook Online version of this chapter provides a brief overview of what open information exchange standards are, followed by a descriptive list of current and developing open information exchange standards. Selecting the right software does not guarantee that using a CMMS will improve maintenance productivity; it is important to evaluate, document, and align facility management processes with how the CMMS will be used. When implementing or upgrading a CMMS, schedule three to six months to design new processes and develop a set of system requirements, using a participatory approach that includes all stakeholders (Berger 2009).

5. STAFFING

Determining the correct number of staff when implementing a maintenance program is a complex exercise. Multiple factors must be considered in order to have sufficient maintenance staff available to do the work. Such factors include but are not limited to skill level of maintenance staff, complexity and criticality of the equipment and systems to be maintained, the rigor of the maintenance program, source of the maintenance staff, available maintenance program funding, labor agreement provisions, business imperatives, and certification credentials required.

The number of maintenance staff working at a facility depends on how the systems and equipment are operated. For example, multiple-shift or 24/7 operations require a larger staff than a typical 5-day, 8-hour business week. The requirements of a maintenance program are a second major influence on staffing levels. The maintenance plan can be translated into expected time to perform a given task, considering both number and frequency of tasks. Staffing levels can be adjusted to account for vacation and staff sick days. Several references, such as APPA (2011), provide standard labor units for maintenance tasks to help develop the projections.

It is important for maintenance staff to be able to provide customer service for requested operations and maintenance work. This means responding to requests and complaints from building occupants. In nonmanufacturing facilities, the level of customer service provided, or the perceived level of service provided, is a key component of a successful maintenance organization.

Training

To be effective and efficient, operation and maintenance management staff must have both technical and managerial skills. Technical skills include the ability to understand how mechanical systems operate and how maintenance of mechanical equipment is performed, as well as the analytical problem-solving expertise of a physical plant engineer. Physical plant engineers require a variety of skills to effectively operate HVAC systems, implement a maintenance program, manage operations and maintenance staff, and meet requirements of the investment plan. Good physical plant engineering solutions are developed while the investment plan is being formulated, and continue throughout the life of the facility. Managerial skills include managing the facility to achieve reliability and efficiency targets to support the business enterprise. Facility management responsibilities may include development of maintenance strategies; determination of program goals and objectives; and administration of contracts with tenants, service providers, and labor unions. Even when specialized contract maintenance companies provide service, the facility manager requires these skills in order to be a smart buyer. With increased interest in sustainable, high-performance buildings, it is also suggested that staff be trained about how to retrocommission or recommission mechanical

systems. Doing so will ensure optimum comfort, efficient system operation, and minimal operation and maintenance costs. The importance of detailed commissioning documentation should be included in the training. This will help staff to effectively consider factors such as energy budgets when addressing building occupants' comfort complaints.

An effective facility manager should be able to manage and train staff, and plan and control a facility's operation and maintenance with the cooperation of senior management and all departments. The facility manager's responsibilities include administering the O&M budget and protecting the life-cycle objectives. There are eleven core competencies of facility management (IFMA 2009b), eight of which apply to operations and maintenance management:

- **Operations and maintenance:** Oversee acquisition; installation; operation; maintenance; and disposition of building systems, furniture and equipment, grounds, and exterior elements
- **Human factors:** Develop and implement practices that promote and protect health, safety, security, quality of work life, the environment, and organizational effectiveness
- **Project management:** Develop facility plans; plan and manage each phase of the project, including construction and relocations
- **Leadership and strategy:** Plan, organize, administer, manage and lead facility's functions; manage personnel assigned to each function
- **Quality:** Manage the process of assessing the quality of services and facility effectiveness; manage benchmarking process and audits
- **Communication:** Communicate plans and processes effectively
- **Technology:** Plan, direct, and manage facility management business and operational technologies, and support the organization's technological infrastructure
- **Environmental stewardship and sustainability:** Management of the built and natural environment using sustainable practices

Training should be an important part a facility management department. The use of technology in buildings continues to increase, making training for all facility teams more important than ever. Training can be done in house or by a contracted third party who provides training as a business. When developing an in-house training program or evaluating training by a third party, make sure these key components are addressed:

- **Personnel:** Who will attend the training; create a list of maintenance managers, supervisors, and trades workers
- **Course content:** Course requirements, type of training, and media required
- **Schedule:** When the training will take place and how it will be coordinated with day-to-day assignments
- **Master training plan:** A written document to record personnel, course content, and time schedule requirements

Self-Perform versus Contract Considerations

For most enterprises with large facilities, maintenance organizations are not usually part of the core business, and economics becomes an important factor in determining whether maintenance will be self performed or done by a contractor. Wage structures, available labor pool, skill level of maintenance staff, and ability to perform specialized tasks are among the characteristics evaluated and compared when making a decision. When reducing operational overhead costs is important, the lowest-cost option tends to be the most attractive. For self performance, another cost factor to consider is the cost of training for development and training for various credentials.

Owners of one or several small buildings often cannot justify the expense of employing in-house maintenance personnel. Thus, they may decide to contract out all maintenance work. In these cases, it

is important that the contract specifies that the work to be carried out is consistent with the recommendations in this chapter. In particular, it should include periodic operational checks, such as equipment operating schedules, set points, and indoor air quality.

When the owner employs in-house maintenance staff, they should carry out operational checks, in addition to responding to occupant complaints and overseeing corrective actions, as needed. In addition, they should carry out maintenance tasks within their capabilities. At minimum, changing filters, belts, and motors; lubricating bearings; and similar routine maintenance is generally expected. In many buildings, particularly larger ones or campuses, in-house maintenance staff may include specialized expertise, reducing the need to retain contractors. Whenever the operator cannot service and repair the systems or components installed, the owner should ensure that qualified contractors and technicians perform the work. When there are regulatory requirements or certification is required to perform specialized maintenance work, the owner's in-house staff must either have the certification, or the work must be contracted out to someone who has it.

A mix of the two approaches is common: routine inspection tasks are self performed, and repairs to major equipment are more likely contracted out to factory-authorized service providers. This approach can reduce expenses associated with maintaining an inventory of special tools and keeping in-house staff up to date with training for an activity that is usually performed once or twice a year.

Cost-plus service agreements, those in which the service provider is paid for all allowed expenses, plus a fee for profit, are common because they make it easy to begin work when certain required tasks are known but the entire scope is not known, because of unforeseen risks or other factors. In many cases where there are unknown risks, such as emergency repairs, many service contractors favor cost-plus to enable the work to proceed without delay due to task or scope revision. Where maintenance programs are well defined and thus conducive to firm, fixed-price contracts, alternative contracting methods can be used. These agreements may have some form of indefinite-quantity, indefinite-delivery provisions to cover unplanned maintenance or repair requirements. Recently, performance incentives such as savings sharing, extending the contract term, and award fees have been provided to contractors.

6. MANAGING CHANGES IN BUILDINGS

Renovation and Retrofit Projects

Design and Construction Coordination in Occupied Facilities. Retrofit of mechanical systems in occupied buildings requires a level of design and construction planning beyond what is normally required in new construction. Often, owners must keep the building operating during construction, which usually affects system design and phases of installation. It is often helpful to select the construction team before design completion, so that the expertise of all parties can focus on constructability and budget consequences before the design is complete.

Design for Ease of Operation and Maintenance. Operation, maintenance, and maintainability of all HVAC&R systems should be considered during building design. Any successful operation and maintenance program must include proper documentation of design intent and criteria. ASHRAE *Guideline 4* provides a methodology to properly document HVAC systems. Newly installed systems should be commissioned according to the methods and procedures in ASHRAE *Guideline 1.1* to ensure that they are functioning as designed. It is then the responsibility of management and operational staff to maintain design functionality throughout the life of the building.

For new construction or renovation, the building owner should work with the designer to clearly define facility requirements. In

addition to meeting the owner's project requirements, the designer must provide a safe and efficient facility with adequate space to inspect and repair components. The designer must reach agreement with the owner on the criticality of each system to establish issues such as access, redundancy, and component isolation requirements.

Conversion to New Technology

Building systems and equipment are based on the technology available to planners and designers at the time of preparation, construction, and installation. Maintenance, repairs, and operating schemes should be adhered to throughout the required service life of the facility or system. During the service life, new technology (e.g., high-efficiency equipment, smart technology systems, sustainability advances) may become available to increase overall efficiency and affect maintenance, repair, and replacement programs. Potential conversion from existing to new technology must be assessed in life-cycle terms. The conversion to new technology must be assessed for (1) all initial, operation, and maintenance costs; (2) the correlation between service life and the facility's remaining service life; and (3) the cost of conversion, including revenue losses from associated downtime. As facilities and systems are upgraded, facility operations and maintenance personnel must be trained to ensure that new equipment operates efficiently and effectively throughout its service life to maintain the anticipated benefits.

Document and Communicate

As a facility is planned, designed, constructed, and occupied, the documentation and information about the facility increases. To ensure minimal loss of information about a facility, information must be documented and communicated from the early stages of planning through the entire facility life. During planning and design, documentation must include detailed plans and specifications identifying all aspects of the equipment, including physical size, location, system interactions, operating set points (e.g., temperature, humidity, airflow, energy usage, relative pressure), flow diagrams, instrumentation, and sequences of operation. The equipment supplier must provide equipment meeting the specifications, and should also recommend alternatives that offer lower life-cycle costs for the owner and designer to evaluate. The installing contractor must turn over the newly installed system to the owner in an organized and comprehensive manner, including complete documentation with O&M manuals and commissioning reports (e.g., air and water balance, fume hood certification). The design and commissioning team should ensure that a comprehensive systems manual as outlined in ASHRAE *Guideline 0* is provided to the owner, along with training on equipment and systems. The design team and the contractor should also ensure that a complete and correct set of record drawings are provided showing the actual facility as built, including all changes from the initial construction drawings made during the construction process.

Technological advances now allow much of this information to be provided electronically. During facility planning and construction, software and hardware systems can create building information models (BIMs) that can become a resource for the owner throughout the facility's service life. BIMs can be linked into the CMMS, building automation, and other smart building systems to allow building owners, operating engineers, technicians, and other facility personnel immediate access to the information required to maintain, operate, and service the building systems. During the building's life cycle, as modifications and changes are made to the facility, this information must be continuously updated to ensure accurate records continue to be maintained.

Commissioning Through Turnover to Operation and Maintenance

Existing systems may need to be reconfigured and recommissioned to accommodate changes. For existing buildings, the two most common types of commissioning are retrocommissioning and ongoing commissioning. **Retrocommissioning** is the process of commissioning existing building systems that were not commissioned when originally constructed (ASHRAE *Guideline 0*). The process ensures that building systems perform interactively according to the design intent and/or to meet the owner's current operational need. Per ASHRAE *Guideline 0*, **ongoing commissioning** is the process that verifies that building systems remain optimized throughout the life of the building, essentially a perpetual form of retrocommissioning (commissioning a building that was initially commissioned during construction), with an emphasis of benchmarking historical performance compared with current operation. See Chapter 43 for additional information.

CHAPTER 40

COMPUTER APPLICATIONS

<i>Computer System Components and Technologies</i>	40.1
<i>Networking Components</i>	40.5
<i>Internet and Applications</i>	40.7
<i>HVAC Software Applications</i>	40.9
<i>Monitoring and Control</i>	40.17
<i>Wireless Communication</i>	40.19

COMPUTERS are used in a wide variety of applications in the HVAC industry. Rapid technological advances and the decreasing cost of computing power, memory, and secondary storage have changed many aspects of the HVAC industry. New HVAC design tools allow optimal solutions to be found in engineering applications. Building operations benefit from low-cost networking to achieve multivendor control system interoperability. Consulting engineers can search manufacturers' equipment and specifications interactively over the Internet. Designers can collaborate from remote locations. More powerful applications that are also easier to use are now affordable by a wider segment of the industry; many HVAC calculations, such as heating and cooling loads, can be performed easily and automatically.

Business applications and infrastructure have also positively affected the HVAC industry. Open communications standards and internetworking allow fast, efficient communications throughout company and industry circles. HVAC design, manufacture, installation, and maintenance functions benefit as businesses build computing infrastructure through corporate information services (IS) or information technology (IT). Many advances in the business community have been adopted by the HVAC industry as de facto standards.

1. COMPUTER SYSTEM COMPONENTS AND TECHNOLOGIES

Because of rapid advances in computer technology, computers offer tremendous power at very low cost. However, the total cost of ownership of a personal computer is not limited to the cost of the computer hardware. Software, network connectivity, support, and maintenance expenses quickly surpass the initial cost of hardware.

Selecting a computer platform includes a wide variety of issues, such as

- Analysis of application needs
- Corporate computer support architecture and standards
- Vendor support, including guaranteed response time
- Central processing unit (CPU) power, random-access memory (RAM), and secondary or hard disk storage capacity
- System compatibility and interoperability between vendors
- Ease of use and required training
- Data backup strategy: how will the data on the computer be restored in the event of a system failure?
- Security issues: what data will be accessible, and how will data be protected from unauthorized access?
- Network communications capability and compatibility
- Technical support live and/or online, including driver update support
- Cost/benefits comparison
- Information system infrastructure/interoperability requirements

The preparation of this chapter is assigned to TC 1.5, Computer Applications.

- Technology reliability and obsolescence
- Total cost of ownership

Virtually all brand-name personal computers now have more than enough speed for basic business applications such as word processing and spreadsheets. Personal computers differ in their ability to handle multimedia graphics and sound, which are useful in advanced software applications.

An information system comprised of computer networks depends on the ability of computers to communicate with each other in a standard architecture. Technological advances have resulted in computer systems becoming obsolete in less than five years. Therefore, it is important to plan for compatibility with future business computer requirements. Software and hardware must match the needs of the user, and be consistent with the business system architecture.

System architecture standards from organizations such as the Institute of Electrical and Electronics Engineers (IEEE), the American National Standards Institute (ANSI), and the International Organization for Standardization (ISO) have resulted in well-defined standards such as Ethernet, TCP/IP, and HTTP, further described in the section on Networking Components. The combination of popular standards has resulted in network and Internet accessibility from local computers.

1.1 COMPUTER HARDWARE

Hardware is the physical equipment (electronic parts, cables, printed circuit boards, etc.) that provides the foundation for the software to run. Hardware processing power has increased dramatically, such that the average business system provides much more capacity than the average user needs. Specialized tasks, however, often require specialized hardware.

Mainframes are large, expensive computer systems that serve the majority of large-scale business and technical needs. Mainframe computers best serve large nationwide databases, weather prediction, and scientific modeling applications. They support many users simultaneously, and are usually accessed over a network from a personal computer (PC). More powerful mainframes are called **supercomputers**.

Personal computers (PCs) are desktop computers tailored to individual user needs, and provide much more convenient access to computing resources than the traditional mainframe. PCs are used in a wide variety of information-gathering, communication, organization, computation, and scheduling roles.

PC servers allow access to files and data on a network. PC servers are a special class of computers that support large amounts of memory, fast connection speed to the network, large disk storage for access of many files, and applications designed to be usable from other computer systems. Because system reliability is critical, there are additional features such as better construction, component redundancy, and removable hard drives.

Workstations are application-specific computers serving specialized needs such as computer-aided design (CAD) and manufacturing

(CAM), product design and simulation, mapping geographic information system (GIS), or specialized graphics design. Workstations have greater processing power and graphical display capabilities than personal computers, and may also have other improvements found in PC servers.

Clusters are several computers organized to work together. Clusters of PCs can approach the computing power of a mainframe at a fraction of the cost, if efficient application software is available. Clusters of workstations can provide more computing power than even the largest mainframe. Clusters of mainframes can be extremely powerful tools.

Minicomputers are medium-sized business computer systems that serve medium to large application needs. Minicomputers have been used to economically scale applications that have grown too large for PC servers. Many small business e-commerce applications have moved to the minicomputer platform.

A **web server** is a PC server, minicomputer, or mainframe that stores and distributes web-based information; it is typically used to distribute documents and other information across the Internet.

Laptop computers are smaller, battery-powered personal computers optimized for light weight and portability. Compared to a similarly priced personal computer, laptops are generally slower and have fewer features, though they generally include most basic features found in a desktop computer. A smaller, lighter laptop computer is called a **notebook** or **netbook**.

Palmtop computers serve a specialized niche, allowing access to some of the same information available from a laptop, but in a much smaller package. Palmtops may have no keys, or very small keys that are much smaller than the standard keyboard.

Personal digital assistants (PDAs) support limited functionality of laptop computers in a notecard-sized format. A typical interface method is a stylus with a graphical touch-sensitive screen; standard functions include a calendar, address book, e-mail, and a calculator. Options include synchronizing hardware to upload address lists or e-mail to a PC, and a modem or wireless card for portable Internet access. Some models combine the functionality of a PDA with a cell phone and a digital camera.

Smartphones are mobile phones that offer advanced computing ability and connectivity. Smartphones run complete operating system software, providing a platform for application developers, and are able to run many different types of software applications, including those specific to HVAC engineering. The advantages of smartphone applications over desktop applications are that they are simple to use and can easily be deployed in the field for quick calculations.

Calculators and organizers are available usually for fixed arithmetic functions and, on the high end, programmable applications. This hardware format is typically inexpensive and portable, but software is typically proprietary. Laptops, palmtops, and PDAs have challenged the advantages of calculators and organizers.

1.2 COMPUTER SOFTWARE

Software is computer instructions or data that can be stored electronically in storage hardware, such as random access memory (RAM), or secondary storage such as hard disk drives, DVDs, or CDs.

Software is often divided into two categories:

- *Systems software* includes the operating system and utilities associated with the operating system, such as file copying.
- *Applications software* includes the programs used to do the user's work, such as word processors, spreadsheets, or databases. HVAC-specific programs belong to the applications software category.

Operating Systems

The operating system (OS) is the basic control program that allows execution and control of application software. Operating

systems (system software) also provide a common environment for applications to use shared resources such as memory, secondary storage (e.g., hard disk storage), processing time, network access, the keyboard, graphic display environments, desktops, file services, and printer services. Application software must be selected first; that decision will typically limit the hardware computer platform and OS.

Utility Software

Utility programs perform a wide variety of organizing and data-handling operations such as copying files, printing files, file management, network analysis, disk size utilities, CPU speed tests, improving security, and other related operations. Most utilities perform one or two specific functions.

Compression Software. These utilities compress and archive data files in a standard format, such as ZIP. Compression utilities allow files and file systems to be compressed, making the transfer of information and files much more efficient without any loss of content or data. These utilities are valuable when file size is important, such as transmitting files over a limited-bandwidth communication system, and for archival purposes. A typical compression ratio for text files is 3:1. E-mail attachments are often compressed.

Antivirus Software. An important software package for most computer systems is antivirus software (see the section on E-mail, Viruses, and Hoaxes). Antivirus software detects, quarantines, repairs, and eliminates files that contain viruses. A computer virus may take various forms and is commonly attached invisibly to a word-processed or e-mailed document. Antivirus software is imperative when a computer is accessing Internet-based information. Antivirus software must be updated frequently to be able to catch new viruses. Updates are often available for free after purchasing antivirus software.

Antispyware Software. Spyware is a type of program that sends information from your computer to another computer, usually with malicious intent. It may send passwords, credit card numbers, or any other information that is typed into your computer. Antispyware software will detect spyware and remove it.

Firewall Software. A firewall is a utility that controls and limits all network communications going from or to your computer. With a firewall, only programs with permission are allowed to communicate over the network. This should stop spyware and other similar malicious programs. Also, a firewall limits the communications it accepts over the network, which acts against other types of attacks. A large organization should have a firewall separating their entire network from the Internet, but it is still important to have a firewall on each PC.

Back-Up Software. The ability to recover from a massive failure such as a successful virus attack, accidental deletion of files, flood, fire, hardware (especially hard disk) failure, and other inevitable disasters is extremely important. Typically, information service (IS) computers use a rotating digital tape back-up strategy that performs massive back-ups of network resources. Individual computers may not be included in these back-ups, so regularly scheduled back-ups must be performed. A relatively inexpensive way to back up small amounts of data is to store data files and documents in a compact disk recordable (CD-R) format, which allows roughly up to 700 MB of storage at low cost. Digital versatile disks (DVDs) promise roughly 10 times the storage capacity of CD-R. Tape back-up provides an extremely low cost per megabyte stored and is useful if quick access and retrieval of individual back-up files is not an issue. Back-ups should be stored in a secure location away from the computer system. There are two basic types of back-ups: complete, in which all files are backed up, or incremental, in which only files changed since the last back-up are stored. A typical strategy is to perform a complete back-up once a week or month, and an incremental back-up every day.

Application Software

Most useful application software falls into one of these categories:

Word Processing. Word processing applications are used for tasks that range from creating simple printable documents to providing products for advanced enterprise-level electronic distribution and publishing systems. Features may include automatic text layout, spellchecking, printing, index and table of contents generation, simple graphics, and the ability to save files in a variety of formats such as rich text format (RTF), hypertext markup language (HTML), plain text, or American Standard Code for Information Interchange (ASCII). Most word processors allow the user to view the output before printing.

Specification Writing. A useful extension to word processors is application software to create specifications for the consulting engineer. Features include ensuring selectable sections for creating desired features, and consistent naming of materials, specifications, and processes or sequences.

Specification software can save time by allowing the reuse of sections from a master specification, along with previously developed specification details, sometimes with small changes. Specification tools are most useful in situations that do not require completely new specifications from project to project.

Desktop Publishing. This is a specialized class of word processors with high-end, professional text and graphics layout features. Desktop publishing systems have been extended to incorporate professional-quality graphical images, many different styles of text and fonts, and special effects such as color fading, shadowing, and artistic effects. Using inexpensive, high-quality printers, the quality of output from desktop publishing software can be remarkable. In general, the limiting factor in the use of desktop publishing software is the time and training investment to use it efficiently.

Web Publishing. Word processors are best suited for printing documents on paper; web publishing tools are designed to format information and transfer the documents to web sites. In many regards, web publishing software is similar to word processing software, allowing text, graphics, and tables to be formatted for display. Unique extensions from web software include the ability to manage links, or connections within a related collection of documents.

Web publishing software saves information in HTML, a standard format used by web browsers. Web browsers can display information in many different screen resolutions and sizes, which makes a standard layout of documents especially difficult.

Other features of web publishing software include tools to enforce consistency of web page format and style, lower resolution of pictures and graphics to reduce loading time, and preview what the final web page will look like to the end user.

Standardized Web Document Formats. Created as a result of special formatting requirements for printing and display on web pages, this software converts word processing documents to a standard format. This standard format requires the use of a web browser software extension called a "plug-in," typically offered at no charge as a viewing tool. The viewing tool allows users to see and print the document in exactly the same format. The disadvantage of standardized formats is the inability to modify the information.

Spreadsheets. Spreadsheet applications allow the user to create tables for adding and subtracting columns of numbers in one complete view. Spreadsheets contain thousands of cells into which the user may enter labels, numbers, formulas, or even programs ("macros") to execute such functions as subroutines for a specific calculation, database sorting and searching, conversions, and other calculations. Automatic recalculations allow displayed information to be evaluated quickly. Spreadsheets are useful for importing and formatting data into a graphical display, trend analysis, and/or statistical computations. Users can input different variable values into a mathematical representation of the process or system, and

evaluate the results immediately or save them as separate files of graphs for later analysis.

Databases. Database applications are designed to store, organize, and sort information in a specialized format optimized for speed and utility. Simple PC database applications are typically designed for single users, whereas database management systems (DBMSs) are designed for larger applications involving multiple-user access. DBMSs support security hierarchies, record and file locking, and mission-critical network-accessible applications such as financial and banking applications. The standard language for accessing the database information is structured query language (SQL).

Presentations. Software optimized for group presentations displays information on digital projection systems. Presentation software is able to present simple text and graphics in an attractive screen format package for seminars, demonstrations, and training. Additionally, most presentation software allows the creation of notes for the speaker to consult during the presentation, and slide handouts. Popular extensions to presentation software include sound effects and multimedia effects such as video and audio clips. Libraries of vendor and third-party graphics are available at extra charge or from the Internet.

Accounting. Accounting software for accounts receivable, accounts payable, payroll, and taxes is available for many hardware platforms. Many accounting software packages contain extra modules and applications that allow extensions for unique accounting requirements. Financial reports for projects can be easily generated from standard report packages. Large accounting systems can be integrated with databases and automatic tax-reporting functions. Individual accounts and corrections can be monitored and updated automatically. Large accounting systems also allow integration and reporting from individual employees via web browser applications.

Project Scheduling. Meeting project requirements and efficiently coordinating project resources are difficult tasks; project scheduling software helps solve these problems. Most project scheduling software can take resources (such as individual workers), length of task, percent allocation of resources, and task interdependencies, and present the information as a critical path method (CPM) chart or as a program evaluation and review technique (PERT) chart to evaluate the schedule. Many applications can perform resource leveling, resulting in an efficient allocation of resources to complete the project.

As project scheduling software is updated to include real data, the predicted completion date and the total amount of resources used (e.g., hours worked on individual tasks, material requirements) can be used as predictive record for future projects.

Management. Management software can review past and current data on inventory, accounting, purchasing, and project control, and predict future performance. As more data are accumulated, statistical analysis can predict performance with a specified level of confidence.

Much of the data required for these techniques may require access to standard industry data in industry-wide databases, financial forecasts, code standards, and demographic and other resources. In many cases, this information can be obtained on the Internet for a nominal fee.

Web Meetings. Similar to teleconferences, web meetings coordinate demonstrations and meetings over the Internet. Participants use a common web site to view and update a slide show presentation, with optional voice commentary handled either through traditional teleconferencing or through streaming audio or video feeds. Some types allow participants to view the desktop of the moderator's computer, allowing them to share a live view of any application the moderator chooses.

Graphics and Imaging. Graphics software packages readily produce images, x - y charts, graphs, pie charts, and custom graphics.

Libraries of graphics and images exist for use in word processing, presentation, desktop publishing, and web page applications. Many graphics programs can produce output in numerous popular computer graphics formats such as Joint Photographic Experts Group (JPG), graphics interchange format (GIF), tagged information file format (TIFF), bitmap (BMP), and other standards. Specialty programs allow graphics files to be converted between graphics formats. Multimedia tools allow video and sound to be combined with traditional text and graphics.

Images require large amounts of data to be represented accurately. Graphics are usually stored in either bitmap or vector format. The **bitmap** format is commonly used for picture and photo-oriented graphics, whereas **vector** formats are commonly used in CAD/CAM and architectural drawings. Although the output of bitmap images is simple on devices such as graphic printers, rescaling these images does not always produce satisfactory output. Conversions between formats give varying results. Bitmap images are frequently converted to JPG (typically for photographic images) and GIF (typically for simple drawings) file formats.

Web Browsers. Most Internet-enabled computers have web browsers that support text and graphical web page displays. The underlying language of the World Wide Web is HTML, and navigation is by clicking on links to access different computer systems and pages on the web.

Browsers are a preferred interface for accessing vastly different computer systems. Full-feature browsers also support Java® applets (small programs) and a host of extension applications that are available at nominal or no charge. These include streaming sound, streaming multimedia, and graphics formats other than GIF and JPG, which are natively supported by browsers. Some other available features include access to e-mail, file transfer protocol (FTP; for transferring files to and from servers over the Internet), chat rooms, newsgroups and forums, Telnet access to computers, and access to secure e-commerce sites that use encryption routines to protect sensitive data such as credit card information, bank account balances, and stock transfer information.

Communications Applications. Communication over the Internet has become widespread, for both business and personal use. Voice over Internet protocol (VOIP) services allow users to place phone calls over a data network, such as the Internet or a local intranet. Calls can be placed to another user on the network, or to users on the traditional telephone (land-line) network. Text messaging sends short messages (less than 160 characters), usually from a digital cell phone. Instant messaging (IM) allows interactive text-based messaging, usually from a PC to another user on a PC. It is also possible to send messages between text messaging and IM systems.

1.3 SOFTWARE AVAILABILITY

Freeware is copyrighted software that is free. The user can run the software, but must obey the copyright restrictions.

Public domain software is available to the public for little or no charge. Public domain software, which is not copyrighted, is often confused with freeware, which is copyrighted. Public domain software can be used without the restrictions associated with copyrighted software.

Shareware is software available for users to try before buying it; after the trial period, users are expected to register or stop using the application. There is usually a nominal registration fee.

Software can be **purchased** from manufacturers, distributors, representatives, discount stores, and computer specialty stores. Software price, support, return policies, and distribution vary from vendor to vendor. During installation, most software displays a detailed software license granting *use* rather than *ownership* of the software program. This license gives specific restrictions on how

the software is to be used. Most high-volume software does not offer direct support, but many software companies offer pay-per-incident and other fee arrangements if desired. Many applications have discussion groups or message boards on the Internet, where solutions to problems may be found. Most off-the-shelf, shrinkwrapped software is nonreturnable once opened.

1.4 CUSTOM PROGRAMMING

Using an existing software package is usually preferable to designing a custom application, which is much more expensive and potentially riskier, especially for large, mission-critical software such as client-server applications. If, after careful evaluation, pre-packaged software will not suffice, the choice must be made between in-house and outside development. Custom software can be (1) contracted out to a specialized firm, (2) developed solely by internal staff, or (3) developed by internal staff with consultation help by an outside firm.

Contracting to an outside firm involves hiring a specialized outside party to define, estimate, schedule, and create the software. Funds should be budgeted for the outside organization to support modifications or enhancements not specifically covered in the contract. Contracting outside is suitable for an organization that does not have the resources or expertise to accomplish the project. Disadvantages of this approach include the expense and lack of control over the program. Licensing and ownership issues must be defined in the contract.

Developing the program internally is viable only if the skills and resources are available. Internal projects are easier to control because the people involved are co-located.

Consultation help from an outside firm involves a skilled outside party assisting internal staff, who may have insufficient skill in the area on their own. Outside firms can provide expertise to get a project going quickly. Long-term support and maintenance of the software are done in-house.

Specifications are key to the success of a software project. Calculations, human interface, reports, user documents, and testing procedures should be carefully detailed and agreed on by all parties before development begins. Software testing should be specified at the beginning of the project to avoid the common problem of low quality because of hasty and inadequate testing. Design testing should address the human interface, a wide range of input values including improper input, the various functions, and output to screen, disk, or other media. Field tests should include conditions experienced by the final users of the software.

With any development approach, good, understandable documentation is required. If for any reason the software cannot be adequately supported, the program will have to be replaced at substantial cost.

1.5 SOFTWARE LANGUAGES

Application software is written in a variety of computer languages. Most commercial software today is written in C++ or C to allow fast speed and efficient use of resources.

Visual Basic® is an extremely popular and easy-to-use graphical programming language for Windows® that has proprietary extensions of the original BASIC language. High-performance software modeling tools such as finite element analysis (FEA) and graphics modeling use languages such as FORTRAN and C.

Several modern languages, such as Java® and Smalltalk, use object-oriented programming. Java is a favored programming language for applications that run over computer networks such as the Internet. C++ mixes both traditional procedural C language programming and object-oriented extension concepts. The major disadvantage of Java and C++ is the high level of programming skill required to create programs.

Java is a powerful programming language and environment with extensions to support Internet, security, and multiplatform implementation. Java applets are small, secure, self-contained programs that need a host environment, such as a web browser, to run. Many new applications use standard web browsers with applets to create useful displays and interfaces. JavaBeans are modular components that provide users with standard modular and graphical interfaces of components. Enterprise JavaBeans (EJB) are server-based programs that allow interoperability and language standardization to be scalable and interchangeable between server vendors.

Relational system databases use structured query language (SQL). Object databases are still relatively new, but fully support the object-oriented paradigm of object references, instead of the traditional relational model.

1.6 INPUT/OUTPUT (I/O) DEVICES

Basic computer peripherals (e.g., monitor, keyboard, mouse, etc.) allow interaction with the computer and are sufficient for many applications. More advanced I/O capability is available through digital cameras, scanners, bar code readers, stylus pads, voice recognition devices, and fax machines. Common devices include the following.

Printer types include laser and ink-jet. Laser printers offer a lower cost per sheet, double-sided printing, faster throughput, and large storage capacity. Ink-jet printers offer color printing and lower initial cost but have a higher operating cost.

CD and DVD drives can be used to read data from a CD or DVD. CD and DVD burners can be used to write data to a new CD or DVD, or to copy an existing one. A CD typically holds 700 MB of data, whereas a DVD holds 4.7 GB. There are two types of writeable CDs: CD-R, and CD-RW. Once data is written to a CD-R, it cannot be changed. Data written to a CD-RW can be modified or deleted, like data on a floppy disk. DVD+R and DVD-R are similar to CD-R, and DVD+RW and DVD-RW are similar to CD-RW. There is also a double-layer (DL) DVD that holds 8.5 GB. Newer types of disks can hold up to 50 GB.

External storage can be used to store files on a location other than the local computer. USB flash drives are a simple way to save files or to move files between computers. They are typically very small (1.5 to 2.75 in.), but offer less capacity than other methods (usually between 128 MB and 64 GB). External hard drives offer a wide range of capacity (typically 2 to 1000 GB), but are often larger and less convenient to move between computers. External hard drives are often used to supplement the storage located on a PC's internal hard drive, or to store a back-up of data on an internal hard drive.

Digital cameras are useful for photographs and digital storage of images. These digitized images can be transmitted electronically and viewed or incorporated into web or traditional documents. Most digital cameras can store dozens or hundreds of pictures, depending on the amount of memory they have. Some can also store up to several minutes of video. PC video cameras (web cams) allow a live image such as live conferencing to be viewed and recorded. A cell phone with a digital camera may allow users to transmit (e-mail) pictures or video from any location where there is cell phone service.

Scanners digitize printed photographs and images, and have a characteristic image quality expressed in dots per inch (dpi). The image files can be large and should preferably be stored using a compression format such as JPG. Special scanner software can also read text from a scanned document through a process called optical character recognition (OCR). The scanned text can then be viewed or edited in a word processor.

Bar code readers speed database input by converting a manual scan of a bar code to the alphanumeric input in a database field.

Stylus pads combine the navigational functionality of a mouse with the ability to enter handwritten notes and sketches and run automated scripts based on movements on the pad.

Voice recognition software automatically converts speech to typed text. These programs take some tuning to learn the accent, diction, and idioms of the user. Many voice recognition software packages also enable automated scripts or macros to run on verbal commands.

Fax software emulates a printer driver. It allows the user to print a document to a target fax machine through a modem. It also allows the user to receive faxes as electronic documents. Other features include integration with electronic contact databases, templates for transmittal pages, and automated tracking of faxes sent and received.

Convergence

Many devices serve more than one purpose. A common example is devices that combine the functions of a scanner, printer, fax machine, and copier. Many new cell phones also have cameras and MP3 players, and can also function like a USB flash drive or a modem. This trend toward multifunctionality is expected to continue.

2. NETWORKING COMPONENTS

Computers use resources that are commonly arranged into networks comprised of hardware and software components. Hardware network components include hubs, switches, routers, bridges, and repeaters.

Software network components usually take one of two forms: (1) dynamic link libraries (DLLs) to control network hardware, or (2) applications to communicate between computers according to adopted networking standards (e.g., IEEE 802.3 Ethernet).

Numerous computer network configurations exist for intra-, inter-, and extra-office data communication. Some common examples include local area networks (LANs), wide-area networks (WANs), metropolitan area networks (MANs), intranets, extranets, and the Internet.

Figure 1 is a diagram of large business system architecture with Internet connections. The system has a large number of personal computers connected via Ethernet to a central wiring closet device called a hub. This hub simplifies the wiring infrastructure by allowing centralized wiring termination for modular utility connections to individual computers. The firewall, a computer security barrier, protects against unauthorized access from the outside Internet to individual nodes inside the firewall. Users may connect to the Internet either through a corporate router or indirectly from home through an Internet service provider (ISP), which may charge a fee for the service. Higher-bandwidth connections typically cost more as speed increases.

2.1 LAN PROTOCOLS

The Ethernet protocol is the most widely used and accepted local area network (LAN) standard, and is used extensively in industry. Because of its pervasive acceptance in industry, HVAC building automation protocols such as BACnet[®] and LonWorks[®] allow their protocols to use Ethernet in their physical layer. Ethernet is a multi-access, packet-switching network where each node can request access to the network on an equal basis with any other node. Ethernet uses the collision sense, multiple access/collision detect (CSMA/CD) technique: if two nodes transmit at the same time, a collision occurs; both nodes then wait a random period of time and try again. This allows efficient allocation of bandwidth based on need.

An Ethernet LAN can use different media, such as the following:

- 10Base5, also known as Thick Net, which uses the large coaxial cable RG-11
- 10Base2, also known as Thin Net, which uses the smaller coaxial cable RG-58

Fig. 1 Example of Business System Architecture

- Fiber-optic cable
- 10Base-T (Twisted Pair), the most popular type, which has a wiring limitation length of 30 m and is typically used in centralized wiring systems. These cables typically use a RJ-45 connector.

Faster versions of Ethernet include 100Base-T or Fast Ethernet, 1000Base-T or Gigabit Ethernet, and 10GBase-T or 10-Gigabit Ethernet, which support data rates of 100 Mbps, 1000 Mbps (1 Gbps), and 10 Gbps respectively. 1000Base-T and 10GBase-T have variants that use fiber or twisted pair connections.

802.11, also known as Wi-Fi, is a wireless LAN standard created and maintained by the IEEE LAN/MAN Standards Committee (IEEE 802). The base current version is IEEE Standard 802.11-2007, and the older protocols are 802.11a, 802.11b, and 801.11g; the latest protocol is 802.11n. Instead of a cable, the computer and hub communicate using low-power radio waves.

802.16, also known as WiMAX, is a wireless protocol that can be used over a much longer distance than Wi-Fi. It may be configured to act as an element of a LAN, a WAN, or a MAN.

2.2 TRANSMISSION CONTROL PROTOCOL/INTERNET PROTOCOL

Transmission control protocol/Internet protocol (TCP/IP, RFC1122) is a set of protocols that allow computers to communicate with each other. TCP/IP is the language of the Internet, and is also used in local networks, intranets, and extranets. As communication protocols such as TCP/IP have gained acceptance, availability of components based on these protocols has increased and driven networking costs down. A complementary protocol, UDP/IP (RFC768), is often used by HVAC controllers, as well as by many streaming audio, video, and VOIP sites.

2.3 WIRELESS SERVICE

One of several immediately applicable new technologies is wireless connections for computers and equipment (e.g., to the Internet

or to a LAN). Wireless communications to remote sensors can provide a low-cost solution where the cost of running conventional wiring is prohibitive or inappropriate.

Wireless monitoring components include a wireless transmitter and a web site. The transmitter is mounted on or near the equipment being monitored. The web site determines what alerts are sent to whom, and the method of delivery (e.g., e-mail, pager, telephone). Alert messages specify the condition that triggered the alert and the location, make, model, and serial number of the equipment. Also, field service technicians can inspect service procedures, service requests, and maintenance from a remote computer at the job site to determine repair history on a piece of equipment.

Issues such as reliability, battery replacement alerts, maintenance, and reliability because of electromagnetic noise and interference should be considered when using wireless communications.

2.4 TELEPHONY STANDARDS

Regular analog phone service offers limited bandwidth and can support analog phone modems up to 56 kilobits per second (kbps). Digital phone standards include digital subscriber line (DSL), which can support bandwidth from 640 kbps to 3 Mbps but is limited to a 10,000 ft wire length from the telephone switching office. Cable modems provide high-speed access from traditional cable TV service companies. Cable networks generally have download speeds roughly between 500 kbps and 6 Mbps, but are often limited to about 768 kbps upload speed. Fiber-optic Internet connections are available in some areas, offering download bandwidth up to 50 Mbps and upload bandwidth up to 20 Mbps. As with DSL and cable modems, fiber-optic users may not have the maximum bandwidth available at all times. Note that, for most Internet users, even the slowest bandwidth available from a DSL, cable, or fiber-optic connection is sufficient. Higher bandwidth is most useful for users who frequently download music, video, or other large files. In addition to the wired connection types, wireless connection standards

with a range and bandwidth suitable to compete with DSL, cable, and fiber connections are being developed.

T1 and T3 are high-speed digital communication lines used by main communications trunks between servers, or for access to the Internet from an Internet service provider or company connection line. T1 connection speed is a maximum of 1.5 Mbps; T3 maximum speed is 44.736 Mbps. Asynchronous transfer mode (ATM) digital service provides high-speed communication at a typical maximum data rate of 155 Mbps.

2.5 FIREWALLS

Firewalls (computer security barriers), frequently used to prevent outside individuals from accessing internal, proprietary networked resources, can be designed to block certain messages from coming into or leaving the network. Firewalls may be implemented in a high-speed router, or as a separate device connected to a router. They can efficiently block all communication to or from a specific IP address. All messages that enter and leave the intranet pass through the firewall, which examines each message and halts progress of illegal communications. Firewalls are an essential part of corporate computer security systems, and are also commonly implemented as software on a PC.

3. INTERNET AND APPLICATIONS

The Internet originated in 1969 as an experimental project of the Advanced Research Project Agency (ARPA), and was called ARPANET. From its inception, the network was designed to be a decentralized, self-maintaining series of redundant links between computers and computer networks, capable of rapidly transmitting communications without direct human involvement or control, and with the automatic ability to reroute communications if one or more individual links were damaged or otherwise unavailable. Among other goals, this redundancy of linked computers was designed to allow vital research and communications to continue even if portions of the network were damaged by a war or other catastrophic event.

Messages between computers on the Internet do not necessarily travel entirely along the same path. The Internet uses packet-switching communication protocols that allow individual messages to be subdivided into smaller packets. These are then sent independently to the destination and automatically reassembled by the receiving computer. Although all packets of a given message often travel along the same path to the destination, if computers along the route become overloaded, packets can be rerouted to less loaded computers.

No single entity (academic, corporate, governmental, or non-profit) administers the Internet. It exists and functions because hundreds of thousands of separate operators of computers and computer networks independently decided to use common data transfer protocols to exchange communications and information with other computers. No centralized storage location, control point, or communications channel exists for the Internet, and no single entity can control all of the information conveyed on the Internet.

3.1 INTERNET COMMUNICATION METHODS

The most common methods of communications on the Internet (as well as within the major on-line services) can be grouped into the following categories and are described in the following sections:

- One-to-one messaging (e.g., e-mail or text messaging)
- One-to-many messaging (e.g., mailing list servers)
- Distributed message databases (e.g., USENET news groups)
- Real-time communication (e.g., Internet Relay Chat, IM, VOIP)
- Real-time remote computer use (e.g., Telnet)
- Remote information retrieval (e.g., ftp, gopher, the World Wide Web)

Most of these methods of communication can be used to transmit text, data, computer programs, sound, visual images (i.e., pictures), and moving video images.

Servers

Network servers are fast becoming an important part of building automation and computer services systems. A web page runs on a generic web server. Files available for central storage and shared resources among users of a network are referred to as a file server. FTP servers allow users outside a company to store and manage large files such as drawing and construction documents. Mail servers are central storage servers that provide e-mail services to users. Database servers provide core database functionality, and can be added to application servers to access specific application services.

E-mail

Electronic mail (e-mail) is an extremely useful communications tool for use with local area networks, wide area networks, and the Internet. Using e-mail software, a message can be sent to individuals or to groups. Unlike postal mail, simple e-mail generally is not "sealed" or secure, and can be accessed or viewed on intermediate computers between the sender and recipient unless the message is encrypted. Modern e-mail software can attach graphics, executable programs, and other types of files. These features should be used with caution because of the large network resources required to support the file transfer.

Computer Viruses, Worms, and Trojan Horses. **Computer viruses** are programs that replicate themselves and typically do damage to the host system; they are frequently received through e-mail attachments. A **worm** is a self-contained program that spreads working copies of itself to other computer systems, typically through network connections. A **Trojan horse** is a program that performs undocumented activities not desired by the program user.

Antivirus software is vital to maintaining system security. Some PC operating systems are more vulnerable to viruses and worms than others.

Some e-mail programs automatically execute script files attached to e-mail; this leaves the user open to viruses and other types of attack. As a precaution, e-mail programs that automatically execute script files should not be used, or, if no other program is available, automatic script execution should be turned off. Only attachments from reputable or trusted sources should be opened, and then only after scanning the attachment with antivirus software.

Hoaxes. A common problem associated with e-mail is the hoax or chain letter. A hoax is commonly spread as a warning about serious consequences of a new virus, offers of free money or prizes, or dubious information about a person, product, or organization. A common request from the hoax is to send it to everyone you know, in effect overloading the system with useless information. Although hoaxes and chain letters do not damage the host computer, they tax network resources, spread misinformation, and distract users from real work. Users should not pass hoaxes along, but should simply delete the message. Legitimate warnings about viruses come from IT staff or antivirus vendors. Individual hoaxes can be investigated through web sites devoted to hoaxes and virus myths (e.g., Lawrence Livermore National Laboratory 2002).

Mailing Lists

The Internet also contains automatic mailing list services (e.g., LISTSERV) that allow communication about particular subjects of interest to a group of people. Users can subscribe to a mailing list on a particular topic of interest to them. The subscriber can submit messages on the topic to the mailing list server that are forwarded, either automatically or through a human moderator overseeing the list, to the e-mail accounts of all list subscribers. A recipient can reply to the message and have the reply also distributed to everyone on

the mailing list. Most mailing lists automatically forward all incoming messages to all mailing list subscribers (i.e., they are unmoderated).

Distributed Message Databases

Distributed message databases, such as USENET newsgroups, are similar to mailing lists but differ in how communications are transmitted. User-sponsored newsgroups are among the most popular and widespread applications of Internet services, and cover all imaginable topics of interest. Like mailing lists, newsgroups are open discussions and exchanges on particular topics. Users can view the entire database of messages at any time. Some newsgroups are moderated, but most are open. One common variation of a user-generated message database is called a **wiki**.

Real-Time Communication

Internet users can also engage in an immediate dialogue, in real time, with other people on the Internet, ranging from one-to-one communications to Internet Relay Chat (IRC), which allows two or more to type messages to each other that almost immediately appear on the receivers' computer screens. IRC is analogous to a telephone party line, using a computer and keyboard rather than a telephone. With IRC, however, at any one time there are thousands of different party lines available, with collectively tens of thousands of users discussing a huge range of subjects. Moreover, a user can create a new party line to discuss a different topic at any time. Some IRC conversations are moderated or have channel operators. Commercial online services often have their own chat systems to allow their members to converse.

Real-Time Remote Computer Use

Another method to access and control remote computers in real time is using Telnet, the main Internet protocol for connecting remote computers. For example, using Telnet, a researcher can use the computing power of a supercomputer located at a different university, or a student can connect to a remote library to access the library's online catalog program.

Remote Information Retrieval

The most well-known use of the Internet is searching for and retrieving information located on remote computers. The three primary methods to locate and retrieve information on the Internet are ftp, Gopher, and HTTP (the World Wide Web).

A simple method, **file transfer protocol** (ftp) allows the user to transfer files between the local computer and a remote computer. The program and format named **Gopher** guides a search through the resources available on a remote computer.

World Wide Web. The World Wide Web (WWW) serves as the platform for a global, online store of knowledge, containing information from diverse sources and accessible to Internet users around the world. Though information on the web is contained in individual computers, the fact that each of these computers is connected to the Internet allows all of the information to become part of a single body of knowledge. It is currently the most advanced information system developed on the Internet, and encompasses most information in previous networked information systems such as ftp, Gopher, wide-area information server (WAIS) protocol (used to search indexed databases on remote servers), and USENET.

Basic Operation. The WWW is a series of documents stored in different computers all over the Internet. An essential element of the web is that each document has an address (like a telephone number).

Most organizations now have home pages on the web, which guide users through links to information about or relevant to that organization. Links may also take the user from the original web site to another web site on another computer connected to the Internet.

These links from one computer to another, from one document to another across the Internet, are what unify the web into a single body of knowledge, and what makes the web unique.

Publishing. The WWW allows people and organizations to communicate easily and quickly. Publishing information on the web requires only a computer connected to the Internet and running WWW server software. The computer can be anything from an inexpensive personal computer to several state-of-the-art computers filling a small building. Many web publishers choose instead to lease disk storage space from a company with the necessary facilities, eliminating the need to own any equipment.

Information to be published on the web must be formatted according to web standards, which ensure that all users who want to view the material will be able to do so.

Web page design can significantly affect user satisfaction. Pages with content limited to one screen tend to be easier to use than long pages that require scrolling. Large graphics files or special software requirements for viewing may discourage low-bandwidth-connection users (e.g., Internet access over regular analog phone lines) because of long waits. Maintaining and updating content is important: regular changes encourage repeat users. Web pages that give current information available nowhere else create value for users and encourage new and repeat visitors. However, care must be taken to obtain written permission for use of copyrighted material. Web sites can be open to all Internet users, or closed (an **intranet**), accessible only to those with advance authorization. Many publishers choose to keep their sites open to give their information the widest potential audience.

Searching the Web. Systems known as **search engines** allow users to search by category or by key words for particular information. The engine then searches the web and presents a list linked to sites that contain the search term(s). Users can then follow individual links, browsing through the information on each site, until the desired material is found. There are also web-based directories maintained by humans that can often give more precise results for a search in a particular area.

Search engines results can be narrowed by adding more key words: for example, a search for the word "HVAC" may end up with a list several hundred pages long, but a search for "HVAC VAV" could narrow the focus.

Common Standards. The web links disparate information on Internet-linked computers by using a common information storage format called **hypertext markup language (HTML)** and a common language for the exchange of web documents, **hypertext transfer protocol (HTTP)**. HTML documents can contain text, images, sound, animation, moving video, and links to other resources. Although the information itself may be in many different formats and stored on computers that are not otherwise compatible, these web standards provide a basic set of standards that allow communication and exchange of information.

Many specialized programs exist to create and edit HTML files. Like HTML, **extensible markup language (XML)**, is a subset of the standard generalized markup language (SGML) protocol. XML applies the same document presentation principles of HTML to data interchange beyond simply displaying the data. XML separates data content from its presentation. This allows for different visual renditions of the same message, for displays on different devices.

Supervisory Groups. No single authority controls the entire Internet, but it is guided by the Internet Society (ISOC). ISOC is a voluntary membership organization intended to promote global information exchange through the Internet. The Internet Architecture Board (IAB) defines Internet communication standards. The IAB also keeps track of information that must remain unique. For example, each computer on the Internet has a unique 32-bit address. The IAB does not actually assign the addresses, but it makes the rules about how to assign them.

Collaborative Design

The Internet is revolutionizing how project teams collaborate. Interactions such as sharing or jointly developing drawings, documents, or software can now take place efficiently with collaborators around the world.

Collaborative design raises many coordination issues. Methods of sharing data, such as distributed databases, revision and developmental accounting, and security concerns associated with the transmission of design information must be carefully considered.

3.2 SECURITY ISSUES

Computer security requires sound planning and continuous maintenance and monitoring. Mail servers can scan for viruses before users open e-mail, and individual virus software loaded on individual machines serves as a second layer of protection (see also the section on Computer Viruses, Worms, and Trojan Horses). Always save attached files to a safe directory and scan with antivirus software before using. Typically, IS and IT staff have a dedicated support person and strategy to maintain security.

A critical area for computer security is user names and passwords. Many systems require frequent changes of passwords with minimum length, number, case, and other requirements. Passwords should never be released to anyone.

4. HVAC SOFTWARE APPLICATIONS

Over the past decade, the use of computer software designing mechanical systems has increased. The advantages of software-assisted design over traditional manual methods include the following:

- Computers can better preserve design assumptions and document the design intent through consolidating and organizing resources (e.g., central databases, web sites with design documents)
- It is often faster and easier to modify assumptions used in a calculation and recalculate the results using a computer
- The computational speed of computers allows designers to tackle more difficult design problems and to use more accurate (but computationally intensive) methods
- Computers assist designers in analyzing design alternatives.

In the future, interoperable software design and application of expert systems could reduce the burden of design. Interoperable applications automatically pass design assumptions and calculation results between applications, reducing both the burden of user input and the opportunity for user error. Expert and rule-based systems could automate design standards to the point where simple system selection or distribution system sizing can be automated.

There is a wide variety of software used in the HVAC industry. This section covers applications that assist mechanical engineers in design, analysis, and specification of mechanical systems, including

- HVAC design software
- HVAC simulation software
- CAD/graphics software
- Miscellaneous utilities and applets

Much of this software is also used by HVAC equipment manufacturers to design their products, and by controls contractors to develop control systems.

In addition, sources for these applications and the fundamentals of interoperable computer applications for the HVAC&R industry are discussed.

The distinction between HVAC design and simulation is subtle. The convention used here is that design software is used for static analysis: evaluating equipment and distribution systems under a specific design condition. In contrast, HVAC simulation is used for

dynamic system analysis over a range of time or operating conditions. Many applications provide both functions through a single interface.

4.1 HVAC DESIGN CALCULATIONS

HVAC design software includes programs for the following tasks:

- HVAC heating and cooling load calculations
- Duct system sizing and analysis
- Pipe system sizing and analysis
- Acoustical analysis
- Equipment selection

Although computers are now widely used in the design process, most programs perform analysis, not design, of a specified system. That is, the engineer proposes a design and the program calculates the consequences of that design. When the engineer can define alternatives, a program may aid design by analyzing the performance of the alternatives and then selecting the best according to predetermined criteria. Thus, a program to calculate the cooling load of a building requires specifications for the building and its systems; it then simulates that building's performance under certain conditions of weather, occupancy, and scheduling. Although most piping and duct design tools can size pipe or ductwork based on predetermined criteria, most engineers still decide duct dimensions, air quantities, duct routing, and so forth and use software to analyze the performance of that design.

Some interoperable software can pass values from one design phase to be used as inputs in the next. For example, a load program may be used to determine the design air quantities at the zone and space level. Through interoperability, this information can be preserved in the building model and used as an input for the duct sizing program. Interoperable software is further described in the section on Interoperable Computer Applications for the HVAC&R Industry.

Because computer programs perform repetitive calculations rapidly, the designer can explore a wide range of alternatives and use selection criteria based on annual energy costs or life-cycle costs.

Heat and Cooling Load Design

Calculating design thermal loads in a building is a necessary step in selecting HVAC equipment for virtually any building project. To ensure that heating equipment can maintain satisfactory building temperature under all conditions, peak heating loads are usually calculated for steady-state conditions without solar or internal heat gains. This relatively simple calculation can be performed by hand or with a computer.

Peak cooling loads are more transient than heating loads. Radiative heat transfer within a space and thermal storage cause thermal loads to lag behind instantaneous heat gains and losses. This lag can be important with cooling loads, because the peak is both reduced in magnitude and delayed in time compared to the heat gains that cause it. A further complication is that loads peak in different zones at different times (e.g., the solar load in a west-facing zone will peak in the afternoon, and an east-facing zone will usually peak in the morning). To properly account for thermal lag and the noncoincidence of zone loads, a computer program is generally required to calculate cooling loads for a multiple-zone system. These programs simulate loads for each hour of the day for every day of the year (or a representative subset of the days of the year), and report peak loads at both the zone and system level, recording the date and time of their occurrence. Because the same input data are used for heating and cooling loads, these programs report peak heating loads, as well.

Various calculation methods are used to account for the transience of cooling loads; the most common methods are described in

detail in Chapters 17 and 18 of the 2013 *ASHRAE Handbook—Fundamentals*. The most accurate but computationally intensive method, the heat-balance (HB) method, is a fundamental calculation of heat transfer from all sources with the construction elements of the building (walls, floor, windows, skylights, furniture, ceiling, slab, and roof). Only the computational speed of present-day personal computers allows these calculations to be performed for large multizone buildings in a reasonable amount of time (ranging from several minutes to an hour or more). Several simplified methods or approximations of thermal lag are available to speed computation time, including the radiant time-series (RTS), transfer function (TFM), total equivalent temperature differential with time averaging (TETD/TA) and cooling load temperature differential with cooling load factors (CLTD/CLF) methods. These approximations are less accurate than the heat balance method, but can be sufficient if they are appropriately applied.

Both the TETD/TA and the TFM methods require a history of thermal gains and loads. Because histories are not initially known, they are assumed zero and the building under analysis is taken through a number of daily weather and occupancy cycles to establish a proper 24 h load profile. Thus, procedures required for the TFM and TETD/TA methods involve so many individual calculations that noncomputerized calculations are highly impractical. The CLTD/CLF method, on the other hand, is meant to be a manual calculation method and can be implemented by a spreadsheet program. The CLTD and CLF tables presented in the 2001 *ASHRAE Handbook—Fundamentals* are, in fact, based on application of the TFM to certain geometries and building constructions. An automated version of TFM is preferred to CLTD/CLF because it is more accurate. The automated TETD/TA method, however, can provide a good approximation with significantly less computation than the TFM.

Characteristics of a Loads Program. In general, a loads program requires user input for most or all of the following:

- Full building description, including the construction and other heat transfer characteristics of the walls, roof, windows, and other building elements; size; orientation; geometry of the rooms, zones, and building; and possibly also shading geometries
- Sensible and latent internal loads from lights and equipment, and their corresponding operating schedules
- Sensible and latent internal loads from people
- Indoor and outdoor design conditions
- Geographic data such as latitude and elevation
- Ventilation requirements and amount of infiltration
- Number of zones per system and number of systems

With this input, loads programs calculate both the heating and cooling loads and perform a psychrometric analysis. Output typically includes peak room and zone loads, supply air quantities, and total system (coil) loads.

Selecting a Loads Program. Beyond general characteristics, such as hardware and software requirements, type of interface (icon-based, menu-driven versus command-driven), availability of manuals and support, and cost, some program-specific characteristics should be considered when selecting a loads program. The following are among items to be considered:

- Ease of use and compatibility with the existing operating system
- Type of building to be analyzed: residential versus commercial (residential-only loads programs tend to be simpler to use than more general-purpose programs meant for commercial and industrial use, but residential-only programs generally have limited abilities)
- Method of calculation for the cooling load (note that some programs support more than one method of calculation)

- Program limits on such items as number of systems, zones, rooms, and surfaces per room
- Sophistication of modeling techniques (e.g., capability of handling exterior or interior shading devices, tilted walls, daylighting, skylights, etc.)
- Units of input and output
- Program complexity (in general, the more sophisticated and flexible programs require more input and are somewhat more difficult to use than simpler programs)
- Capability of handling the system types under investigation
- Certification of the program for energy code compliance
- Ability to share data with other programs, such as CAD and energy analysis

Duct Design

Chapter 21 of the 2013 *ASHRAE Handbook—Fundamentals* describes several methods for duct design. Major considerations in duct design include the physical space required by the duct, cost of the ductwork and fittings, energy required to move air through the duct, acoustics, minimum velocities to maintain contaminants in suspension (fume exhaust), flexibility for future growth, zoning, and constructability. Duct software can help with the layout and analysis of new and/or existing distribution systems.

Duct design is more an art than a science, which complicates automation of design. Duct design programs and calculation methods are limited in their ability to (1) calculate actual operating pressures because of the impact of fan and duct system effects, and (2) take into consideration many unmeasurable factors in the process of laying out and sizing ducts (e.g., provision for space limitations, local duct construction preferences and practices, local labor and material costs, acoustics, and accommodating future remodeling).

Selecting and Using a Program. Duct design involves routing or laying out ductwork, selecting fittings, and sizing ducts. Computer programs can rapidly analyze design alternatives and determine critical paths in long and complicated distribution systems. Furthermore, programs and printouts can preserve the assumptions used in the design: any duct calculation requires accurate estimates of pressure losses in duct sections and the definition of the interrelations of velocity heads, static pressures, total pressures, and fitting losses.

The general computer procedure is to designate nodes (the beginning and end of duct sections) by number. Details about each node (e.g., divided flow fitting and terminal) and each section of duct between nodes (maximum velocity, flow rate, length, fitting codes, size limitation, insulation, and acoustic liner) are used as input data (Figure 2).

Characteristics of a duct design program include the following:

- Calculations for supply, return, and exhaust
- Sizing by constant friction, velocity reduction, static regain, and constant velocity methods
- Analysis of existing ducts
- Inclusion of fitting codes for a variety of common fittings
- Identification of the duct run with the highest pressure loss, and tabulation of all individual losses in each run
- Printout of all input data for verification
- Provision for error messages
- Calculation and printout of airflow for each duct section
- Printout of velocity, fitting pressure loss, duct pressure loss, and total static pressure change for each duct section
- Graphics showing schematic or line diagrams indicating duct size, shape, flow rate, and air temperature
- Calculation of system heat gain/loss and correction of temperatures and flow rates, including possible system resizing
- Specification of maximum velocities, size constraints, and insulation thicknesses

Fig. 2 Example of Duct System Node Designation

- Consideration of insulated or acoustically lined duct
- Bill of materials for sheet metal, insulation, and acoustic liner
- Acoustic calculations for each section
- File-sharing with other programs, such as spreadsheets and CAD

Because many duct design programs are available, the following factors should be considered in program selection:

- Maximum number of branches that can be calculated
- Maximum number of terminals that can be calculated
- Types of fittings that can be selected
- Number of different types of fittings that can be accommodated in each branch
- Ability of the program to balance pressure losses in branches
- Ability to handle two- and three-dimensional layouts
- Ability to size a double-duct system
- Ability to handle draw-through and blow-through systems
- Ability to prepare cost estimates
- Ability to calculate fan motor power
- Provision for determining acoustical requirements at each terminal
- Ability to update the fitting library

Optimization Techniques for Duct Sizing. For an optimized duct design, fan pressure and duct cross sections are selected by minimizing the life-cycle cost, which is an objective function that includes initial and energy costs. Many constraints, including constant pressure balancing, acoustic restrictions, and size limitations, must be satisfied. Duct optimization is a mathematical problem with a nonlinear objective function and many nonlinear constraints. The solution must be taken from a set of standard diameters and standard equipment. Numerical methods for duct optimization exist, such as the T method (Tsal et al. 1988), coordinate descent (Tsal and Chechik 1968), Lagrange multipliers (Kovarik 1971; Stoecker et al. 1971), dynamic programming (Tsal and Chechik 1968), and reduced gradient (Arkin and Shitzer 1979).

Piping Design

Many computer programs are available to size or calculate the flexibility of piping systems. Sizing programs normally size piping and estimate pump requirements based on velocity and pressure drop limits. Some consider heat gain or loss from piping sections.

Fig. 3 Examples of Nodes for Piping System

Several programs produce a bill of materials or cost estimates for the piping system. Piping flexibility programs perform stress and deflection analysis. Many piping design programs can account for thermal effects in pipe sizing, as well as deflections, stresses, and moments.

Numerous programs are available to analyze refrigerant piping layouts. These programs aid in design of properly sized pipes or in troubleshooting existing systems. Some programs are generic, using the physical properties of refrigerants along with system practices to give pipe sizes that may be used. Other programs “mix and match” evaporators and condensers from a particular manufacturer and recommend pipe sizes. See Chapters 2 and 3 of the 2014 *ASHRAE Handbook—Refrigeration* for specifics on refrigerant pipe sizing.

The general technique for computerizing piping design problems is similar to that for duct design. A typical piping problem in its nodal representation is shown in Figure 3.

Useful piping programs do the following:

- Provide sufficient design information
- Perform calculations for both open and closed systems
- Calculate flow, pipe size, and pressure drop in each section
- Handle three-dimensional piping systems
- Cover a wide selection of common valves and fittings, including specialized types (e.g., solenoid and pressure-regulating valves)
- Consider different piping materials such as steel, copper, and plastic by including generalized friction factor routines
- Accommodate liquids, gases, and steam by providing property information for a multiplicity of fluids
- Calculate pump capacity and head required for liquids
- Calculate available terminal pressure for nonreturn pipes
- Calculate required expansion tank size
- Estimate heat gain or loss for each portion of the system
- Prepare a cost estimate, including costs of pipe and insulation materials and associated labor
- Print out a bill of materials
- Calculate balance valve requirements
- Perform a pipe flexibility analysis
- Perform a pipe stress analysis
- Print out a graphic display of the system
- Allow customization of specific design parameters and conditions, such as maximum and minimum velocities, maximum pressure drops, condensing temperature, superheat temperature, and subcooling temperature
- Allow piping evaluation for off-design conditions
- Provide links to other programs, such as equipment simulation programs

Limiting factors to consider in piping program selection include the following:

- Maximum number of terminals the program can accommodate
- Maximum number of circuits the program can handle
- Maximum number of nodes each circuit can have
- Maximum number of nodes the program can handle
- Compressibility effects for gases and steam
- Provision for two-phase fluids

Acoustic Calculation

Chapter 48 summarizes sound generation and attenuation in HVAC systems. Applying these data and methodology often requires a large amount of computation. All sound-generation mechanisms and transmission paths are potential candidates for analysis. Adding to the computational work load is the need to extend the analysis over, at a minimum, octave bands 1 through 8 (63 Hz through 8 kHz). A computer can save a great amount of time and difficulty in the analysis of any noise situation, but the HVAC system designer should be wary of using unfamiliar software.

Caution and critical acceptance of analytical results are necessary at all frequencies, but particularly at low frequencies. Not all manufacturers of equipment and sound control devices provide data below 125 Hz; in such cases, the HVAC designer conducting the analysis and the programmer developing the software must make experience-based assumptions for these critical low-frequency ranges.

The designer/analyst should be well satisfied if predictions are within 5 dB of field-measured results. In the low-frequency “rumble” regions, results within 10 dB are often as accurate as can be expected, particularly in areas of fan discharge. Conservative analysis and application of results is necessary, especially acoustically critical spaces.

Several easy-to-use acoustics programs are currently available, but they are often less detailed than custom programs developed by acoustic consultants for their own use. Acoustics programs are designed for comparative sound studies and allow the design of comparatively quiet systems. Acoustic analysis should address the following key areas of the HVAC system:

- Sound generation by HVAC equipment
- Sound attenuation and regeneration in duct elements
- Wall and floor sound attenuation
- Ceiling sound attenuation
- Sound breakout or break-in in ducts or casings
- Room absorption effect (relation of sound power criteria to sound pressure experienced)

Algorithm-based programs are preferred because they cover more situations (see Chapter 48); however, algorithms require assumptions. Basic algorithms, along with sound data from the acoustics laboratories of equipment manufacturers, are incorporated to various degrees in acoustics programs. The HVAC equipment sound levels in acoustics programs should come from the manufacturer and be based on measured data, because there is a wide variation in the sound generated by similar pieces of equipment. Some generic equipment sound generation data, which may be used as a last resort in the absence of specific measured data, are found in Chapter 48. Whenever possible, equipment sound power data by octave band (including 32 Hz and 63 Hz) should be obtained for the path under study. A good sound prediction program relates all performance data.

Many more specialized acoustics programs are also available. Various manufacturers provide equipment selection programs that not only select optimum equipment for a specific application, but also provide associated sound power data by octave bands. Data from these programs should be incorporated in the general acoustic

analysis. For example, duct design programs may contain sound predictions for discharge airborne sound based on the discharge sound power of fans, noise generation/attenuation of duct fittings, attenuation and end reflections of VAV terminals, attenuation of ceiling tile, and room effect. VAV terminal selection programs generally contain subprograms that estimate the space NC level near the VAV unit in the occupied space. However, projected space NC levels alone may not be acceptable substitutes for octave-band data. The designer/analyst should be aware of assumptions, such as room effect, made by the manufacturer in presenting acoustical data.

Predictive acoustic software allows the designer to examine HVAC-generated sound in a realistic, affordable time frame. HVAC-oriented acoustic consultants generally assist designers by providing cost-effective sound control ideas for sound-critical applications. A well-executed analysis of the various components and sound paths enables the designer to assess the relative importance of each and to direct corrective measures, where necessary, to the most critical areas. However, computer-generated results should supplement the designer’s skills, not replace them.

Equipment Selection and Simulation

Equipment-related computer applications include programs for equipment selection, equipment optimization, and equipment simulation.

Equipment selection programs are basically computerized catalogs. The program locates an existing equipment model that satisfies the entered criteria. The output is a model number, performance data, and sometimes alternative selections.

Equipment optimization programs display all possible equipment alternatives and let the user establish ranges of performance data or first cost to narrow the selection. The user continues to narrow performance ranges until the best selection is found. The performance data used to optimize selections vary by product family.

Equipment simulation programs calculate the full- and part-load performance of specific equipment over time, generally one year. The calculated performance is matched against an equipment load profile to determine energy requirements. Utility rate structures and related economic data are then used to project equipment operating cost, life-cycle cost, and comparative payback. Before accepting output from an equipment simulation program, the user must understand the assumptions made, especially concerning load profile and weather.

Some advantages of equipment programs include the following:

- High speed and accuracy of the selection procedure
- Pertinent data presented in an orderly fashion
- More consistent selections than with manual procedures
- More extensive selection capability
- Multiple or alternative solutions
- Small changes in specifications or operating parameters easily and quickly evaluated
- Data-sharing with other programs, such as spreadsheets and CAD

Simulation programs have the advantages of (1) projecting part-load performance quickly and accurately, (2) establishing minimum part-load performance, and (3) projecting operating costs and offering payback-associated higher-performance product options.

There are programs for nearly every type of HVAC equipment, and industry standards apply to the selection of many types. The more common programs and their optimization parameters include the following:

Air distribution units	Pressure drop, first cost, sound, throw
Air-handling units, rooftop units	Power, first cost, sound, filtration, footprint, heating and cooling capacity
Boilers	First cost, efficiency, stack losses

Cooling towers	First cost, design capacity, power, flow rate, air temperatures
Chillers	Power input, condenser head, evaporator head, capacity, first cost, compressor size, evaporator size, condenser size
Coils	Capacity, first cost, fluid pressure drop, air pressure drop, rows, fin spacing
Fan-coils	Capacity, first cost, sound, power
Fans	Volume flow, power, sound, first cost, minimum volume flow
Heat recovery equipment	Capacity, first cost, air pressure drop, water pressure drop (if used), effectiveness
Pumps	Capacity, head, impeller size, first cost, power
Air terminal units (variable- and constant-volume flow)	Volume flow rate, air pressure drop, sound, first cost

Some extensive selection programs have evolved. For example, coil selection programs can select steam, hot-water, chilled-water, and refrigerant (direct-expansion) coils. Generally, they select coils according to procedures in AHRI *Standards* 410 and 430.

Chiller and refrigeration equipment selection programs can choose optimal equipment based on factors such as lowest first cost, highest efficiency, best load factor, and best life-cycle performance. In addition, some manufacturers offer modular equipment for customization of their product. This type of equipment is ideal for computerized selection.

However, equipment selection programs have limitations. The logic of most manufacturers' programs is proprietary and not available to the user. All programs incorporate built-in approximations or assumptions, some of which may not be known to the user. Equipment selection programs should be qualified before use.

4.2 HVAC SIMULATION

Energy Simulation

Unlike peak load calculation programs, building energy simulation programs integrate loads over time (usually a year), consider the systems serving the loads, and calculate the energy required by the equipment to support the system. Most energy programs simulate the performance of already designed systems, although programs are now available that make selections formerly left to the designer, such as equipment sizes, system air volume, and fan power. Energy programs are necessary for making decisions about building energy use and, along with life-cycle costing routines, quantify the effect of proposed energy conservation measures during the design phase. In new building design, energy programs help determine the appropriate type and size of building systems and components; they can also be used to explore the effects of design trade-offs and evaluate the benefits of innovative control strategies and the efficiency of new equipment.

Energy programs that track building energy use accurately can help determine whether a building is operating efficiently or wastefully. They have also been used to allocate costs from a central heating/cooling plant among customers of the plant. However, such programs must be adequately calibrated to measured data from the building under consideration.

Characteristics of Building Energy Simulation. Most programs simulate a wide range of buildings, mechanical equipment, and control options. However, computational results differ substantially across programs. For example, the shading effect from overhangs, side projections, and adjacent buildings frequently affects a building's energy consumption; however, the diverse approaches to load calculation result in a wide range of answers.

The choice of weather data also influences the load calculation. Depending on the requirements of each program, various weather data are used:

- Typical hourly data for one year only, from averaged weather data
- Typical hourly data for one year, as well as design conditions for typical design days
- Reduced data, commonly a typical day or days per month for the year
- Typical reduced data, nonserial or bin format
- Actual hourly data, recorded on site or nearby, for analysis where the simulation is being compared to actual utility billing data or measured hourly data

Simulation programs differ significantly in the methods they use to simulate the mass effects of buildings, ground, and furniture. How accurate these methods are and how well they delay peak heating and cooling can lead to significant uncertainty in predicting building heating and cooling needs, sizing equipment to meet those loads, and predicting system energy needs.

Both air-side and energy conversion simulations are required to handle the wide variations among central heating, ventilation, and air-conditioning systems. To properly estimate energy use, simulations must be performed for each combination of system design, operating scheme, and control sequence.

Simulation Techniques. Two methods are used in computer simulation of energy systems: the fixed schematic technique and the component relation technique.

The **fixed-schematic-with-options technique**, the first and most prevalent method, involves writing a calculation procedure that defines a given set of systems. The schematic is then fixed, with the user's options usually limited to equipment performance characteristics, fuel types, and the choice of certain components.

The **component relation technique** is organized around components rather than systems. Each component is described mathematically and placed in a library. User input includes the definition of the schematic, as well as equipment characteristics and capacities. Once all components have been identified and a mathematical model for each has been formulated, they may be connected and information may be transferred between them. Although its generality leads to certain inefficiencies, the component relation technique does offer versatility in defining system configurations.

Selecting an Energy Program. In selecting an energy analysis program, factors such as cost, availability, ease of use, technical support, and accuracy are important. However, the fundamental consideration is whether the program will do what is required of it. It should be sensitive to the parameters of concern, and its output should include necessary data. For other considerations, see Chapter 19 of the 2013 *ASHRAE Handbook—Fundamentals*.

Time can be saved if the initial input file for an energy program can also be used for load calculations. Some programs interface directly with computer-aided design (CAD) files, greatly reducing the time needed to create an energy program input file.

Comparisons of Energy Programs. Because energy analysis programs use different calculation methods, results vary significantly. Many comparisons, verifications, and validations of simulation programs have been made and reported (see the Bibliography). Conclusions from these reports can be summarized as follows:

- Results obtained by using several programs on the same building range from good agreement to no agreement at all. The degree of agreement depends on interpretations by the user and the ability of the programs to model the building.
- Several people using several programs on the same building will probably not agree on the results of an energy analysis.
- The same person using different programs on the same building may or may not find good agreement, depending on the complexity

of the building and its systems and on the ability of the programs to model specific conditions in that building.

- *Forward* computer simulation programs, which calculate the performance of a building given a set of descriptive inputs, weather conditions, and occupancy conditions, are best suited for design.
- Calibrating hourly forward computer simulation programs is possible, but can require considerable effort for a moderately complex commercial office building. Details on scheduled use, equipment set points, and even certain on-site measurements may be necessary for a closely calibrated model. Special-purpose graphic plots are useful in calibrating a simulation program with data from monthly, daily, or hourly measurements.
- *Inverse, empirical, or system parameter identification* models may also be useful in determining the characteristics of building energy usage. Such models can determine relevant building parameters from a given set of actual performance data. This is the inverse of the traditional building modeling approach, hence the name.

Energy Programs to Model Existing Buildings. Computer energy analysis of existing buildings can accommodate complex situations; evaluate the energy effects of many alternatives, such as changes in control settings, occupancy, and equipment performance; and predict relative magnitudes of energy use. There are many programs available, varying widely in cost, degree of complexity, and ease of use.

A general input-data acquisition procedure should be followed in computer energy analysis of existing buildings. First, **energy consumption data** must be obtained for a one- to two-year period. For electricity, these data usually consist of metered electrical energy consumption and demand on at least a month-by-month basis. For natural gas, the data are in a similar form and are almost always on a monthly basis. For both electricity and natural gas, it is helpful to record the dates when the meters were read; these dates are important in weather normalization for determining average billing period temperatures. For other types of fuel, such as oil and coal, the only data available may be delivery amounts and dates.

Unless fuel use is metered or measured daily or monthly, consumption for any specific period shorter than one season or year is difficult to determine. Data should be converted to per-day usage or adjusted to account for differences in length of metering periods. The data tell how much energy went into the building on a gross basis. Unless extensive submetering is used, it is nearly impossible to determine when, how, and for what that energy was used. It may be necessary to install such meters to determine energy use.

The **thermal and electricity usage characteristics** of a building and its energy-consuming systems as a time-varying function of ambient conditions and occupancy must also be determined. Most computer programs can use as much detailed information about the building and its mechanical and electrical system as is available. Where the energy implications of these details are significant, it is worth the effort of obtaining them. Testing fan systems for air quantities, pressures, control set points, and actions can provide valuable information on deviations from design conditions. Test information on pumps can also be useful.

Data on **building occupancy** are among the most difficult to obtain. Because most energy analysis programs simulate the building on an hourly basis for a one-year period, it is necessary to know how the building is used for each of those hours. Frequent observation of the building during days, nights, and weekends shows which energy-consuming systems are being used and to what degree. Measured, submetered hourly data for at least one week are needed to begin to understand weekday/weekend schedule-dependent loads.

Weather data, usually one year of hour-by-hour weather data, are necessary for simulation (see Chapter 14 of the 2013 *ASHRAE*

Handbook—Fundamentals). The actual weather data for the year in which energy consumption data were recorded significantly improves simulation of an existing building. Where the energy-consuming nature of the building is related more to internal than to external loads, selection of weather data is less important; however, for residential buildings or buildings with large outdoor air loads, the selection of weather data can significantly affect results. The purpose of the simulation should also be considered when choosing weather data: either specific-year data, data representative of long-term averages, or data showing temperature extremes may be needed, depending on the goal of the simulation.

Usually, the results of the first computer runs do not agree with actual metered energy consumption data. The following are possible reasons for this discrepancy:

- Insufficient understanding of energy-consuming systems that create the greatest use
- Inaccurate information on occupancy and time of building use
- Inappropriate design information on air quantities, set points, and control sequences

The input building description must be adjusted and trial runs continued until the results approximate actual energy use. Matching the metered energy consumption precisely is difficult; in any month, results within 10% are considered adequate.

The following techniques for calibrating a simulation program to measured data from a building should be considered:

- Matching submetered loads or 24 h day profiles of simulated whole-building electric loads to measured data
- Matching x - y scatter plots of simulated daily whole-building thermal loads versus average daily temperature to measured data
- Matching simulated monthly energy use and demand profiles to utility billing data

Having a simulation of the building as it is being used permits subsequent computer runs to evaluate the energy effects of various alternatives or modifications. The evaluation may be accomplished simply by changing the input parameters and running the program again. The effect of various alternatives may then be compared and an appropriate one selected.

Computational Fluid Dynamics

Computational fluid dynamics (CFD) is a technique for simulation, study, analysis, and prediction of fluid flow and heat transfer in well-defined, bounded spaces. It is based on equations (Navier-Stokes, thermal energy, and species equations, with the appropriate equation of state) that govern the physical behavior of a flow/thermal system, under the premise that mass, momentum, thermal energy, and species concentration are conserved locally and globally within the model.

Usually these equations are in the form of nonlinear partial differential equations relating velocities, pressure, temperature, and some scalar variables to space directions and time. Initial and boundary conditions are specified for each domain, and numerical methods such as finite difference, finite volume, or finite element analysis are utilized to solve these equations. The domain (typically space) is divided (discretized) into cells or elements, the nodal points are defined, then equations are solved for each discrete cell. After solving these equations, the dependent variables (velocities, pressure, temperature, and scalar) are made available at the nodes.

CFD analysis can be applied to a variety of tasks, including location of airflow inlets/outlets in a space, velocities required for system performance, flow pattern determination, temperature distribution in space, and smoke movement and build-up in a space with fire.

4.3 HVAC GRAPHICS, CAD, AND BUILDING DATA MODELS

Computer-Aided Design

Computer graphics of buildings and their systems help coordinate interdisciplinary designs and simplify modifications. CAD (referring to computer-aided drafting at times and to computer-aided design at other times) is a subset of CADD (computer-aided design and drafting). CADD encompasses the creation of **building data models** and the storing and use of attributes of graphic elements, such as automated area takeoff or the storage of design characteristics in a database. Drafting, or the creation of construction documents, is quickly becoming a mere by-product of the design process. The distinction between engineering and drafting in engineering firms is decreasing as design and production work become unified. In this section, CADD refers to all aspects of design.

Building data models express not only true dimensions, but also how different elements are connected and where they are located. Some “intelligent” models can even calculate how different components interact with each other, and how all the components act as a system. It is easy to extract lengths, areas, and volumes, as well as the orientation and connectedness (topology) of building parts from computerized drawings of buildings. Drawings can be changed easily and, in most cases, do not require redrawing construction documents. Building walls or ductwork, for example, can be added, removed, enlarged, reduced, and relocated. The user can rotate an entire building on the site plan without redrawing the building or destroying the previous drawing. Section and elevation views can also be specified and drawn almost instantly, as can fabrication drawings. Building data models can also be exported using standard formats and then imported to other programs, such as those for calculating heating and cooling loads, duct sizing, or operating sheet metal plasma cutting machines.

CAD systems automate (1) material and cost estimating, (2) design and analysis of HVAC systems, (3) visualization and interference checking, and even (4) manufacturing of HVAC components such as ductwork. These systems are now customized to HVAC applications; for instance, double- and single-line duct layout can be re-represented with a single command and automatically generate three-dimensional (3D) building data models.

Computer-generated drawings of building parts can be linked to nongraphic characteristics, which can be extracted for reports, schedules, and specifications. For instance, an architectural designer can draw wall partitions and windows, and then have the computer automatically tabulate the number and size of windows, the areas and lengths of walls, and the areas and volumes of rooms and zones. Similarly, the building data model can store information for later use in reports, schedules, design procedures, or drawing notes. For example, the airflow, voltage, weight, manufacturer, model number, cost, and other data about a fan displayed on a drawing can be stored and associated with the fan in the data model. The link between the graphics and attributes makes it possible to review the characteristics of any item or to generate schedules of items in a certain area on a drawing. Conversely, the graphics-to-data links allow the designer to enhance graphic items having a particular characteristic by searching for that characteristic in the data files and then making the associated graphics brighter, flashing, bolder, or different-colored in the display.

Computer-generated data models can also help the designer visualize the building and its systems and check for interferences, such as structure and ductwork occupying the same space. Some software packages now perform automatic interference checking. Layering features also help an HVAC designer coordinate designs with other disciplines. Mistakes in design can be corrected even before the drawings are plotted to eliminate costly field rework or, worse, at-fault litigation. For complex projects, interference software applications

are available that assist in managing interferences throughout the building data model.

HVAC system models and associated data can be used by building owners and maintenance personnel for ongoing facilities management, strategic planning, and maintenance. For instance, an air-handling unit can be associated with a preventative maintenance schedule in a separate facility management application. Models are useful for computer-aided manufacturing such as duct construction. The 3D building data model can also aid in developing sections and details for building drawings. CAD programs can also automate cross-referencing of drawings, drawing notations, and building documents.

In addition to the concept of the single-building data model, the Internet has greatly influenced engineering workflows. As bandwidth continues to widen, the speed of the Internet has allowed engineering firms to expand their clients, partners, and services worldwide. Software applications are available that allow users to design projects and share building model data globally over the Internet, and can be used for simple viewing and redlining as well. Project managers can view all aspects of the design process live and redline drawings simply by using a web browser.

Computer Graphics and Modeling

Computer graphics programs may be used to create and manipulate pictorial information. Information can be assimilated more easily when presented as graphical displays, diagrams, and models. Historically, building scale models has improved the design engineer’s understanding and analysis of early prototype designs. The psychometric chart has also been invaluable to HVAC engineers for many years.

Combining alphanumeric (text) with computer graphics lets the design engineer quickly evaluate design alternatives. Computers can simulate design problems with three-dimensional color images that can predict the performance of mechanical systems before they are constructed. Simulation graphics software is also used to evaluate design conditions that cannot ordinarily be tested with scale models because of high costs or time constraints. Product manufacturability and economic feasibility may thus be determined without constructing a working prototype. Whereas historically only a few dozen scale-model tests could be performed before full-scale manufacturing, combined computer and scale-model testing allows hundreds or thousands of tests to be performed, improving reliability in product design. Graphic modeling and simulation of complex fluid flow fields are also used to simulate airflow fields in unidirectional cleanrooms, and may eventually make cleanroom mock-ups obsolete (Busnaina et al. 1988). Computer models of particle trajectories, transport mechanisms, and contamination propagation are also commercially available (Busnaina 1987).

Integrated CADD and expert systems can help the building designer and planner with construction design drawings and with construction simulation for planning and scheduling complex building construction scenarios (Potter 1987).

Architects use software that creates a 3D model of the building. **Building information modeling (BIM)** is a building design and documentation methodology that relies on the creation and collection of interrelated computable information about a building project so that reliable, coordinated, and internally consistent digital representations of the building are available for design decision making, production of high-quality construction documents, construction planning, and predicting performance in various ways.

BIM is about (1) integrating design and construction processes, (2) making them interoperable, and (3) the software tools needed to achieve that. ASHRAE’s (2009) *Introduction to Building Information Modeling (BIM)* is intended to serve as a starting point for members considering adopting BIM tools and applications as part of their business practices. It explores the benefits, costs, risks and

rewards associated with BIM, interoperability, and integration. In addition, for those already applying BIM and BIM-related technologies, it may provide ideas to help them unearth new opportunities and expand their services into new markets.

Engineers using BIM today are working with software where objects carry information that describes their individual characteristics as well as how they interact with other objects to create a system. Systems created with these “intelligent” objects allow creation of drawings that are a virtual representation of building systems exactly as they would be installed during construction. Because these systems then inherit the intelligence of the objects that compose them, powerful modification capabilities allow these systems to propagate design changes throughout the system. As required systems are created, a full 3D systems model is assembled that accurately represents what is to be constructed in the field. It is this 3D systems model that enables quick and accurate generation of construction documents. The 3D model can simply be presented from various orientations to create the necessary views and plans rather than needing to reproduce a representation from a separate perspective. Section and elevation views can be generated instantly through a few simple steps to identify the view required to section and the plane that cuts through the design to create these views directly from the systems model. As a design evolves and design changes are made, these views can be updated automatically. By taking advantage of the design model, tools such as automated collision detection can quickly identify conflicts in designs in both 2D and 3D before construction begins. Schedules can be produced that are directly linked to the design and, as additions or changes are made, these are automatically updated. Schedules can also include formulas to calculate values; therefore, even detailed design information, such as heating or electrical load requirements, can be captured in the schedules or extracted for use in other applications, such as spreadsheets.

Models can be exported in standard file formats to quickly calculate heating and cooling loads, size duct systems using equal friction or static regain methods, as well as carry out full-building energy simulation using equipment performance parameters established in the BIM design.

Estimating software imports data directly for sheet metal, piping, plumbing, and mechanical cost estimating and generates a comprehensive labor and materials estimate, eliminating manual data entry and the potential for error.

Fabrication drawings can be created directly from design documents, eliminating the need to redraw. The fabrication software automatically produces an actual cost estimate of the system as it is to be fabricated without time-consuming manual measurements and data entry through “takeoff” of the system. The ductwork model can be exported to an application that controls the sheet metal plasma cutting machine to directly manufacture the ductwork, reducing the time required to complete construction projects while eliminating errors.

A simple, helpful tool for the HVAC engineer is graphic representation of **thermodynamic properties and thermodynamic cycle analysis**. These programs may be as simple as computer-generated psychrometric charts with cross-hair cursor retrieval of properties and computer display magnification of chart areas for easier data retrieval. More complex software can graphically represent thermodynamic cyclic paths overlaid on 2D or 3D thermodynamic property graphs. With simultaneous graphic display of the calculated results of Carnot efficiency and COP, the user can understand more readily the cycle fundamentals and the practicality of the cycle synthesis (Abtahi et al. 1986).

Typical **piping and duct system simulation** software produces large amounts of data to be analyzed. Pictorially enhanced simulation output of piping system curves, pump curves, and load curves speeds the sizing and selection process. Hypothetical scenarios with numeric/graphic output increase the designer’s understanding of the

system and help avoid design problems that may otherwise become apparent only after installation (Chen 1988). Graphic-assisted fan and duct system design and analysis programs are also available (Mills 1989).

Airflow analysis of flow patterns and air streamlines is done by solving fundamental equations of fluid mechanics. Finite-element and finite-volume modeling techniques are used to produce two- or three-dimensional pictorial-assisted displays, with velocity vectors and velocity pressures at individual nodes solved and numerically displayed.

An example of pictorial output is Figure 5 in Chapter 18, where calculated airflow streamlines have been overlaid on a graphic of the cleanroom. With this display, the cleanroom designer can see potential problems in the configuration, such as the circular flow pattern in the lower left and right.

Major features and benefits associated with most computer flow models include the following:

- Two- or three-dimensional modeling of simple cleanroom configurations
- Modeling of both laminar and turbulent airflows
- CAD of air inlets and outlets of varying sizes and of room construction features
- Allowance for varying boundary conditions associated with walls, floors, and ceilings
- Pictorial display of aerodynamic effects of process equipment, workbenches, and people
- Prediction of specific airflow patterns in all or part of a cleanroom
- Reduced costs of design verification for new cleanrooms
- Graphical representation of flow streamlines and velocity vectors to assist in flow analysis

A graphical representation of simulated particle trajectories and propagation is shown in Figure 6 of Chapter 18. For this kind of graphic output, the user inputs a concentrated particle contamination and the program simulates the propagation of particle populations. In this example, the circles represent particle sources, and the diameter is a function of the concentration present. Such simulations help the cleanroom designer determine protective barrier placement.

Although research shows excellent correlation between flow modeling done by computer and in simple mock-ups, modeling software should not be considered a panacea for design; simulation of flow around complex shapes is still being developed, as are improved simulations of low-Reynolds-number flow.

Simulations range from two-dimensional and black and white to three-dimensional, color, and fully animated. Three-dimensional color outputs are often used not only for attractive presentations, but to increase user productivity (Mills 1989).

4.4 HVAC UTILITIES

Utility programs and modules are calculation tools that can be used both alone and integrated into other design tools.

Unit Conversion Programs

Many small utilities automatically convert between different sets of measurement units. Many of these are available as freeware or shareware. Chapter 38 of the 2013 *ASHRAE Handbook—Fundamentals* provides factors for unit conversions between SI and I-P units.

Psychrometric Utilities

Chapter 1 of the 2013 *ASHRAE Handbook—Fundamentals* provides equations to calculate psychrometric properties. Most of the utilities and Visual Basic® functions that are available to automate these calculations determine psychrometric properties from any two

of the properties and a barometric pressure. Some also calculate entering and leaving properties from entering state-point(s) and a defined process (e.g., mixing of air streams, dehumidification), and plot to a psychrometric chart. Charting can be performed by scanning a psychrometric chart and determining the x and y axes by using the linear properties of dry-bulb temperature and humidity ratio.

Thermal Comfort Modules

An ASHRAE utility (ASHRAE 1997) calculates the predicted mean vote (PMV) for thermal comfort from the inputs for clothing, metabolic rate, mean radiant temperature, air speed, dry-bulb temperature, and relative humidity. This utility uses the calculations presented in ASHRAE *Standard 55-1992*.

Refrigeration Properties and Design

The program REFPROP (NIST; see <http://www.nist.gov/srd/nist23.cfm>) allows the user to examine thermodynamic and transport properties for 109 pure refrigerants and blends as of version 8.0. It may be used in an interactive mode. Because source code is included, it may also be used as part of a program that requires refrigerant properties. Other refrigerant property programs are also available from sources such as universities. Programs should be able to address the following refrigerant properties:

- Enthalpy
- Entropy
- Viscosity
- Thermal conductivity

Ventilation

Many ventilation programs are available to help designers meet the requirements of ASHRAE *Standard 62*, Ventilation for Acceptable Indoor Air Quality. As with any computer program, users should evaluate any program's technical capabilities, such as

- Ventilation requirements by application
- Application of the Multiple Space equation in *Standard 62*
- Use of ventilation effectiveness
- Application for spaces with intermittent or variable occupancy

In addition to technical capabilities, the units of input and output and the ability to interface with programs for input or output should also be examined.

4.5 SOURCES OF HVAC SOFTWARE

Many applications have been developed as the result of ASHRAE-funded research, ranging from database retrieval for use in HVAC&R calculations to demonstration versions of advanced tools.

The ASHRAE web site (www.ashrae.org) and the ASHRAE Online Bookstore are good sources for obtaining this software, and provide information about these programs and their system requirements, as well as other sources of HVAC-related software.

4.6 INTEROPERABLE COMPUTER APPLICATIONS FOR THE HVAC&R INDUSTRY

HVAC&R computer applications have historically been stand-alone tools that require manual reentry of data to accomplish multi-disciplinary analysis. In most projects, these data must then be manually transcribed for use in other professional software, for work such as HVAC calculations and design, cost estimating, building energy performance simulation, and energy code compliance checking. This process requires time and resources. Furthermore, error detection and correction can be just as resource consuming; undetected errors can lead to serious problems. Any changes to the design require corresponding changes in transcription for other applications. Each data element in a building design may typically

Fig. 4 Software Interoperability Based on IFC Data Model Standard

be independently recreated seven times in the course of design. Much of this information may be lost and/or outdated later in the building life cycle during construction, renovation, and facility maintenance.

The goal of automatically sharing data between different tools is becoming possible because of software interoperability, the ability to share the same information among software applications used by practitioners performing different industry tasks. National and international efforts to develop standardized data models that allow software interoperability are well under way. A commonly used format for interoperability between BIM tools and HVAC analysis software today is Green Building XML (gbXML), an open schema that can store all information about a building needed by building analysis software applications. gbXML is supported by an international consortium of software vendors. Another key product of these efforts is the Industry Foundation Classes (IFC) data model developed by the International Alliance for Interoperability (IAI; now BuildingSMART). Members of the IAI, such as ASHRAE, work to develop cross-platform and cross-application communication standards.

Interoperability also requires that software vendors incorporate standard data models in their software applications. As shown in Figure 4, this can be done either by directly accessing and updating an IFC or gbXML data file or by indirect access through an IFC- or gbXML-compliant data server. Several CAD tools now have implementations based on the evolving IFC and gbXML data model standard, allowing building geometry input in these tools to be easily shared with other IFC- and gbXML-compliant tools. Nongeometric building data (e.g., construction material properties, HVAC&R equipment characteristics) are also included in the IFC and gbXML data models. In addition to CAD tools, many other IFC- and gbXML-based HVAC&R software applications are available. Current information on state-of-the-art software interoperability is available in the section on Further Internet Resources at the end of the chapter.

5. MONITORING AND CONTROL

A control system performs two primary functions: monitoring (also referred to as data acquisition or data gathering) and control (also referred to as device control). A control consists of a set of measured (monitored) parameters, a set of controlled parameters, and a control function that translates the measurement data into control signals applied to controlled parameters.

Supervisory control includes (1) **total system monitoring** (functions such as alarm reporting, energy measurement and calculation, logs, and trend reports) and (2) **overall control** (functions such as manual overrides, optimizing modification or discharge local loop set points, optimizing start-stop of subsystems, and controlled interaction between subsystems).

Types of supervisory control, depending on focus, include the following:

- Building automation system (BAS): automating monitoring and control
- Energy monitoring and control system (EMCS): conserving energy by both automatic and manual control with the aid of energy monitoring
- Energy management system (EMS): conserving energy by specific automatic control programs
- Facility management system (FMS): HVAC control of a subset of multiple subsystems or buildings, including fire, security, elevator, or manufacturing systems

BAS has become the most popular term for description of a computerized control system that may provide one or more of these functions.

5.1 INTEROPERABILITY

Standard communication protocols are developed in committee by professional societies, *open* protocols are created by manufacturers but available for all to use, and *proprietary* protocols are developed by manufacturers but not freely distributed. User needs should be determined before selecting a particular protocol for a given application.

There are two major standard protocols used in HVAC building automation today: BACnet® and LONWORKS®.

BACnet is the ASHRAE *Standard* 135 Building Automation and Control Networks Protocol. It provides mechanisms by which computerized equipment for a variety of building control functions may exchange information, regardless of the particular building service it performs. As a result, the BACnet protocol may be used by head-end computers, general-purpose direct digital controllers, and application-specific or unitary controllers. Working groups represented in BACnet include lighting, life safety and security, network security, utility integration, wireless networking, and XML applications.

BACnet is based on a four-layer collapsed architecture that corresponds to the physical, data link, network, and application layers of the ISO/OSI (International Organization for Standardization Open Systems Interconnection) model. The application layer and a simple network layer are defined in the BACnet standard.

The **physical layer** provides a means of connecting devices and transmitting the electronic signals that convey the data. BACnet devices often use Ethernet networking, and can coexist with PCs on the same network.

The **data link layer** organizes the data into frames or packets, regulates access to the medium, provides addressing, and handles some error recovery and flow control.

Functions provided by the **network layer** include translation of global addresses to local addresses, routing messages through one or more networks, accommodating differences in network types and in the maximum message size permitted by those networks, sequencing, flow control, error control, and multiplexing. BACnet is designed so that there is only one logical path between devices, thus eliminating the need for optimal path routing algorithms.

The **presentation layer** provides a way for communicating partners to negotiate the transfer syntax used to conduct the communication. This transfer syntax is a translation from the abstract user view of data at the application layer to sequences of octets treated as data at the lower layers.

The **application layer** of the protocol provides the communication services required by the applications to perform their functions, in this case monitoring and control of the HVAC&R and other building functions.

LONWORKS defines a protocol for interoperability between control and automation devices. Task groups represented in LONMARK include HVAC, fire, industrial, lighting, vertical transportation

(elevators), automated food service equipment, home/utility, network tools, refrigeration, router, security, semiconductor, sunblinds, system integration, and transportation.

Building automation system networks are local area networks, even though some applications must exchange information with devices in a building that is very far away. This long-distance communication is typically done through telephone networks. Using the Internet is becoming a popular, low-cost alternative to telephones.

5.2 DIRECT DIGITAL CONTROL (DDC) APPLICATIONS

Building management systems use standard workstation technology to connect or view system information. Standardization of building and vendor control protocol will allow future systems to access BACnet® and LONWORKS® systems. Although there are many approaches to communicating building information, the web-browser-based client/server approach is becoming a standard interface.

Graphical representation of data from automation systems (e.g., operating conditions, trend data) is effective for enhancing operation and corrective action.

Direct digital control (DDC) allows precise and repeatable control using vendor hardware and software platforms. Many vendors allow access to DDC and set-point parameters, or are supporting common application standards such as distributed component object model (DCOM) ActiveX® and Enterprise JavaBeans®/common object request broker architecture (EJB/CORBA). Purchasing outside standards from companies specializing in certain components allows HVAC workstation providers to use common components for analysis, trending, and graphical presentation.

5.3 CONTROL COMPONENTIZATION

HVAC manufacturers use DDC microprocessors to create powerful, low-cost controls and feature-rich equipment. In the past, many of the control devices were proprietary and information was not shared between manufacturers. With standard communication protocols, diverse applications such as HVAC, energy, security, lighting, and fire controls in large buildings can use a single integrated control system.

Standard protocols allow application-specific component control systems designed for particular HVAC equipment to be included in building-wide strategies. For example, low-cost componentized DDCs provide operation, safety, maintenance, and even self-diagnostic information and control functions. Making a chiller or a variable-speed drive controller a part of a cohesive, building-wide control system is now possible because of standard protocols.

In the past, because all major HVAC equipment required some type of control system, control points were duplicated. Acceptance of communication standards has greatly reduced total control costs and increased functionality by providing information (e.g., part-load performance criteria) to users that was previously only available from manufacturer's testing.

As the functionality of component control increases and associated cost decreases, component-level interaction makes building-wide system integration less critical.

5.4 INTERNET-ENABLED BUILDING AUTOMATION SYSTEMS

With Internet-enabled building automation systems, additional information outside the traditional control system (e.g., weather data, real-time energy data, pricing rates, manufacturers' equipment data) can be combined with real-time equipment data to create valuable analysis information. Commercial applications allow device integration to view real-time data, command equipment, and trend

data. Users can manage energy consumption and costs, correct comfort problems, and solve equipment issues from distributed locations. Access control systems are available through the Internet using existing Internet standards such as TCP/IP and HTTP/XML.

5.5 CONVERGENCE OF INFORMATION SYSTEMS AND INFORMATION TECHNOLOGY

As the information system (IS) and information technology (IT) industry has advanced, so have applications that can be used in building automation. Internet browser technology is a standard application, allowing information to be shared across nontraditional computer boundaries.

Because there is such demand in business for IT products, expertise and knowledge formerly reserved for IT applications can be applied to, for instance, user interface and building automation applications. A critical concern about integrating IT systems and building automation is information security. New security standards, such as the BACnet Network Security specification, should help address these concerns. Another common concern is that building automation systems will use a large amount of network bandwidth, but experience shows that bandwidth use by a properly configured system is not appreciable.

Web-based building controls that use the IT approach should create an open, interoperable structure for control automation systems. Implementing common field-bus standards and integration with web browsers can be helpful for legacy system support. Rapid adoption of the Internet and standardization efforts in the field bus and building automation protocols have made developing a single standard for both Internet and control a goal for many vendors.

Combining building automation with Internet functionality will provide functionality in a user-friendly form.

6. WIRELESS COMMUNICATION

Wireless communication technologies present many opportunities for enhanced information exchange in buildings. By removing the cost and time associated with wiring sensors, controllers, actuators, data acquisition systems, and computers to each other, wireless systems open new possibilities for designing and operating buildings to perform efficiently while maintaining a comfortable indoor environment. This section gives an overview of wireless communication technologies relevant to building operations, discusses applications where wireless equipment can be used, and provides guidance on selecting wireless systems for HVAC&R applications.

6.1 TECHNOLOGIES

Radiofrequency Data Transfer

In this section, *wireless* refers to the technique by which data are transferred between devices, as opposed to how power is delivered to the devices. A wireless transmitter and receiver must both consist of a radio, antenna, and microprocessor. For a transmitter, the microprocessor converts the data to a signal that is sent over the air through the antenna; for a receiver, it converts the radiofrequency (RF) signal received at the antenna to data. Radios can often be configured to serve as both transmitters and receivers. Data can be encoded in RF signals in a number of ways; for details, see Rappaport (2002). These data transmission design schemes allow for timing and/or frequency modulation as well as error checking, ensuring that the signal is properly sent and received.

Data can theoretically be transmitted at any frequency in the electromagnetic spectrum, but the radio communications spectrum is generally considered to be from 3 kHz to 300 GHz. Most practical uses, however, occur in the lower portion of that range (U.S. General

Accounting Office 2004). The industrial, scientific, and medical (ISM) bands are reserved for license-free operations, and other segments of the spectrum are dedicated to licensed operation. The International Telecommunication Union defined 12 ISM bands, with the most popular bands for communications for these applications centered at 434 MHz, 915 MHz, 2.45 GHz, and 5.80 GHz. The 434 MHz band is valid only in Europe, Africa, the Middle East, and the former Soviet Union, and the 915 MHz band is allotted only in the Americas, Greenland, and parts of the Pacific Islands. Consequently, designers often select the 2.45 and 5.80 GHz bands because of their worldwide acceptance.

System Design

Collections of wireless sensors, controllers, and actuators form a network. Figure 5 shows three main topologies for wireless networks. In a star network, all wireless devices communicate directly to a base station. In a mesh network, each wireless device, or node, can communicate with all other wireless devices in the network, with each node serving as a transmitter, receiver and repeater of signals. The networks can be designed to relay messages from one device to another, and messages can bypass a central receiving point to allow direct communication between wireless devices, such as a sensor and an actuator. Mesh networks are often designed to set themselves up in an ad-hoc manner and to be self-healing. Ad-hoc configuration allows the user to simply physically place the wireless equipment, and software then determines the best path through the available nodes for messages from a wireless device to reach their destinations. These ad-hoc networks also allow wireless nodes to be added automatically to an existing network. Self-healing mesh networks automatically find alternative routes for messages to be passed should a radio node in the network fail or should a link between two nodes become lost. This failure can happen for a number of reasons such as physical obstacles introduced between nodes, new sources of electromagnetic interference between nodes, and often difficult-to-determine causes for communication loss between specific sets of nodes.

The sophistication of mesh networks allows for robust networks that are easily expanded. One drawback of the mesh network compared to star networks is the added complexity and, hence, cost of the equipment. A second downside of these networks is that radio nodes are expected to relay (or repeat) data and commands from neighboring nodes in addition to their own information, thereby using more energy and decreasing battery life.

Hybrid networks combine the concepts of both mesh and star networks. An example would be a series of data collection points connected in a mesh network to which sensors and actuators are each attached in a star configuration.

Standards

Various standards have been developed for wireless data communications, the most familiar of which is the IEEE 802.11 family of standards for wireless local area networks (IEEE *Standard* 802.11). The most recent addendum (802.11g) allows for data transfer at a rate of 54 Mbps, although the next-generation standard (802.11n) promises data transfer at up to 600 Mbps. The 802.11 standard forms the basis of products that conform to the Wi-Fi™ specification, an industry-based specification developed by the Wi-Fi Alliance. Products that comply with this standard can be used to transfer data at the primary controller level in buildings, where significant amounts of data and control signals are transmitted. Many other applications in buildings, however, do not need the high bandwidth that is a priority in the IEEE 802.11 standard, which is intended primarily for communication of personal and other computer data and must, therefore, handle the transfer of large files such as audio, photos and other video. To address low-data-rate applications such as personal area networks, in which minimizing radios' energy

Fig. 5 (A) Star, (B) Mesh, and (C) Hybrid Wireless Network Topologies

consumption is a priority, IEEE developed *Standard* 802.15.4. This framework calls for a data transfer rate of up to 250 kbits/s at a range of 10 m (32.8 ft). Similarly to the way in which the Wi-Fi specification uses IEEE *Standard* 802.11, the ZigBee™ specification uses IEEE *Standard* 802.15.4 as a basis for promoting interoperable solutions for wireless sensor and control networks that involve low-data-rate communications and that require minimal energy consumption by radio equipment. ASHRAE's BACnet committee recently added an amendment to the BACnet standard that allows BACnet messages to be sent over ZigBee™ networks (Martocci 2008).

Other standards are also in place for wireless data communications. The Bluetooth™ standard is based on IEEE 802.15.1 standard for wireless personal area networks (IEEE *Standard* 802.15.1). This standard focuses on higher-data-rate applications than those addressed by 802.15.4 and has gained acceptance in short-distance applications such as wireless headsets for phones and wireless peripherals for computers. The WiMedia Alliance promotes open standards based on Ultra-Wideband data communications. The target bandwidth enabled by these standards is 480 Mbps. WiMedia™ is not to be confused with WiMAX™, which is based on IEEE *Standard* 802.16 and is designed for broadband Ethernet transmission as part of a metropolitan area network.

6.2 APPLICATIONS

RF wireless data communication can be used in the same building automation applications as wired data communication. Wireless equipment can be used at any point in the building control network as well as in monitoring applications that are separate from the control system. The major advantage of wireless technology over wired methods is the ease of installation, which leads to labor cost savings, greater flexibility in installation scheduling, less damage to existing construction, and less interference with occupants of existing buildings.

In new and existing construction, advantages include the following:

- Installation may be quicker because it is not necessary to pull communication wires and/or power wiring (in some cases), or to run conduit
- No need for unattractive conduits or wire molding.
- Systems can be used in buildings with aesthetic restrictions on visible wires.
- Deployment involves less complicated coordination between construction trades (e.g., no need to wait for electricians to run wires, or concern if drywall goes up before the electrician arrives).

- Wi-Fi can be used to set up monitoring and control networks before structured Ethernet cabling is installed (e.g., during construction).

Advantages when adding sensing and control systems to existing buildings include the following:

- There is less disruption to the physical facility and occupants during installation.
- Installation does not require opening up walls and ceilings.
- Less dust and wire clippings are generated (especially important in health care setting).
- Structural integrity is never compromised by drilling holes to run wires.
- The need for asbestos mitigation is minimized because potential disturbance of existing asbestos materials is limited.
- There is no need to drill wiring holes in difficult construction such as cinderblock walls, drywalled ceiling, or underfloor air distribution, where it is costly or time consuming.
- The technology is particularly appropriate for historic or vintage facilities where architectural preservation rules preclude tearing up walls.
- Otherwise inaccessible sites of measurement like behind water walls or up on tall ceilings or atriums are more compatible with wireless communications.

Wireless equipment provides added flexibility in locating sensors, actuators, and controls in the following ways:

- Wireless devices can be moved without the burden of running new communication cabling. This is especially useful for building operators who reconfigure their facility's spaces frequently.
- Wireless devices can be placed in the optimal location for sensing and control. They are not restricted only to the places where cabling can be run. Open floor plans can easily be accommodated.
- Wireless devices can also easily be added to an existing wireless network in an open floor plan area because there is no concern about finding a communication cable to tap into.

Finally, wireless technology affords the ability to incrementally modify a building automation system and may add a degree of redundancy that is not possible in wired applications:

- Incremental deployment of devices can proceed based on the application needs instead of being dictated by the location of the nearest live communication cable.
- Old wired networks can be upgraded incrementally to wireless networks without concern about disrupting communication to the

rest of the wired devices caused by removal of data wiring or power wiring on the old devices.

- Wireless technology eliminates dependency on unreliable, previously installed network cabling that may suffer from deterioration due to age, years of miswiring, or simple incompatibilities.
- A wireless network can result in reduced single points of failure. If a wired communication cable gets cut, all the downstream devices are lost. In a wireless mesh network, redundant paths of communication exist that automatically correct for failures in the network.

Examples of Applications of Wireless Systems in Buildings

Several documented cases of the use of wireless communication systems in buildings have been presented (Healy 2005; Kintner-Meyer and Brambley 2002; Raimo 2006; Ruiz 2007; Wills 2004). These articles discuss the application of wireless sensor networks for equipment and environmental monitoring in both commercial and residential installations, the use of wireless systems for HVAC controls, and wireless architectures for buildings.

6.3 SELECTION OF WIRELESS SYSTEMS

This section is based on information in Brambley et al. (2005).

Challenges

The primary issues in applying wireless technologies inside buildings are associated with (1) powering devices (mainly sensors) where line power is not available, (2) the maximum distance over which devices can communicate, (3) interference caused by signals from other radio transmitters (such as wireless LANs) and microwave ovens that leak electromagnetic energy, (4) attenuation as the RF signal travels from the transmitter through walls, furnishings, and even air to reach the receiver, and (5) security.

Powering Sensors. Many different wireless technologies are available, ranging from cellular phone networks to wireless temperature sensors. In building automation applications, line power may not be conveniently available at all locations where sensors should be placed. These sensors need (1) a source of electrical power with an acceptably long life (usually at least 5 years), and (2) a low rate of power consumption by the wireless nodes to minimize the amount of power required. Most wireless sensor nodes use batteries; to maximize battery life, communication protocols for wireless sensor networks must minimize power use. Although not widely available today for wireless sensor applications, environmental power harvesting shows promise to power wireless sensors in the future. A limited number of products using power harvesting are available today, such as a light switch that uses electric power generated when a person pushes the switch to power transmission of the signal to an actuator on the light circuit remote from the switch, creating a movable electric switch that would simplify remodeling in cases where switches must be relocated.

Communication Range. A radio that has a maximum line-of-sight range of 300 ft outdoors may be limited to 60 ft or even less indoors. The range depends on several factors, including the frequency at which the radio communicates (lower frequencies penetrate materials better), the specific materials used in building construction (e.g., wood absorbs more signal power per unit path length than air), and layout of walls and spaces. Therefore, the wireless technology and communication protocol for indoor sensor networks must provide adequate communication ranges in less-than-ideal indoor environments.

Interference. Interference is usually caused by electromagnetic noise from other wireless devices or random thermal noise. Spread spectrum techniques increase resistance to interference from a single-frequency source by spreading the signal over a defined

Table 1 Signal Attenuation for Selected Building Materials for 900 to 908 MHz Band

Construction Material	Attenuation, dB	
Drywall,	1/4 in.	0.2
	1/2 in.	0.3
	3/4 in.	0.5

Source: Stein (2004)

spectrum. Multiple transmitters usually can communicate clearly in a common frequency band, although spread spectrum is not immune to interference (particularly with heavily loaded frequency bands used by large numbers of wireless devices). Early tests in buildings with 30 to 100 wireless sensors did not identify problems with crosstalk or data loss in transmission, but communications may become less reliable as frequency band crowding increases (e.g., hundreds or thousands of devices sharing the band). Field testing under these usage conditions is needed.

Attenuation. RF signals weaken over distance; the amount of attenuation depends on how far the signal travels, and through what materials. Different materials have different levels of attenuation per unit of path through the material (Table 1).

Signal attenuation can be compensated for by using repeaters. Repeaters are usually placed close enough to transmission sources that a high percentage of the signals will successfully reach the repeater. The repeater receives signals, amplifies them, and retransmits them (often at higher power) to extend the transmission range. In a wireless mesh network, every node serves as a repeater.

Security. Growing threats to networking infrastructure have increased security requirements for facility automation systems. Wireless networks are particularly vulnerable because no direct “hard” physical link is required to connect to them. Data encryption (encoding data in a format that is not readable except by someone with the “key”) has successfully defended against intrusion and provided security for wireless local area networks (LANs). Encryption, however, requires additional computational power on each wireless device, which raises the cost of wireless networks and the power requirements of individual devices. Research is ongoing by developers, vendors, and standards committees to provide security without additional power requirements.

Practical Design and Installation Considerations

Laying out a wireless network indoors is probably as much art as it is science. Every building is unique, if not in its construction and floor plan, then at least in the type and layout of its furnishings. Predicting wireless signal strength throughout a building requires characterizing the structure and its layout, furnishings, and equipment in great detail and using that information to model RF signal propagation. No tools are available to do this accurately, although equipment can test RF signal propagation in buildings, which can help with sensor placement. Changes in space use or furnishings can make these data obsolete, however. The following are some practical points to keep in mind when designing a wireless network.

Fig. 6 Example of RF Propagation Area Increasing with Distance from Transmitter

Determining Receiver Location. The number and locations of receivers strongly influences the design of a wireless sensor network for in-building monitoring. A stand-alone wireless network (not connected to a wired control network) may have some flexibility in choosing the location of the primary receiver that provides data to users (e.g., a monitoring workstation). From a communications perspective, the best location is open and provides the best line-of-sight pathways between the most wireless sensors and the receiver. Convenient connection of the receiver to a computer where data will be processed and viewed is another important consideration. These factors must be balanced. If the design requires integration of the wireless sensor network with an existing building automation system (BAS), then receivers must be located near points of connection to the BAS. Locations are constrained somewhat in this case, but there are typically still many options. Frequently, a convenient integration point is a control panel that provides easy access to communication cables as well as electricity to power the receiver and integration devices. In commercial buildings, BAS network wires are often laid in cabling conduits (open or closed) above the ceiling panel, and are relatively easily accessible. Often, though, the lack of electric power in the ceiling space makes a control panel more convenient.

Signal Attenuation and Transmitter Range. Estimating the range of the transmitting devices is important from a cost point of view. If a single transmission path cannot connect a transmitting device to the ultimate end node, additional hardware will be required for signal repeating or amplification, adding to the installation's total cost. The following discussion provides an overview of how to estimate how many repeater or amplification devices an installation requires. It does not replace a thorough RF survey of a facility to determine the exact number and locations of receivers, repeaters, or intermediate nodes necessary to ensure robust communication.

A transmitter's range depends on the three variables: (1) attenuation because of distance between wireless devices, (2) attenuation caused by the signals traveling through construction material along the signal pathways, and (3) overall electromagnetic noise levels in the facility.

Attenuation of signal strength caused by distance between the transmitter and receiver (free path loss) depends on the relation of the transmitter's electromagnetic energy per unit area to the distance of the receiving surface (see Figure 6). The energy per unit area at a distance d from the transmitter decreases in proportion to $1/d^2$. Therefore, every time d doubles, the energy density or signal strength received decreases by a factor of $1/4$.

This relationship accounts only for signal dispersion across a large area distant from the source. In practice, other factors also affect the strength of signal received, even for an unobstructed path:

Table 2 Attenuation of RF Signal in Free Air for Selected Distances

Distance, ft	0.2	3	8	16	33	66	131	262
Signal strength, dB	0	-26	-34	-40	-46	-52	-58	-64
Attenuation along propagation path, dB	0	26	34	40	46	52	58	64

absorption by moisture in the air or by the ground, partial signal cancellation by waves reflected by the ground, and other reflections. In general, this causes signal strength at distance d from the transmitter to decrease in proportion to $1/d^m$, where $2 < m < 4$ (Su et al. 2004).

The following example illustrates signal attenuation with distance from the transmitter in free air for a 900 MHz transmitter, and shows how simple relations can be used to estimate potential transmission range.

Example 1. Assume that the measured signal strength of a small transmitter is 645 mW/in^2 at a distance of 2 in. from the transmitter's antenna. The transmission path efficiency or transmission loss is customarily expressed in decibels, a logarithmic measure of a power ratio, and is defined as

$$\text{dB} = 10 \log_{10} (p_1/p_0)$$

where p_1 is the power density in W/cm^2 and p_0 is the power density at a reference point in W/cm^2 .

For p_0 , select the power density measured 5 cm from the transmitter's antenna. Table 2 shows the emitted signal's attenuation (traveling through air only) as a function of distance from the transmitter. For every doubling of the distance, the signal strength decreases by 6 dB (i.e., the attenuation increases by 6 dB).

Further, assume that the measured ambient noise is -75 dB . For a signal to be detectable, its strength should be at least 10 dB above the noise level (i.e., a signal margin of 10 dB or greater is recommended) (Inovonics 1997). Using Table 2, the transmission range for this system that meets the 10 dB signal margin requirements is about 262 ft, because $-75 \text{ dB} + 10 \text{ dB} = -65 \text{ dB}$, which is less than -64 dB at 262 ft.

If the receiver is placed in a mechanical room of a building, the signal from the most distant transmitter must go through two brick walls and two layers of drywall. Using signal attenuation estimates from Table 1, the combined attenuation of the brick and drywall is 14.6 dB [2×0.3 (for the 1/2 in. drywall) + 2×7 (for the 10.5 in. brick wall) = 14.6]; for practical purposes, round this to 15 dB. Adding the material-related attenuation of 15 dB to the -65 dB signal strength requirement yields -50 dB as the new indoor signal strength requirement for the free air transmission segment. Table 2 shows that the transmission range is between 33 and 66 ft, only 1/8 to 1/4 of the range in open air. This example illustrates how significantly radio signals can be attenuated simply by the structure itself. Furniture further adds to attenuation and complicates prediction of signal strength as a function of location in buildings. Therefore, to characterize indoor environments with respect to RF signal propagation, empirical surveying is recommended.

RF Surveying. The purpose of an RF facility survey is to determine the actual attenuation of RF signal strength throughout the facility. This information, together with knowledge of the locations at which sensors will be positioned, is used to lay out the wireless network. The layout will include the number of repeaters and receivers in the network and their locations. For instance, for a multistory facility there may be good reasons for placing one receiver on each floor, provided the data are needed only on each floor (e.g., one user per floor for that floor) or there is another means to communicate the data between floors (such as a wired BAS connection on each floor). If the data are needed at a computer located on a specific floor (such as a control room in the basement), a repeater might be used on each floor to transmit signals to the location of a central receiver located close to where the data are needed. If communication between receivers on different floors is not sufficient, there may be opportunities to route signals inside an elevator shaft, stair case,

or on the exterior of the building. The most cost-effective solution is usually determined by the difference between the cost of repeaters and receivers for a completely wireless network and the cost of interfacing the receivers for separate wireless networks on each floor to a preexisting wired network that would communicate the data from all wireless networks to the control room. The layout with the lowest total cost that provides sufficiently reliable communication is generally optimal.

Most vendors of wireless sensor networks offer RF survey kits that are specific for the vendors' technologies. These kits consist of a transmitter and a receiver. The transmitter is often a modified sensor transmitter that is programmed to transmit at frequent time intervals. The receiver generally is connected to (or part of) an indicator of signal strength, together making a wireless signal-strength meter. These meters may simply give an indication whether the signal strength is adequate or provide numerical values of signal strength and background noise levels from which the adequacy of signal strength can be determined.

Before the RF facility survey is performed, potential receiver and sensor locations need to be known. The survey is then performed by placing the transmitter in anticipated locations for the receivers, then moving the signal-strength meter to locations where sensors will be positioned. By taking measurements throughout the facility, the limits of transmission range where the signal can no longer be detected (or is not of sufficient strength) can be identified. Repeaters will then need to be located in the layout within the transmission range to extend the range further.

Radiofrequency surveying is generally done by the wireless technology vendor or installer. Depending on the diversity of noise level in the facility and the complexity of the interior layout, an RF survey can be performed for office buildings with a floor space of 100,000 ft² in 2 to 4 h.

Although RF surveys are critical for successfully designing and installing a wireless network that uses a star topology, systems using a mesh network topology with sufficient sensor density will ultimately not require RF surveys for installation. With sufficient densities of sensors (i.e., relatively short distances between sensors and multiple neighboring sensors within the communication range of each node), these networks are self-configuring and the multiple potential transmission paths ensure reliable, consistent communications. In the near term, use caution when assuming that mesh networks will perform reliably for every application, especially in cases where high sensor density is not anticipated. For low sensor density installations, communication over long distances may require a higher-power repeater to connect a local mesh network to the point where the data are needed (or a daisy-chain of nodes for this communication). In these cases, the advantages of mesh networking are lost in the region where individual devices carry all data communicated and those devices become potential single points of failure for the entire mesh that they connect to the point of data use.

Other Practical Considerations. Several other factors should be considered in deciding to use wireless sensing in buildings. Stein (2004) provides a nice summary of practical considerations for monitoring with wireless sensor networks. In addition to communication range, some of the key considerations that need to be assessed when selecting a wireless sensing network are

- Component prices
- Availability of support
- Compatibility with different types of sensors with different outputs
- Battery backup for line powered devices
- Low-battery indicators for battery-powered devices
- On-board memory
- Proper packaging and technical specifications for the environment where devices will be located

- Battery life and factors that affect it
- Frequency of data collection and its relationship to battery life (where applicable)
- Need for and availability of integration boxes or gateways to connect wireless sensor networks to BASs, other local area networks, or the Internet
- Availability of software for viewing or processing the data for the intended purpose
- Compatibility among products from different vendors; this is rare today but will improve as manufacturers adopt new standards such as IEEE *Standard* 802.15.4 (Gutierrez et al. 2003) and Zigsbee (Kinney 2003)
- Tools for configuring, commissioning, repairing, and adding nodes to the sensor network
- Software to monitor network performance

Most important is ensuring the selected wireless network meets the requirements of the intended application. All factors need to be considered and assessed with respect to satisfying the requirements of the application and the specific facility. Each installation is unique.

CHAPTER 41

BUILDING ENERGY MONITORING

<i>Reasons for Energy Monitoring</i>	41.1
<i>Small Projects</i>	41.3
<i>Protocols for Performance Monitoring</i>	41.3
<i>Common Monitoring Issues</i>	41.6
<i>Steps for Project Design and Implementation</i>	41.6

BUILDING energy monitoring was conducted on a large scale in the 1980s and 1990s, and the need to capture lessons learned and document project requirements that often were not addressed adequately in these large projects led to the development of this chapter. The intent of such projects is to provide realistic, empirical information from field data to enhance understanding of actual building energy performance and help quantify changes in performance over time. Although different building energy monitoring projects can have different objectives and scopes, all have several issues in common that allow methodologies and procedures (monitoring protocols) to be standardized.

This chapter provides guidelines for developing building monitoring projects that provide the necessary measured data at acceptable cost. The intended audience comprises building owners, building energy monitoring practitioners, and data end users such as energy and energy service suppliers, energy end users, building system designers, public and private research organizations, utility program managers and evaluators, equipment manufacturers, and officials who regulate residential and commercial building energy systems. A new section has been added on small projects to show how the methodology can be simplified.

Monitoring projects can be **uninstrumented** (i.e., no additional instrumentation beyond the utility meter) or **instrumented** (i.e., billing data supplemented by additional sources, such as an installed instrumentation package, portable data loggers, or building automation system). Uninstrumented approaches are generally simpler and less costly, but they can be subject to more uncertainty in interpretation, especially when changes made to the building represent a small fraction of total energy use. It is important to determine (1) the accuracy needed to meet objectives, (2) the type of monitoring needed to provide this accuracy, and (3) whether the desired accuracy justifies the cost of an instrumented approach.

Instrumented field monitoring projects generally involve a data acquisition system (DAS), which typically comprise various sensors and data-recording devices (e.g., data loggers) or a suitably equipped building automation system. Projects may involve a single building or hundreds of buildings and may be carried out over periods ranging from weeks to years. Most monitoring projects involve the following activities:

- Project planning
- Site installation and calibration of data acquisition equipment (if required)
- Ongoing data collection and verification
- Data analysis and reporting

These activities often require support by several professional disciplines (e.g., engineering, data analysis, management) and construction trades (e.g., electricians, controls technicians, pipe fitters).

Useful building energy performance data cover whole buildings, lighting, HVAC equipment, water heating, meter readings, utility

demand and load factors, excess capacity, controller actuation, and building and component lifetimes. Current monitoring practices vary considerably. For example, a utility load research project may tend to characterize the average performance of buildings with relatively few data points per building, whereas a test of new technology performance may involve monitoring hundreds of parameters in a single facility. Monitoring projects range from broad research studies to very specific, contractually required savings verification carried out by performance contractors. However, all practitioners should use accepted standards of monitoring practices to communicate results. Key elements in this process are (1) classifying the types of project monitoring and (2) developing consensus on the purposes, approaches, and problems associated with each type (Haberl et al. 1990; Misuriello 1987). For example, energy savings from energy service performance contracts can be specified on either a whole-building or component basis. Monitoring requirements for each approach vary widely and must be carefully matched to the specific project. Procedures in ASHRAE *Guideline* 14-2002 and the IPMVP (2007) can be used to determine monitoring requirements.

1. REASONS FOR ENERGY MONITORING

Monitoring projects can be broadly categorized by their goals, objectives, experimental approach, level of monitoring detail, and uses (Table 1). Other factors, such as resources available, data validation and analysis procedures, duration and frequency of data collection, and instrumentation, are common to most, if not all, projects.

Energy End Use

Energy end-use projects typically focus on individual energy systems in a particular market sector or building type. Monitoring usually requires separate meters or data collection channels for each end use, and analysts must account for all factors that may affect energy use. Examples of this approach include detailed utility load research efforts, evaluation of utility incentive programs, and end-use calibration of computer simulations. Depending on the project objectives, the frequency of data collection may range from one-time measurements of full-load operation to continuous time-series measurements.

Specific Technology Assessment

Specific technology assessment projects monitor field performance of particular equipment or technologies that affect building energy use, such as envelope retrofit measures, major end-use system loads or savings from retrofits (e.g., lighting), or retrofits to or performance of mechanical equipment.

The typical goal of retrofit performance monitoring projects is to estimate savings resulting from the retrofit despite potentially significant variation in indoor/outdoor conditions, building characteristics, and occupant behavior unrelated to the retrofit. The frequency and complexity of data collection depend on project objectives and site-specific conditions. Projects in this category assess variations in

The preparation of this chapter is assigned to TC 7.6, Building Energy Performance.

Table 1 Characteristics of Major Monitoring Project Types

Project Type	Goals and Objectives	General Approach	Level of Detail	Uses
Energy end use	Determine characteristics of specific energy end uses in building.	Often uses large, statistically designed sample. Monitor energy demand or use profile of each end use of interest.	Detailed data on end uses metered. Collect building and operating data that affect end use.	Load forecasting by end use. Identify and confirm energy conservation or demand-side management opportunities. Simulation calculations. Rate design.
Specific technology assessment	Measure field performance of building system technology or retrofit measure in individual buildings.	Characterize individual building or technology, occupant behavior, and operation. Account and correct for variations.	Uses detailed audit, sub-metering, indoor temperature, on-site weather, and occupant surveys. May use weekly, hourly, or short-term data.	Technology evaluation. Retrofit performance. Validate models and predictions.
Energy savings measurement and verification	Estimate the impact of retrofit, commissioning, or other building alteration to serve as basis for payments or benefits calculation.	Preretrofit consumption is used to create baseline model. Post-retrofit consumption is measured; the difference between the two is savings.	Varies substantially, including verification of potential to provide savings, retrofit isolation, or whole-building or calibrated simulation.	Focused on specific campus, building, component, or system. Amount and frequency of data varies widely between projects.
Building operation and diagnostics	Solve problems. Measure physical or operating parameters that affect energy use or that are needed to model building or system performance.	Typically uses one-time and/or short-term measurement with special methods, such as infrared imaging, flue gas analysis, blower door, or coheating.	Focused on specific building component or system. Amount and frequency of data vary widely between projects.	Energy audit. Identify and solve operation and maintenance, indoor air quality, or system problems. Provide input for models. Building commissioning.

performance between different buildings or for the same building before and after the retrofit.

Field tests of end-use equipment are often characterized by detailed monitoring of all critical performance parameters and operational modes. In evaluating equipment performance or energy efficiency improvements, it is preferable to measure in situ performance. Although manufacturers' data and laboratory performance measurements can provide excellent data for sizing and selecting equipment, installed performance can vary significantly from that at design conditions. The project scope may include reliability, maintenance, design, energy efficiency, sizing, and environmental effects (Phelan et al. 1997a, 1997b).

Savings Measurement and Verification (M&V)

Accountability is increasingly necessary in energy performance retrofits, whether they are performed as part of energy savings performance contracting (ESPC) or performed directly by the owner. In either case, savings measurement and verification (M&V) is an important part of the project. Because the actual energy savings cannot be measured directly, the appropriate role of energy monitoring methodology is to

- Ensure that appropriate data are available, including preretrofit data if retrofits are installed
- Accurately define baseline conditions and assumptions
- Confirm that proper equipment and systems were installed and have the potential to generate the predicted energy savings
- Take postretrofit measurements
- Estimate the energy savings achieved

Proper assessment of an energy retrofit involves comparing before and after energy use, and adjusting for all nonretrofit changes that affected energy use. Weather and occupancy are examples of factors that often change. To assess the effectiveness of the retrofit alone, the influence of these other complicating factors must be removed as best possible. Relationships must be found between energy use and these factors to remove the influence of the factors from the energy savings measurement. These relationships are usually determined through data analysis, not textbook equations. Because data analysis can be conducted in an infinite number of ways, there can be no absolute certainty about the relationship chosen. The need for certainty must be carefully balanced with measurement and analysis costs, recognizing that absolute certainty is not achievable. Among the numerous sources of uncertainty are instrumentation or

measurement error, normalization or model error, sampling error, and errors of assumptions. Each source can be minimized to varying degrees by using more sophisticated measurement equipment, analysis methods, sample sizes, and assumptions. However, more certain savings determinations generally follow the law of diminishing returns, where further increases in certainty come at progressively greater expense. Total certainty is seldom achievable, and even less frequently cost-effective (ASHRAE *Guideline 14*).

Other resources are also available. One of the widest known is the *International Performance Measurement and Verification Protocol* (IPMVP 2007). The IPMVP is more general than ASHRAE *Guideline 14* but provides important background for understanding the larger context of M&V efforts.

Building Diagnostics

Diagnostic projects measure physical and operating parameters that determine the energy use of buildings and systems. Usually, the project goal is to determine the cause of problems, model or improve energy performance of a building or system(s), or isolate effects of components. Diagnostic tests frequently involve one-time measurements or short-term monitoring. To give insight, the frequency of measurement must be several times faster than the rate of change of the effect being monitored. Some diagnostic tests require intermittent, ongoing data collection.

The most basic energy diagnostic for buildings is determining rate of energy use or power for a specific period, from essentially a single point in time to a few weeks. The scope of measurement may include the whole building or only one component. The purpose can range from measurement system parameter estimation to verification of nameplate information. Daily or weekly profiles may also be of interest.

A large number of diagnostic measurement procedures are used for energy measurements in residential buildings, particularly single-family. Typical measurements for single-family residences include (1) flue gas and other analysis procedures to determine steady-state furnace combustion efficiency and the efficiency of other end uses, such as air conditioners, refrigerators, and water heaters; (2) fan pressurization tests to measure and locate building envelope air leakage (ASTM *Standard E779*) and tests to measure airtightness of air distribution systems (Modera 1989; Robison and Lambert 1989); and (3) infrared thermography to locate thermal defects in the building envelope and other methods to determine overall building envelope parameters (Subbarao 1988).

Table 2 Comparison of Small Projects to Overall Methodology

Project Characteristic	Small Project Approach	Overall Methodology Coverage
Project problem areas	<ul style="list-style-type: none"> • Project goals and resources are iteratively evaluated in short time. Only one to possibly a few people involved. Small group allows more informal procedures and high interaction as needed. • Data products loosely defined. Data collection starts. Initial and ongoing analysis indicates any data management or quality control issues. • Data products refined over time as needed, based on analysis. • Accuracy evaluated on the fly as data are collected. • Commitment is simply needing to finish the work. • Advice still sought where needed. 	Project goals, project costs and resources, data products, data management, data quality control, commitment, accuracy requirements, advice.
Building and occupant characteristics	Typically, only one to few buildings included; work is reasonably local. Characteristic data collected on site, at convenience of project person(s), depending on project location. Return trips likely already needed for simplified data collection approach; supporting data can be collected on return trips.	Fairly extensive data structure (e.g., a characteristic database) and definition of levels of detail may be needed to handle possibly many buildings and improve ability to report results. With many buildings, only one trip per building may be acceptable.
Project design	Project personnel usually know what they want to measure and report, and may not want to be confused by complex approach in this chapter. Knowledge of experimental approaches may also be understood minimally but still applied successfully, without specific declaration, to small project.	Three higher-level general approaches: (1) fewer buildings or systems with more detailed measurements, (2) many buildings or systems with less detailed measurements, or (3) many buildings or systems with more detailed measurements. Six major experimental design approaches: on/off, before/after, test/reference, simulated occupancy, nonexperimental reference, engineering field test.
Reporting	Reporting is informal to somewhat formal (more like straightforward engineering project than research project). Reported results are often minimal but provide key information sought.	Research project report is likely required, possibly hundreds of pages long, with multiple appendices. Extensive databases likely generated and must be quality checked and corrected for use by others. Data user access procedures may have to be developed. Databases must be maintained over years in many cases and must be well documented. Extensive research results may have been generated and should be reported. For example, Fracastoro and Lyberg (1983) discussion of guiding principles for residential projects is 300 pages long.

Energy systems in multifamily buildings can be much more complex than those in single-family homes, but the types of diagnostics are similar: combustion equipment diagnostics, air leakage measurements, and infrared thermography to identify thermal defects or moisture problems (DeCicco et al. 1995). Some techniques are designed to determine the operating efficiency of steam and hot-water boilers and to measure air leakage between apartments.

Diagnostic techniques have been designed to measure the overall airtightness of office building envelopes and the thermal performance of walls (Armstrong et al. 2001; Persily et al. 1988; Sellers et al. 2004). Practicing engineers also use a host of monitoring techniques to aid in diagnostics and analysis of equipment energy performance. Portable data loggers are often used to collect time-synchronized distributed data, allowing multiple data sets (e.g., chiller performance and ambient conditions) to be collected and quickly analyzed. Similar short-term monitoring procedures are used to provide more detailed and complete commercial building system commissioning. Short-term, in situ tests have also been developed for pumps, fans, and chillers (Phelan et al. 1997a, 1997b).

Diagnostics are also well suited to support development and implementation of building energy management programs (see Chapter 36). Long-term diagnostic measurements have even supported energy improvements (Liu et al. 1994). Diagnostic measurement projects can generally be designed using procedures adapted to specific project requirements (see the section on Steps for Project Design and Implementation).

Equipment for diagnostic measurement may be installed temporarily or permanently to aid energy management efforts. Designers should consider providing permanent or portable check metering of major electrical loads in new building designs. Building automation systems also can be used to collect the data required for diagnostics. The same concept can be extended to fuel and thermal energy use.

2. SMALL PROJECTS

Most energy metering projects are done on a small scale and will have the project steps described in this chapter simplified and compacted. This section describes briefly how to use the information in this chapter for a small project.

Small projects will still be potentially impacted by the issues described here, but if only a small group of people are doing all the work, they can choose what to address and how to address the project requirements. Table 2 compares small-project approaches and the material in this chapter.

How to Use This Chapter for Small Projects

- Skim through the chapter and make a few notes on items that may apply for the project in question.
- Generate a brief project plan to make sure major issues that may cause problems are not overlooked.
- Generate a brief checklist from the item notes for final check-off during or at the end of project.
- Clarify what building or site characteristics data may be needed, and be sure to collect those data.
- Analyze data from the start, to make sure there are no quality or data issues.
- Consider whether any data should be made available to others at the end of the project, and if so, develop a data format for exchange.
- Skim through the chapter again when the report is being prepared to gather ideas about what to include in the report.

3. PROTOCOLS FOR PERFORMANCE MONITORING

Examples of procedures (**protocols**) for evaluating energy savings for projects involving retrofit of existing building energy systems are

presented here. These protocols should also be useful to those interested in more general building energy monitoring.

Building monitoring has been significantly simplified and made more professional in recent years by the development of fairly standardized monitoring protocols. Although there may be no way to define a protocol to encompass all types of monitoring applications, repeatable and understandable methods of measuring and verifying retrofit savings are needed. However, following a protocol does not replace adequate project planning and careful assessment of project objectives and constraints.

Residential Retrofit Monitoring

Protocols for residential building retrofit performance can answer specific questions associated with actual measured performance. For example, Ternes (1986) developed a single-family retrofit monitoring protocol, a data specification guideline that identifies important parameters to be measured. Both one-time and time-sequential data parameters are covered, and parameters are defined carefully to ensure consistency and comparability between experiments. Discrepancies between predicted and actual performance, as measured by the energy bill, are common. This protocol improves on billing data methods in two ways: (1) internal temperature is monitored, which eliminates a major unknown variable in data interpretation; and (2) data are taken more frequently than monthly, which potentially shortens monitoring duration. Utility bill analysis generally requires a full season of pre- and post-retrofit data. The single-family retrofit protocol may require only a single season.

Ternes (1986) identified both a minimum set of data, which must be collected in all field studies that use the protocol, and optional extensions to the minimum data set that can be used to study additional issues. See Table 3 for details. Szydowski and Diamond (1989) developed a similar method for multifamily buildings.

The single-family retrofit monitoring protocol recommends a before/after experimental design, and the minimum data set allows performance to be measured on a normalized basis with weekly time-series data. (Some researchers recommend daily.) The protocol also allows hourly recording intervals for time-integrated parameters, an extension of the basic data requirements in the minimum data set. The minimum data set may also be extended through optional data parameter sets for users seeking more information.

Data parameters in this protocol have been grouped into four data sets: basic, occupant behavior, microclimate, and distribution system (Table 3). The minimum data set consists of a weekly option of the basic data parameter set. Time-sequential measurements are monitored continuously during the field study. These are all time-integrated parameters (i.e., appropriate average values of a parameter over the recording period, rather than instantaneous values).

This protocol also addresses instrumentation installation, accuracy, and measurement frequency and expected ranges for all time-sequential parameters (Table 4). The minimum data set (weekly option of the basic data) must always be collected. At the user's discretion, hourly data may be collected, which allows two optional parameters to be monitored. Parameters from the optional data sets may be chosen, or other data not described in the protocol added, to arrive at the final data set.

This protocol standardizes experimental design and data collection specifications, enabling independent researchers to compare project results more readily. Moreover, including both minimum and optional data sets and two recording intervals accommodates projects of varying financial resources.

Commercial Retrofit Monitoring

Several related guidelines have been created for the particular application of retrofit savings (M&V). ASHRAE *Guideline 14* provides methods for effectively and reliably measuring the energy and demand savings due to building energy projects. The guideline

Table 3 Data Parameters for Residential Retrofit Monitoring

	Recording Period	
	Minimum	Optional
<i>Basic Parameters</i>		
House description		Once
Space-conditioning system description		Once
Entrance interview information		Once
Exit interview information		Once
Pre- and post-retrofit infiltration rates		Once
Metered space-conditioning system performance		Once

defines a minimum acceptable level of performance in measuring energy and demand savings from energy conservation measures in residential, commercial, or industrial buildings. These measurements can serve as the basis for commercial transactions between energy services providers and customers who rely on measured energy savings as the basis for financing payments. Three approaches are discussed: whole building, retrofit isolation, and calibrated simulation. The guideline includes an extensive resource on physical measurement, uncertainty, and regression techniques. Example M&V plans are also provided.

The *International Performance Measurement and Verification Protocol* (IPMVP 2007) provides guidance to buyers, sellers, and financiers of energy projects on quantifying energy savings performance of energy retrofits. The Federal Energy Management Program has produced guidelines specific to federal projects, which include many procedures usable for calculating retrofit savings in nonfederal buildings (FEMP 2008).

On a more detailed level, ASHRAE Research Project RP-827 resulted in separate guidelines for in situ testing of chillers, fans, and pumps to evaluate installed energy efficiency (Phelan et al. 1997a, 1997b). The guidelines specify the physical characteristics to be measured; number, range, and accuracy of data points required; methods of artificial loading; and calculation equations with a rigorous uncertainty analysis.

In addition to these specialized protocols for particular monitoring applications, a number of specific laboratory and field measurement standards exist (see Chapter 57), and many monitoring source books are in circulation.

Table 4 Time-Sequential Parameters for Residential Retrofit Monitoring

Data Parameter	Accuracy ^a	Range	Stored Value per Recording Period	Scan Rate ^b	
				Option 1	Option 2
<i>Basic Parameters</i>					
Heating/cooling equipment energy consumption	3%		Total consumption	15 s	15 s
Indoor temperature	1.0°F	50 to 95°F	Average temperature	1 h	1 min
House gas or oil consumption	3%		Total consumption	15 s	15 s
House electricity consumption	3%		Total consumption	15 s	15 s
Wood heating use	1.0°F	50 to 800°F	Average surface temperature or total use time		1 min
Domestic hot water	3%		Total consumption	15 s	15 s
<i>Optional Data Parameter Sets</i>					
<i>Occupant behavior</i>					
Additional indoor temperatures	1.0°F	50 to 95°F	Average temperature	1 h	1 min
Heating thermostat set point	1.0°F	50 to 95°F	Average set point		1 min
Cooling thermostat set point	1.0°F	50 to 95°F	Average set point		1 min
Indoor humidity	5% rh	10 to 95% rh	Average humidity	1 h	
<i>Microclimate</i>					
Outdoor temperature	1.0°F	-40 to 120°F	Average temperature	1 h	1 min
Solar radiation	10 Btu/h · ft ²	0 to 350 Btu/h · ft ²	Total horizontal radiation	1 min	1 min
Outdoor humidity	5% rh	10 to 95% rh	Average humidity	1 h	1 min
Wind speed	0.5 mph	0 to 20 mph	Average speed	1 min	1 min
Wind direction	5°	0 to 360°	Average direction	1 min	1 min

^aAll accuracies are stated values.

^bApplicable scan rates if nonintegrating instrumentation is used.

Table 5 Performance Data Requirements of Commercial Retrofit Protocol

Projects with Submetering			
	Before Retrofit	After Retrofit	
Utility billing data (for each fuel)	12 month minimum	3 month minimum (12 months if weather normalization required)	
Submetered data (for all recording intervals)	All data for each major end use, up to 12 months	All data for each major end use, up to 12 months	
	Type	Recording Interval	Period Length
Temperature data (daily maximum and minimum must be provided for any periods without integrated averages)	Maximum and minimum —or— Integrated averages	Daily —or— Same as for submetered data but not longer than daily	Same as billing data length —or— Length of submetering
Projects Without Submetering			
	Before Retrofit	After Retrofit	
Utility billing data (for each fuel)	12 month minimum	12 month minimum	
	Type	Recording Interval	Period Length
Temperature data	Maximum and minimum —or— Integrated averages	Daily	Same as billing data length

Finally, MacDonald et al. (1989) developed a protocol for field monitoring studies of energy improvements (retrofits) for commercial buildings. Similar to the residential protocol, it addresses data requirements for monitoring studies. Commercial buildings are more complex, with a diverse array of potential efficiency improvements. Consequently, the approach to specifying measurement procedures, describing buildings, and determining the range of analysis must differ.

The strategy used for this protocol is to specify data requirements, analysis, performance data with optional extensions, and a building core data set that describes the field performance of efficiency improvements. This protocol requires a description of the approach used for analyzing building energy performance. The necessary performance data, including identification of a minimum data set, are outlined in Table 5.

Commercial New Construction Monitoring

New building construction offers the potential for monitoring building subsystem energy consumption at a reasonable cost. Information obtained by monitoring operating hours or direct energy consumption can benefit building owners and managers by

- Verifying design intent
- Alerting them to inefficient or improper operation of equipment
- Providing data that can be useful in determining benefits of alternative operating strategies or replacement equipment
- Evaluating costs of operation for extending occupancy hours for special conditions or event
- Demonstrating effects of poor maintenance or identifying when maintenance procedures are not followed
- Diagnosing and fixing comfort and other space condition problems
- Diagnosing power quality problems
- Submetering tenants
- Verifying/improving savings of a performance contract
- Maintaining persistence of energy savings

To provide data necessary to improve building systems operation, monitoring should be considered for boilers, chillers, cooling towers, heat pumps, air-handling unit fans, large fan-coil units, major exhaust fans, major pumps, comfort cooling compressors, lighting panels, electric heaters, receptacle panels, substations, motor control centers, major feeders, service water heaters, process loads, and computer rooms.

Guidance on energy monitoring to determine energy savings for new construction design modifications is available in IPMVP (2006).

Construction documents may include provisions for various meters to monitor equipment and system operation. Some equipment can be specified to have factory-installed hour meters that record actual operating hours of the equipment. Hour meters can also be easily field-installed on any electrical motor.

More sophisticated power-monitoring systems, with electrical switchgear, substations, switchboards, and motor control centers, can be specified. These systems can monitor energy demand, energy consumption, power factor, neutral current, etc., and can be linked to a computer. These same systems can be installed on circuits to existing or retrofit fans, chillers, lighting panels, etc. Some equipment commonly used for improving system efficiency, such as variable-frequency drives, can be provided with capability to monitor kilowatt output, kilowatt-hours consumed, and other variables.

Using direct digital control (DDC) or building automation systems for monitoring is particularly appropriate in new construction. These systems can monitor, calculate, and record system status, water use, energy use at the main meter or of particular end-use systems, demand, and hours of operation, as well as start and stop building systems, control lighting, and print alarms when systems do not operate within specified limits. Initial specification of the new control system should include specific requirements for sensors, calculations, and trend logging and reporting functions. Special issues related to sensors and monitoring approaches can be found in Piette et al. (2000).

4. COMMON MONITORING ISSUES

Field monitoring projects require effective management of various professional skills. Project staff must understand the building systems being examined, quality control of data, data management, data acquisition, and sensor technology. In addition to data collection, processing, and analysis, the logistics of field monitoring projects require coordinating equipment procurement, delivery, and installation.

Key issues include the **accuracy** and **reliability** of collected data. Projects have been compromised by inaccurate or missing data, which could have been avoided by periodic sensor calibration and ongoing data verification.

Planning

Many common problems in monitoring projects can be avoided by effective and comprehensive planning.

Project Goals. Project goals and data requirements should be established before hardware is selected. Unfortunately, projects are often driven by hardware selection rather than by project objectives, either because monitoring hardware must be ordered several months before data collection begins or because project initiation procedures are lacking. As a result, the hardware may be inappropriate for the particular monitoring task, or critical data points may be overlooked.

Project Costs and Resources. After goal setting, the feasibility of the anticipated project should be reviewed in light of available resources. Projects to which significant resources can be devoted usually involve different approaches from those with more limited resources. This issue should be addressed early on and reviewed throughout the course of the project. Although it is difficult at this early stage to assess with certainty the cost of an anticipated project, rough estimates can be quite helpful.

Data Products. It is important to establish the type and format of the final results calculated from data before selecting data points. Failure to plan these data products first may lead to failure to answer critical questions.

Data Management. Failure to anticipate the typically large amounts of data collected can lead to major difficulties. The

computer and personnel resources needed to verify, retrieve, analyze, and archive data can be estimated based on experience with previous projects.

Data Quality Control. It is also important to check and validate the quality and reasonableness of data before use. Failure to use some type of quality control typically results in data errors and invalid results.

Commitment. Many projects require long-term commitment of personnel and resources. Project success depends on long-term, daily attention to detail and on staff continuity.

Accuracy Requirements. The required accuracy of data products and accuracy of the final data and experimental design needed to meet these requirements should be determined early on. After the required accuracy is specified, the sample size (number of buildings, control buildings, or pieces of equipment) must be chosen, and the required measurement precision (including error propagation into final data products) must be determined. Because trade-offs must usually be made between cost and accuracy, this process is often iterative. It is further complicated by a large number of independent variables (e.g., occupants, operating modes) and the stochastic nature of many variables (e.g., weather).

Advice. Expert advice should be sought from others who have experience with the type of monitoring envisioned.

Implementation and Data Management

The following steps can facilitate smooth project implementation and data management:

- Calibrate sensors before installation. Spot-check calibration on site. During long-term monitoring projects, recalibrate sensors periodically. Appropriate procedures and standards should be used in all calibration procedures [see ASHRAE *Guideline* 14 and IPMVP (2007)].
- Track sensor performance regularly. Quick detection of sensor failure or calibration problems is essential. Ideally, this should be an automated or a daily task. The value of data is high because they may be difficult or impossible to reconstruct.
- Generate and review data on a timely, periodic basis. Problems that often occur in developing final data products include missing data from failed sensors, data points not installed because of planning oversights, and anomalous data for which there are no explanatory records. If data products are specified as part of general project planning and produced periodically, production problems can be identified and resolved as they occur. Automating the process of checking data reliability and accuracy can be invaluable in keeping the project on track and in preventing sensor failure and data loss.

Data Analysis and Reporting

For most projects, the collected data must be analyzed and put into reports. Because the objective of the project is to translate these data into information and ultimately into knowledge and action, the importance of this step cannot be overemphasized. Clear, convenient, and informative formats should be devised in the planning stages and adhered to throughout the project.

Close attention must be paid to resource allocation to ensure that adequate resources are dedicated to verification, management, and analysis of data and to ongoing maintenance of monitoring equipment. As a quality control procedure and to make data analysis more manageable, these activities should be ongoing. Data analysis should be carefully defined before the project begins.

5. STEPS FOR PROJECT DESIGN AND IMPLEMENTATION

This section describes methodology for designing effective field monitoring projects that meet desired goals with available project

Fig. 1 Methodology for Designing Field Monitoring Projects

resources. The task components and relationships among the nine activities constituting this methodology are identified in Figure 1. The activities fall into four categories: project management, project development, resolution and feedback, and production quality and data transfer. Field monitoring projects vary in terms of resources, goals and objectives, data product requirements, and other variables, affecting how methodology should be applied. Nonetheless, the methodology provides a proper framework for advance planning, which helps minimize or prevent implementation problems.

An iterative approach to planning activities is best. The scope, accuracy, and techniques can be adjusted based on cost estimates and resource assessments. The initial design should be performed simply and quickly to estimate cost and evaluate resources. If costs are out of line with resources, such as when desired levels of instrumentation exceed the resources available for the project, adjustments are needed. Planning should identify and resolve any trade-offs necessary to execute the project within a given budget. Examples include reducing the scope of the project versus relaxing instrumentation specifications or accuracy requirements. These decisions often depend on what questions the project must answer and which questions can be eliminated, simplified, or narrowed.

One frequent oversight in project planning is failing to reserve sufficient time and resources for later analysis and reporting of data. Unanticipated additional costs associated with data collection and problem resolution should not jeopardize these resources.

Documenting the results of project planning should cover all nine parts of the process. This report can be a useful part of an overall project plan that may document other important project information, such as resources to be used, schedule, etc.

Part One: Identify Project Objectives, Resources, and Constraints

Start with a clear understanding of the decision to be made or action to be taken as a result of the project. The goals and objectives statement determines the overall direction and scope of the data collection and analysis effort. The statement should also list questions to be answered by empirical data, noting the error or uncertainty associated with the desired result. Realistic assessment of error is needed because requiring too small an uncertainty leads to an overly complex and expensive project. It is important in monitoring projects that a data acquisition plan be developed and followed with a clear idea of the **research questions** to be answered.

Resource requirements for equipment, personnel, and other items must feed into budget estimates to determine expected funding needed for different project objectives. Scheduling requirements must also be considered, and any project constraints defined and considered. Trade-offs on budget and objectives require that priorities be established.

Even if a project is not research-oriented, it is attempting to obtain information, which can be stated in the form of questions. Research questions can have varying scopes and levels of detail, addressing entire systems or specific components. Some examples of research questions follow:

- Measurement and verification: Have contractors fulfilled their responsibilities of installing equipment and improving systems to achieve the agreed-upon energy savings?
- Classes of buildings: To an accuracy of 20%, how much energy has been saved by using a building construction/performance standard mandated in the jurisdiction?
- Particular buildings: Has a lapse in building maintenance caused energy performance to degrade?
- Particular components: What is the average reduction in demand charges during summer peak periods because of the installation of an ice storage system in this building?

Research questions vary widely in technical complexity, generally taking one of the following three forms:

- How does the building/component perform?
- Why does the building/component perform as it does?
- Which building/component should be targeted to achieve optimal cost-effectiveness?

The first form of question can sometimes be answered generically for a class of typical buildings without detailed monitoring and analysis, although detailed planning and thorough analysis are still required. The second and third forms usually require detailed monitoring and analysis and, thus, detailed planning.

In general, more detailed and precise goal statements are better. They ensure that the project is constrained in scope and developed to meet specific accuracy and reliability requirements. Usually, projects attempt to answer more than one research question, and often consider both primary and secondary questions. All data collected should have a purpose of helping to answer a project question; the more specific the questions, the easier identifying required data becomes.

Part Two: Specify Building and Occupant Characteristics

Measured energy data will not be meaningful later to people who were not involved in the project unless the characteristics of the building being monitored and its use have been documented. To meet this need, a data structure (e.g., a characteristic database) can be developed to describe the buildings.

Building characteristics can be collected at many levels of detail, depending on the type of monitoring project and the parameters that affect results. For projects that determine whole-building performance, it is important to provide at least enough detail to document the following:

- General building type, use, configuration, and envelope (particularly energy-related aspects)
- Building occupant information (number, occupancy schedule, activities)
- Internal loads
- HVAC system descriptive information characterizing key parameters affecting HVAC system performance
- Type and quantity of other energy-using systems
- Any building changes that occur during the monitoring project

- Entrance interview information focusing on energy-related behavior of building occupants before monitoring
- Exit interview information documenting physical or lifestyle changes at the test site that may affect data analysis

The minimum level of detail is known as **summary characteristics** data. **Simulation-level characteristics** (detailed information collected for hourly simulation model input) may be desirable for some buildings. Regardless of the level of detail, the data should provide a context for analysts, who may not be familiar with the project, to understand the building and its energy use.

Part Three: Specify Data Products and Project Output

The objective of a monitoring project is typically not to produce data, but to answer a question. However, the data must be of high quality and must be presented to key decision makers and analysts in a convenient, informative format. The specific **data products** (format and content of data needed to meet project goals and objectives) must be identified and evaluated for feasibility and usefulness in answering project questions identified in Part One. Final data products must be clearly specified, together with the minimum acceptable data requirements for the project. It is important to clearly define an **analysis path** showing what will be calculated and what data are necessary to achieve desired results. Clear communication is critical to ensure that project requirements are satisfied and factors contributing to monitoring costs are understood.

Evaluation results can be presented in many forms, often as interim and final reports (possibly by heating and/or cooling season), technical notes, or technical papers. These documents must convey specific results of the field monitoring clearly and concisely. They should also contain estimates of the accuracy of the results.

The composition of data presentations and analysis summaries should be determined early to ensure that all critical parameters are identified (Hough et al. 1987). For instance, mock-ups of data tables, charts, and graphs can be used to identify requirements. Previously reported results can be used to provide examples of useful output. Data products should also be prioritized to accommodate possible cost trade-offs or revisions resulting from other steps in the process such as error analysis (see Part Seven).

Although requirements for the minimum acceptable data results can often be specified during planning, data analysis typically reveals further requirements. Thus, budget plans should include allowances and optional data product specifications to handle additional or unique project output requirements uncovered during data analysis.

Longer-term goals and future information needs should be anticipated and explained to project personnel. For example, a project may have short- and long-term data needs (e.g., demonstrating reductions in peak electrical demand versus demonstrating cost-effectiveness or reliability to a target audience). Initial results on demand reduction may not be the ultimate goal, but rather a step toward later presentations on cost reductions achieved. Thus, it is prudent to consider long-term and potential future data needs so that additional supporting information, such as photographs or testimonials, may be identified and obtained.

Part Four: Specify Monitoring Design Approach

A general monitoring design must be developed that defines three interacting factors: the number of buildings in the study, the monitoring approach (or experimental design), and the level of detail in the data being measured. A less detailed or precise approach can be considered if the number of buildings is increased, and vice versa. If the goal is related to a specific product, the monitoring design must isolate the effects of that product. Haberl et al. (1990) discuss monitoring designs. For example, for retrofit M&V, protocols have been written allowing a range of different monitoring methods,

from retrofit verification to retrofit isolation (ASHRAE *Guideline* 14; FEMP 2008; IPMVP 2007). Some monitoring approaches are more suited than others to larger numbers of buildings.

Specifying the monitoring design approach is particularly important because total building performance is a complex function of several variables, changes in which are difficult to monitor and to translate into performance. Unless care is taken with measurement organization and accuracy, uncertainties, errors (noise), and other variations, such as weather, can make it difficult to detect performance changes of less than 20% (Fracastoro and Lyberg 1983).

In some cases, judgment may be required in selecting the number of buildings involved in the project. If an owner seeks information about a particular building, the choice is simple: the number of buildings in the experiment is fixed at one. However, for other monitoring applications, such as drawing conclusions about effects in a sample population of buildings, some choice is involved. Generally, error in the derived conclusions decreases as the square root of the number of buildings increases (Box 1978). A specific project may be directed at

- Fewer buildings or systems with more detailed measurements
- Many buildings or systems with less detailed measurements
- Many buildings or systems with more detailed measurements

For projects of the first type, accuracy requirements are usually resolved initially by determining expected variations of measured quantities (dependent variables) about their average values in response to expected variations of independent variables. For buildings, a typical concern is the response of heating and cooling loads to changes in temperature or other weather variables. The response of building lighting energy use to daylighting is another example of the relationship between dependent and independent variables. Fluctuations in response are caused by (1) outside influences not quantified by measured energy use data and (2) limitations and uncertainties associated with measurement equipment and procedures. Thus, accuracy must often be determined using statistical methods to describe mean tendencies of dependent variables.

For projects of the second and third types, the increased number of buildings improves confidence in the mean tendencies of the dependent response(s) of interest. Larger sample sizes are also needed for experimental designs with control groups, which are used to adjust for some outside influences. For more information, see Box (1978), Fracastoro and Lyberg (1983), and Hirst and Reed (1991). Projects can also use more complex, multilevel measurement and modeling approaches to handle an array of technologies or help improve confidence in results (Hughes and Shonder 1998).

Most monitoring procedures use one or more of the following general experimental approaches:

Before/After. Building, system, or component energy consumption is monitored before and after a new component or retrofit improvement is installed. Changes in factors not related to the retrofit, such as the weather and building operation during the two periods, must be accounted for, often requiring a model-based analysis (Fels 1986; Hirst et al. 1983; Kissock et al. 1992; Robison and Lambert 1989; Sharp and MacDonald 1990). This experimental design is the primary concern of most current building energy monitoring documents (ASHRAE *Guideline* 14; FEMP 2008; IPMVP 2002).

Test/Reference. The building energy consumption data of two “identical” buildings, one with the product or retrofit being investigated, are compared. Because buildings cannot be absolutely identical (e.g., different air leakage distributions, insulation effectiveness, temperature settings, and solar exposure), measurements should be taken before installation as well, to allow calibration. Once the product or retrofit is installed, any deviation from the calibration relationship can be attributed to the product or retrofit (Fracastoro and Lyberg 1983; Levins and Karnitz 1986).

Table 6 Advantages and Disadvantages of Common Experimental Approaches

Mode	Advantages	Disadvantages
Before/after	No reference building required. Same occupants implies smaller occupant variations. Modeling processes are mostly identical before/after.	Weather different before/after. More than one heating/cooling season may be needed. Model is required to account for weather and other changes.
Test/reference	One season of data may be adequate. Small climate difference between buildings.	Reference building required. Calibration phase required (may extend testing to two seasons). Occupants in either or both buildings can change behavior.
On/off	No reference building required. One season may be adequate. Modeling processes are mostly identical before/after. Most occupancy changes are small.	Requires reversible product. Cycle may be too long if time constants are large. Model is required to account for weather differences in cycles. Dynamic model accounting for transients may be needed.
Simulated occupancy	Noise from occupancy is eliminated. A variety of standard schedules can be studied.	Not “real” occupants. Expensive apparatus required. Extra cost of keeping building unoccupied.
Nonexperimental reference	Cost of actual reference building eliminated. With simulation, weather variation is eliminated.	Database may be lacking in strata entries. Simulation errors and definition of reference problematic. With database, weather changes usually not possible.
Engineering field test	Information focused on product of interest. Minimal number of buildings required. Same occupants during test.	Extensive instrumentation of product processes required. Models required to extrapolate to other buildings and climates. Occupancy effects not determined.

Source: Partially based on Fracastoro and Lyberg (1983).

On/Off. If the retrofit or product can be activated or deactivated at will, energy consumption can be measured in a number of repeated on/off cycles. On-period consumption is then compared to off-period consumption (Cohen et al. 1987; Woller 1989).

Simulated Occupancy. In some cases, the desire to reduce noise can lead the experimenter to postulate certain standard profiles for temperature set points, internal gains, moisture release, or window manipulation and to introduce this profile into the building by computer-controlled devices. The reference is often given by the test/reference design. In this case, both occupant and weather variations are nearly eliminated in the comparison (Levins and Karnitz 1986).

Nonexperimental Reference. A reference for assessing the performance of a building can be derived nonexperimentally using (1) a normalized, stratified performance database, such as energy use per unit area classified by building type (MacDonald and Wasserman 1989) or (2) a reasonable standard building, simulated by a calculated hourly or bin-method calibrated building energy performance model subject to the same weather, equipment type, and occupancy as the monitored building.

This design, also called **calibrated simulation**, is a secondary concern of current building energy monitoring documents (ASHRAE *Guideline 14*; FEMP 2008; IPMVP 2007).

Engineering Field Test. When an experiment focuses on testing a particular piece of equipment, actual performance in a building is often of interest. The building provides a realistic environment for testing the equipment for reliability, maintenance requirements, and comfort and noise levels, as well as energy usage. Energy consumption of mechanical equipment is significantly affected by the system control strategy. Testing procedures related to determining energy impacts should be designed to incorporate the control strategy of the equipment and its system (Phelan et al. 1997a, 1997b). This type of monitoring and testing can also be used to calibrate computer simulation models of as-built and as-operated buildings, which can then be used to evaluate whole-building energy consumption. The equipment may be extensively instrumented.

Some of the general advantages and disadvantages of these approaches are listed in Table 6 (Fracastoro and Lyberg 1983). Combining monitoring design choices has been successful (e.g., the before/after and test/reference approaches). Questions to be considered in choosing a monitoring approach include the following:

- Can the building alteration being investigated be turned on and off at will? The on/off design offers considerable advantages.
- Are occupancy and occupant behavior critical? Changes in building tenants, use schedules, internal gains, temperature set points, and natural or forced ventilation practices should be considered because any one of these variables can ruin an experiment if it is not constant or accounted for.
- Are actual baseline energy performance data critical? In before/after designs, time must be allotted to characterize the before case as precisely as the after case. For instances in which heating and cooling systems are evaluated, data may be required for a wide range of anticipated ambient conditions.
- Is it a test of an individual technology, or are multiple technologies installed as a package being tested? If the effects of individual technologies are sought, detailed component data and careful model-based analyses are required.
- Does the technology have a single mode or multiple modes of operation? Can the modes be controlled to suit the experiment? If many modes are involved, it is necessary to test over a variety of conditions and conduct model-based analysis (Phelan et al. 1997a, 1997b).

Part Five: Specify Data Analysis Procedures and Algorithms

Data are useless unless they are distilled into meaningful products that allow conclusions to be drawn. Too often, data are collected and never analyzed. This planning step focuses on specifying the minimum acceptable data analysis procedures and algorithms and detailing how collected data will be processed to produce desired data products. In this step, monitoring practitioners should do the following:

- Determine the independent variables and analysis constants to be measured in the field (e.g., fan power, lighting and receptacle power, indoor air temperature).
- Develop engineering calculations and equations (algorithms) necessary to convert field data to end products. This may include use of statistical methods and simulation modeling.
- Specify detailed items, such as the frequency of data collection, the required range of independent variables to be captured in the data set, and the reasons certain data must be obtained at different

Table 7 Whole-Building Analysis Guidelines

Project Goal	Class of Method		
	Empirical (Billing Data)*	Time-Integrated Model*	Dynamic Model
Building evaluation	Yes, but expect fluctuations in 20 to 30% range.	Yes, extra care needed beyond 15% uncertainty.	Yes, extra care needed beyond 10% uncertainty.
Building retrofit evaluation	Not generally applicable using monthly data, unless large samples are used. Requires daily data and various normalization techniques for reasonable accuracy.	Yes, but difficult beyond 15% uncertainty. Method cannot distinguish multiple retrofit effects.	Yes, can resolve 5% change with short-term tests. Can estimate multiple retrofit effects.
Component evaluation	Not applicable.	Not applicable unless submetering is done to supplement.	Yes, about 5% accuracy, but best with submetering.

Note: Error figures are approximate for total energy use in a single building. All methods improve with selection of more buildings.

*Accuracy can be improved by decreasing time step to weekly or daily. These methods are of little use when outdoor temperature approaches balance temperature.

intervals. For example, 15 min interval demand data are assembled into hourly data streams to match utility billing data.

Determine proper NIST-traceable calibration standards for each sensor type to be used. For details, see the references in ASHRAE *Guideline 14* and IPMVP (2007) for specific types of sensors. However, it is often impractical to implement standards in the field. For example, maintaining the length of straight ductwork required for an airflow sensor is usually difficult, requiring compromise.

Algorithm inputs can be assumed values (e.g., energy value of a unit volume of natural gas), one-time measurements (e.g., leakage area of a house), or time-series measurements (e.g., fuel consumption and outdoor and indoor temperatures at the site). The algorithms may pertain to (1) utility level aggregates of buildings, (2) particular whole-building performance, or (3) performance of instrumented components.

Chapter 19 of the 2013 *ASHRAE Handbook—Fundamentals* contains a lengthy discussion on modeling procedures, and readers should consult this material for more information on modeling. In this chapter, the discussion is categorized differently, with a view toward procedures and issues related to field energy monitoring projects.

Table 7 provides a guide to selecting an analysis method. The error quotations are rough estimates for a single-building scenario.

Empirical Methods. Although empirical methods are the simplest, they can have large uncertainty and may generate little or no information for small sample sizes. The simplest empirical methods are based on annual consumption values, tracking annual numbers and looking for degradation. Questions about building performance relative to other buildings are based on comparing certain performance indices between the building and an appropriate reference. The ENERGY STAR tools (www.energystar.gov) are probably the best-known performance comparison tools.

For commercial buildings, the most common simple index is the **energy use intensity (EUI)**, which is annual consumption, either by fuel type or summed over all fuel types, divided by the gross floor area [see MacDonald and Wasserman (1989) for a discussion of indices]. Comparison is often made only on the basis of general building type, which can ignore potentially large variations in how much floor area is heated or cooled, climate, number of workers in a building, number and type of computers in a building, and HVAC systems. Variations can be accommodated somewhat by stratifying the database from which the reference EUI is chosen. Computer simulations are often used to set reasonable comparison values.

The Commercial Buildings Energy Consumption Survey (CBECS) database (summarized in Chapter 36) has been used to develop ENERGY STAR energy use benchmarking methods for several building types in the United States. Many of the building tools have been updated to 2003 data. Building types covered as of June 2009 include the following:

- Offices (general offices, financial centers, bank branches, and courthouses)
- K to 12 schools
- Supermarkets/grocery stores
- Hospitals (acute care and children's)
- Medical offices and clinics
- Hotels/motels
- Residence halls/dormitories
- Retail stores
- Warehouses (refrigerated and nonrefrigerated)

For some of these building types, some secondary spaces are allowed:

- Computer data centers
- Garages and parking lots
- Swimming pools

Initial work in this area covered only electricity use for office buildings (Sharp 1996), but the methods have been extended to cover all fuels for the listed building types. Results show that electricity use of office buildings is most significantly explained by the number of workers in the building, number of computers, whether the building is owner-occupied, and number of operating hours each week. Only a subset of these parameters might be used to determine a benchmark within a specific census division. ENERGY STAR documentation on current tools and the performance normalization factors can be found at www.energystar.gov/buildings.

Simple empirical methods applied to retrofit applications should include at least some periods of data on daily energy use and average daily temperature (recorded locally) to account for variations in occupancy and building schedules. Monthly EUI or billing data provide more information for empirical analysis and can be used for extended analysis of energy impacts of retrofit applications, for example, in **conditional demand analysis** (Hirst and Reed 1991). Monthly data can also be used to detect billing errors, improper equipment operation during unoccupied hours, and seasonal space condition problems (Haberl and Komor 1990a, 1990b). Daily data are often used in these analyses, and raw hourly total building consumption data, when available, provide more detailed information on occupied versus unoccupied performance. Hourly, daily, monthly, and annual EUI across buildings can be directly compared when reduced to average power per unit area (power density). To avoid false correlations, the method of analysis should have statistical significance that can be traced to realistic parameters (Haberl et al. 1996).

Model-Based Methods. These techniques allow a wide range of additional data normalization to potentially improve the accuracy of comparisons and provide estimates of cause-and-effect relations. The analyst must carefully define the system and postulate a useful form of the governing energy balance/system performance equation or system of equations. Explicit terms are

retained for equipment or processes of particular interest. As part of the data analysis, whole-building data (driving forces and thermal or energy response) are used to determine the model's significant parameters. The parameters themselves can provide insight, although parameter interpretation can be difficult, particularly with time-integrated billing data methods. The model can then be used for normalization processes as well as future diagnostic and control applications. Two general classes of models are used in analysis methods: time-integrated methods and dynamic techniques (Balcomb et al. 1993). Simulation modeling results used for design of new buildings typically do not cover all energy used in a building and thus are usually difficult to compare with empirical data.

Time-Integrated Methods. Based on algebraic calculation of the building energy balance, time-integrated methods are often used before data comparison to correct annual consumption for variations in outdoor temperature, internal gains, and internal temperature (ASHRAE 2002; Fels 1986; Haberl and Claridge 1987). This type of correction is essential for most retrofit applications.

Time-integrated methods can be used with whole-building energy consumption data (billing data) or with submetered end-use data. For example, standard time-integrated methods are often used to separately integrate end-use consumption data on heating, cooling (Ternes and Wilkes 1993), domestic water heating, and others for comparison and analysis. Time-integrated methods are generally reliable, as long as the following three conditions are accounted for:

- *Appropriate time step.* Generally, the time step should be as long as or longer than the response time of the building or building system for which energy use is being integrated. For example, the response of daylighting controls to natural illumination levels can be rapid, allowing short time steps for data integration. In contrast, the response of cooling system energy use to changes in cooling load can be comparatively slow. In this instance, either a time step long enough to average over these slow variations or a dynamic model should be used. In general, an appropriate time step should account for the physical behavior of the energy system(s) and the expression of this behavior in model parameters.
- *Linearity of model results.* Generally, time-integrated models should not be applied to data used to estimate nonlinear effects. Air infiltration, for example, is nonlinear when estimated using wind speed and indoor/outdoor temperature difference data in certain models. Estimation errors result if these parameters are independently time-integrated and then used to calculate air infiltration. These nonlinear effects should be modeled at each time step (each hour, for example).
- *End-use uniformity within data set.* End-use data sets should be **uniform** (i.e., should not inadvertently contain observations with measurements of end uses other than those intended). During mild weather, for example, HVAC systems may provide both heating and cooling over the course of a day, creating data observations of both heating and cooling measurements. In a time-integrated model of heating energy use, these cooling energy observations lead to error. These observations should be identified or otherwise flagged by their true end use.

For whole-building energy consumption data (billing data), reasonable results can be expected from heating analysis models when the building is dominantly responsive to indoor/outdoor temperature differences. Billing data analysis yields little of interest when internal gains are large compared to skin loads, as in large commercial buildings and industrial applications. Daily, weekly, and monthly whole-building heating season consumption integration steps have been used (Claridge et al. 1991; Fels 1986; Sharp and MacDonald 1990; Ternes 1986). Cooling analysis results have been less reliable because cooling load is not strictly proportional to variable-base cooling degree-days (Fels 1986; Haberl et al. 1996; Kissock et al.

1992). Problems also arise when solar gains are dominant and vary by season.

Dynamic Techniques. Dynamic models, both **macrodynamic** (whole-building) or **microdynamic** (component-specific), offer great promise for reducing monitoring duration and increasing conclusion accuracy. Furthermore, individual effects from multiple measures and system interactions can be examined explicitly. Dynamic whole-building analysis is generally accompanied by detailed instrumentation of specific technologies.

Dynamic techniques create a dynamic physical model for the building, adjusting model parameters to fit experimental data (Duffy et al. 1988; Subbarao 1988). In residential applications, computer-controlled electric heaters can be used to maintain a steady interior temperature overnight, extracting from these data an experimental value for the building steady-state load coefficient. A cooldown period can also be used to extract information on internal building mass thermal storage. Daytime data can be used to renormalize the building response (computed from a microdynamic model) to solar radiation, which is particularly appropriate for buildings with glazing areas over 10% of the building floor area (Subbarao et al. 1986). Once the data with electric heaters have been taken, the building can be used as a dynamic calorimeter to assess the performance of auxiliary heating and cooling systems.

Similar techniques have been applied to commercial buildings (Burch et al. 1990; Norford et al. 1985). In these cases, delivered energy from the HVAC system must be monitored directly in lieu of using electric heaters. Because ventilation is a major variable in the building energy balance, outdoor airflow rate should also be monitored directly. Simultaneous heating and cooling (common in large buildings) requires a multizone treatment, which has not been adequately tested in any of the dynamic techniques.

Equipment-specific monitoring guidelines using dynamic modeling have been successfully tested in a variety of applications. For fans and pumps, relatively simple regression techniques from short-term monitoring provided accurate estimates of annual energy consumption when combined with an annual equipment load profile. For chillers, a thermodynamic model used with short-term monitoring captured the most important operating parameters for estimating installed annual energy performance. In all cases, the key to accurate model results was capturing a wide enough range of the independent load variable in monitored data to reflect annual operating characteristics (Phelan et al. 1997a, 1997b).

Part Six: Specify Field Data Monitoring Points

Careful specification of field monitoring points is critical to identifying variables that need to be monitored or measured in the field to produce required data.

The analysis method determines the data to be measured in the field. The simplest methods require no onsite instrumentation. As methods become more complex, data channels increase. For engineering field tests conducted with dynamic techniques, up to 100 data channels may be required.

Because metering projects are often conducted in buildings with changing conditions, special consideration must be given to identifying and monitoring significant changes in climate, systems, and operation during the monitoring period. Additional monitoring points may be required to measure variables that are assumed to be constant, insignificant, or related to other measured variables to draw sound conclusions from the measurements. Because the necessary data may be obtained in several ways, data analysts, equipment installers, and data acquisition system engineers should work together to develop tactics that best suit the project requirements. It is important to anticipate the need for supplemental measurements in response to project needs that may not become apparent until actual equipment installation occurs.

The cost of data collection is a nonlinear function of the number, accuracy, and duration of measurements that must be considered while planning within budget constraints. Costs per data point typically decrease as the number of points increases, but increase as accuracy requirements increase. Duration of monitoring can have many different effects. If the extent of data applications is unknown, such as in research projects, the value of other concurrent measurements should be considered because the incremental cost of alternative analyses may be small.
