*Nominal values based on ZIP codes. See www.usgs.gov for calculator to check actual S_s using latitude and longitude for best results.

Once the overall seismic forces F_p and F_{pv} have been determined (as indicated in the previous section or per the local code requirement), the loads at the restraint points can be determined. There are many different valid methods that can be used to determine these loads, but this section suggests a couple of simple approaches.

Under some instances (particularly those relating to life-support issues in hospital settings), newer code requirements indicate that critical equipment must be seismically qualified to ensure its continued operation during and after a seismic event. Special care must be taken in these situations to ensure that equipment has been shaker

tested or otherwise certified to meet the maximum anticipated seismic load. Table 6 illustrates some load combination calculations.

1.4 COMPUTATION OF LOADS AT BUILDING CONNECTION

ASCE *Standard 7* is based on **load- and resistance-factor design (LRFD)**. In the past, building codes have been based on **allowable stress design (ASD)**. Both are allowed for seismic restraint design. Load factors and load combinations that must be considered in design are defined in Chapter 2 of ASCE *Standard 7*. If a component is anchored with post-installed anchors, the design is usually accomplished using provisions of LRFD.

The Load Combinations of Section 2.4.1 of ASCE *Standard 7* must be considered in the design. Generally, for rigidly mounted components, Combination 8 is the critical combination to be considered.

The forces of the restraint holding the equipment in position include shear and tensile forces. It is important to determine the number of bolts that are affected by the earthquake forces. The direction of the lateral force should be evaluated in both horizontal directions, as shown in Figure 1. All bolts or as few as a single bolt may be affected.

Simple Case

Figure 1 shows a rigid floor-mount installation of a piece of equipment with the center of gravity at the approximate center of the restraint pattern. To calculate the shear force, the sum of the forces in the horizontal plane is

$$0 = F_p - V \quad (6)$$

The equipment shown in Figure 1 has two bolts on each side, so that four bolts are in shear. Using a single-axis moment equation to calculate the tension force, the sum of the moments for overturning results in an overturning moment (OTM) and resisting moment (RM).

For Figure 1, two bolts are in tension. See Example 1 for applications of the OTM and RM. See ASCE *Standard 7* for load combinations that adjust the D (dead load) and E (earthquake load). Shear and tension forces V and T should be calculated independently for both axes, as shown in the front and side views. See the examples for complete analysis.

General Case

The classic method used to distribute seismic loads equally distributes lateral loads among the restraints and then modifies these loads as a function of the weight eccentricity. Worst-case weight, vertical seismic load, and overturning components are combined to determine a maximum vertical load component. This **polar method** is in common use and works well for most applications.

A second, **lump mass method**, proportions the restraint loads based on the equipment weight and distribution. When working with larger seismic forces or unstable equipment, this offers the option of more evenly distributing the seismic load, reducing anchor size and peak restraint requirements. Eccentric center of gravity (cg) loads are not required to be carried out to the corner restraints as in the polar method; this technique deemphasizes stresses in the equipment frame and is more suitable for nonrigid equipment types. Eccentric loads can be addressed with either the polar method or the lump mass method.

Fig. 1 Equipment with Rigidly Mounted Structural Bases

Note: Although only two methods of computing forces for more general equipment cases are illustrated here, there are many other valid methods that can be used to distribute the restraint forces. It is important that any method used include the ability to account for equipment weight, seismic uplift forces, overturning forces, and an offset center of gravity within the equipment.

Polar Method

Lateral forces are equally distributed among the restraints. If the equipment's center of gravity does not coincide with its geometric center, a rotational factor is added to account for the imbalance. This factor is determined in three steps. First, compute the true chord length in the horizontal plane between the equipment's center of gravity and the restraints' geometric center. Second, multiply the equipment total seismic lateral force by this length (to obtain a rotational moment). Third, divide this figure by the number of moment-resisting restraints times their distance from the geometric center. (The moment-resisting restraints are those farthest and equally spaced from the geometric center.) The resulting load can then be added to the original (balanced) figure. This method transfers all imbalance loads to the corner restraints and provides a valid method of restraint as long as the equipment acts as a rigid body. The assumption that a piece of equipment can transfer these loads out to the corners becomes less accurate as the equipment becomes less rigid.

Calculation of the tensile/compressive forces at the restraints is more complex than that for determining the shear loads, and must include weight, vertical seismic force, overturning forces, and (if isolated) the type of isolator/restraint system used. The total tensile and compressive forces are the worst-case summation of each of these components. For clarity, each component is addressed here as a separate entity.

The nominal weight component at each restraint is simply the total operating weight divided by the number of restraints. The vertical seismic force is simply the weight component at each location multiplied by the vertical seismic force factor in terms of the total F_{pv} load expressed in g s, the gravitational constant (F_{pv}/W_p , where F_{pv} is the vertical seismic load component as defined by the code and W_p is the total operating weight of the equipment). This can be directed either upward or downward when summing forces.

Lump Mass Method

In the lump mass method, the total equipment weight is distributed among the restraints in a manner that reflects the equipment's actual weight distribution. There are many methods of determining the distribution analytically or by testing, although they are not addressed in this section. Frequently, a weight distribution can be obtained from the equipment manufacturer.

Once the static point loads are obtained or computed for each restraint location, they can be multiplied by the lateral seismic acceleration factor (F_p/W_p) to determine lateral forces at each restraint point. Thus, if the weight at each restraint point is W_n , then

$$V_{eff} = (F_p/W_p)W_n \quad (7)$$

This method considers the loads at all the restraints individually and computes the overturning forces for each in 1° increments for a full 360° of possible seismic wave front angle; it is only practical to perform using a spreadsheet. The total lateral seismic force F_p is divided into x - and y -axis components for each possible wave front approach angle. These forces are multiplied by the height of the equipment center of gravity above the point of restraint h_{cg} . The resulting moments are then resolved into forces at each restraint based on the x - and y -axis moment arms associated with the particular restraint location and the proportion of the load that it will bear.

Resilient Support Factors

If the equipment being restrained is isolated, the following three factors must be considered:

- For all forces that are not directed along the principal axes, only the corner restraints can be considered to be effective. Thus, for either distribution method, only the corner restraints can be considered capable of absorbing vertical loads.
- If the restraints are independent (separate entities) from the spring isolation elements and if, when exposed to uplift loads, vertical spring forces are not absorbed within the housing of an integral isolator/restraint assembly, the weight factor determined in the first step of the vertical load analysis should be ignored. (This is because any effect that a weight reduction has on the attachment hardware forces is replaced by an approximately equal vertical force component from the spring.)
- If the gap in the restraint element exceeds 1/4 in., the final computed forces must be doubled per the IBC.

Building Attachment

The common attachment arrangements are directly bolting with steel bolts and lag bolts, welding, or anchoring to concrete using post-installed anchors. To evaluate the combined effective tensile and shear forces that act simultaneously on these connections, a separate analysis is required.

If allowable stress design (ASD) data are used to size hardware for through-bolted connections for the IBC codes, which are strength based, the loads may be reduced by a factor of 1.4. If LRFD is used when selecting for the hardware, the 1.4 factor does not apply. All allowable capacities used for concrete post-installed anchor bolts selection should be drawn from ICC-ES test reports. These values reflect test data on a single anchor and should be derated for applications where embedment, edge distances, spacing, or location vary from the test conditions. Anchor manufacturers may have selection software to determine anchor bolt capacities that consider installation conditions. It should also be noted that the values published in ES reports may be either ASD or LRFD values and may need to be converted for compatibility with the (LRFD) IBC code being used.

1.5 ANSI STEEL BOLTS

For direct attachment with through bolts using ASD criteria, the design capacity of the attachment hardware should be based on criteria established in the American Institute of Steel Construction (AISC) manual. Based on the use of A307 bolts, the basic formula for computing allowable tensile stress when shear stresses are present is

$$T_{allow} = 26,000 - 1.8S_v \quad (8)$$

where S_v is the shear stress in the bolt in psi. T_{allow} , the maximum allowable tensile stress, must not exceed 20,000 psi.

However, because these stresses are appropriate for dead- plus live-load combinations, they can be appropriately inflated by 1.33

when allowable stress design provisions are used and when they are used to resist wind and seismic loads as well. Peak bolt loads are based on the maximum permitted stress multiplied by the nominal bolt area.

1.6 LAG SCREWS INTO TIMBER

Acceptable loads for lag screws into timber can be obtained from the *National Design Specification*® (NDS®) for *Wood Construction* (AWC 2005). Selected fasteners must be secured to solid lumber, not to plywood or other similar material. Withdrawal force design values are a function of the screw size, penetration depth, and wood density and can be increased by a factor of 1.6 for short-term seismic or wind loads. Table 9.2A in the NDS identifies withdrawal forces on a force/embedment depth basis. Note that the values published in this table are capacities in both ASD and LRFD. In addition, NDS Table 9.4.2 introduces deration factors for reduced edge distance and bolt spacing.

In timber construction, the interaction formula given in Equation (8) does not apply. Instead, per Section 9.3.5 of the NDS, the equation is

$$Z'_a = (W'p)Z'/[(W'p)\cos^2\alpha + Z'\sin^2\alpha] \quad (9)$$

where

Z' = shear capacity drawn from Table 9.3A

W' = side grain withdrawal force = $1800G^{3/2}D^{3/4}$

G = specific gravity of the timber

D = diameter

p = embedment depth of screw

α = angle of composite force measured flat with surface of timber

1.7 CONCRETE POST-INSTALLED ANCHOR BOLTS

Capacities are manufacturer/anchor-type specific. Capacity data should be obtained from the anchor's current ES report. Where failure of the steel does not govern the tensile load, strength-based design (LRFD) should be used. Obtain anchor information from the anchor ICC-ES (formerly ICBO-ESR) report based on anchor and installation factors. For groups of anchors, special factors are required and American Concrete Institute *Standard* 318-08 should be consulted.

ASD Applications

Interaction Formula. To evaluate the combined effective tension and shear forces that act simultaneously on the bolt, use the either of the following equations:

$$(T_{eff}/T_{allow\ ASD})^{5/3} + (V_{eff}/V_{allow\ ASD})^{5/3} \leq 1.0 \quad (10)$$

or

$$(T_{eff}/T_{allow\ ASD}) + (V_{eff}/V_{allow\ ASD}) \leq 1.2 \quad (11)$$

However, if $T_{eff} \leq 0.2T_{allow\ ASD}$ the full T_{eff} can equal $T_{allow\ ASD}$, or if $V_{eff} \leq 0.2V_{allow\ ASD}$ the full V_{eff} can equal $V_{allow\ ASD}$.

LRFD Applications

The engineer must select an anchor for use from a current evaluation report for anchors that satisfy provisions of ACI 318 Appendix D or ACI 355 (the provisions are the same). From ACI 318, the capacity of the anchor must be reduced in accordance with the following:

$$T = 0.75\phi N \quad (12)$$

$$V = 0.75\phi V \quad (13)$$

The interaction equation for LRFD is modified as follows:

$$(T_{eff}/T_{allow}) + (V_{eff}/V_{allow}) \leq 1.2 \quad (14)$$

Types of Concrete Post-Installed Anchors

Several types of anchor bolts for insertion in concrete are manufactured. Wedge and undercut anchors perform better than self-drilling, sleeve, or drop-in types. Adhesive anchors are stronger than other anchors, but lose their strength at elevated temperatures (e.g., on rooftops and in areas damaged by fire).

Wedge anchors have a wedge on the end with a small clip around the wedge. After a hole is drilled, the bolt is inserted and the external nut tightened. The wedge expands the small clip, which bites into the concrete.

Undercut anchors expand to seat against a shoulder cut in the bottom of the anchor hole. Although these have the highest capacity of commonly available anchor types, the cost of the extra operation to cut the shoulder in the hole greatly limits the frequency of their use in the field.

A **self-drilling anchor** is basically a hollow drill bit. The anchor is used to drill the hole and is then removed. A wedge is then inserted on the end of the anchor, and the assembly is drilled back into place; the drill twists the assembly fully in place. The self-drilling anchor is heavily affected by the skill of the craft and usually not rated for seismic applications.

Drop-in expansion anchors are hollow cylinders with a tapered end. After they are inserted in a hole, a small rod is driven through the hollow portion, expanding the tapered end. These anchors are only for shallow installations because they have no reserve expansion capacity. These anchors are usually not rated for seismic applications.

A **sleeve anchor** is a bolt covered by a threaded, thin-wall, split tube. As the bolt is tightened, the thin wall expands. Additional load tends to further expand the thin wall. The bolt must be properly preloaded or friction force will not develop the required holding force. These anchors are typically not used in seismic applications because of the limited reserve capacity.

Large screw anchors are one-piece anchors that have a concrete cutting thread. These anchors were initially designed to be installed without a specified torque, but torque is used to ensure contact at the rated embedment.

Adhesive anchors may be in glass capsules or installed with various tools. Pure epoxy, polyester, or vinyl ester resin adhesives are used with a threaded rod supplied by the contractor or the adhesive manufacturer. Some adhesives have a problem with shrinkage; others are degraded by heat. However, some adhesives have been tested without protection to 1100°F before they fail (all mechanical anchors will fail at this temperature). Where required, or if there is a concern, anchors should be protected with fire retardants similar to those applied to steel decks in high-rise buildings.

The manufacturer's instructions for installing the anchor bolts should be followed. ES reports have further information on allowable forces for design. Use a safety factor of 2 or as required by ES reports if the installation has not been inspected as required by the IBC Chapter 17 on special inspection.

Stainless steel anchors are required for use in outdoor applications noted in the latest versions of the IBC code.

1.8 WELD CAPACITIES

Weld capacities may be calculated to determine the size of welds needed to attach equipment to a steel plate or to evaluate raised support legs and attachments. A static analysis provides the effective tension and shear forces. The capacity of a weld is given per unit length of weld based on the shear strength of the weld material. For steel welds, the allowable shear strength capacity is 16,000 psi on the throat section of the weld. The section length is 0.707 times the specified weld size.

For a 1/16 in. weld, the length of shear in the weld is $0.707 \times 1/16 = 0.0442$ in. The allowable weld force $(F_w)_{allow}$ for a 1/16 in. weld is

$$(F_w)_{allow} = 0.0442 \times 16,000 = 700 \text{ lb per inch of weld} \quad (15)$$

For a 1/8 in. weld, the capacity is 1400 lb/in.

The effective weld force is the sum of the vectors calculated in terms of effective shear and tension shall be reduced. Because the vectors are perpendicular, they are added by the method of the square root of the sum of the squares (SRSS), or

$$(F_w)_{eff} = \sqrt{(T_{eff})^2 + (V_{eff})^2} \quad (16)$$

The length of weld required is given by the following equation:

$$\text{Weld length} = (F_w)_{eff} / (F_w)_{allow} \quad (17)$$

1.9 SEISMIC SNUBBERS

Several types of snubbers are manufactured or field fabricated. All snubber assemblies should meet the following minimum requirements to avoid imparting excessive accelerations to HVAC&R equipment:

- Impact surface should have a high-quality elastomeric surface that is not cemented in place.
- Resilient material should be easy to inspect for damage and be replaceable.
- Snubber system must provide restraint in all directions.
- Snubber capacity should be verified either through test or by analysis and should be certified by an independent, registered engineer to avoid serious design flaws.

Typical snubbers are classified as Types A through J (Figure 2).

Type A. Snubber built into a resilient mounting. All-directional, molded bridge-bearing quality neoprene element is a minimum of 1/8 in. thick.

Type B. Isolator/restraint. Stable isolation spring bears on the base plate of the fixed restraining member. Earthquake motion of isolated equipment is restrained close to the base plate, minimizing pullout force to the base plate anchorage.

Type C. Spring isolator with built-in all-directional restraints. Restraints have molded neoprene elements with a minimum thickness of 1/8 in. A neoprene sound pad should be installed between the spring and base plate. Sound pads below the base plate are not recommended for seismic installations.

Type D. Integral all-directional snubber/restrained spring isolator with neoprene element.

Type E. Fully bonded neoprene mount capable of withstanding seismic loads in all directions with no metal-to-metal contact.

Type F. All-directional three-axis snubber with neoprene element. The neoprene element of bridge-bearing quality is a minimum of 3/16 in. thick. Snubber must have a minimum of two anchor bolt holes.

Type G. Lateral snubber. Neoprene element is a minimum of 1/4 in. thick. Upper bracket is welded to the equipment.

Type H. Restraint for floor-mounted equipment consisting of interlocking steel assemblies lined with resilient elastomer. Bolted to equipment and anchored to structure through slotted holes to allow field adjustment. After final adjustment, weld anchor to floor bracket and weld angle clip to equipment or, alternatively, fill slots with adhesive grout to prevent slip.

Type I. Single-axis, single-direction lateral snubber. Neoprene element is a minimum of 1/4 in. thick. Minimum floor mounting is with two anchor bolts. Must be used with a minimum of eight, two per corner.

Type J. A telescopic snubber for floor-mounted equipment, with a molded neoprene element, designed to distribute the seismic

Fig. 2 Seismic Snubbers

force to a larger surface area in a pipe section. This snubber is an all-directional restraint system when a minimum of four snubbers are installed. The molded neoprene element is a minimum of 1/4 in. thick and is installed with an air gap of 3/16 in. not to exceed 1/4 in.

1.10 SEISMIC RESTRAINTS

For suspended equipment, pipes, ducts, and raceways, it is necessary to restrain lateral movement resulting from seismic acceleration applied to the component. Unrestrained, suspended equipment and related systems will sway violently back and forth, impacting nearby building material and possibly overstressing the hanger rods. The overstressed rods will eventually break and the equipment crash down. To prevent this swaying, suspended components are restrained by one of two methods: a wire rope system, or a rigid brace using steel struts, angles, or other steel elements.

Wire rope restraints are a restraint assembly for suspended equipment, piping, or ductwork consisting of high-strength, galvanized steel aircraft cable. A typical cable restraint system is shown in Figure 3. Cable should have a certified break strength. Some

models are color-coded for easy field verification. Cable must be manufactured to meet or exceed minimum materials and standard requirements. Break strengths must be per ASTM E-8 procedures. A safety factor of 2 may be used when prestretched cable is used with end connections designed to meet the cable break strength. Cables are installed to prevent excessive seismic motion and arranged so they do not engage during normal operation. Equipment suspended with vibration isolators must use cable restraints to avoid degrading the isolation. Rigid type bracing will short out the vibration isolators. To prevent buckling of the hanger rods, add a rod stiffener as shown in Figure 4.

Secure the cable to structure and to the braced component through a bracket or stake eye designed to meet the cable restraint rated capacity. Cables are typically secured using one of the following methods:

- Factory-installed permanent stake eye
- Field-looped through bracket and secured with cable grips
- Field-looped through bracket and secured with oval sleeve
- Factory brackets with integral cable clamps to secure cable

When cables are looped through a field-supplied bracket or support hole, a cable thimble should be used to protect the cable. Many factory-supplied brackets are designed specifically for allowing a looped cable through without a thimble. See the manufacturer's instructions for details. Figure 5 shows typical cable restraint details with various attachment methods. Typical attachment methods to secure the rigid brace to the structure and component are shown in Figure 6.

1.11 RESTRAINT OF PIPE AND DUCT RISERS

When piping and ductwork run vertically through a structure, they are identified as risers. They are subject to the same seismic and (less commonly) wind forces as are piping and ductwork oriented horizontally. The primary difference is that the forces that act along the axis of the riser are the summation of the vertical seismic forces

and gravity loads, whereas on horizontal systems, the axial forces are simply the horizontal seismic or wind force.

It is also important to recognize, when providing restraint, that risers of any significant length and variation in temperature require support that allows thermally driven changes in the riser's overall length to be accommodated. Because the vertical seismic and wind forces are small compared to gravity forces, axial restraint for the riser can normally be provided with only minor increases in the size of the specialized components used to support the system. Because of the potential of damage to the restraint or support systems as the system grows or shrinks, it is not recommended that redundant axial restraint systems be fitted to a riser. Instead, the primary support system should be designed or selected to meet the job requirement.

Fig. 3 Cable Restraint

Fig. 4 Rod Stiffener

Fig. 5 Types of Cable Connections

Fig. 6 Strut End Connections

Risers of significant length are also fitted with some type of stabilization devices. These can be as simple as snug-fitting holes in the floors that the risers penetrate, to specialized brackets or guiding devices that maintain the alignment of the piping or duct while still allowing it to expand or contract. As is the case with the vertical forces, the components used for guidance can frequently be used to provide resistance against seismic or wind events if they are sized and attached appropriately.

If, in the lateral load case, the components used to provide guidance are not adequate to resist the design seismic or wind load conditions, redundant, seismically qualified systems should be fitted to perform this task.

All axial and lateral restraints fitted to risers must be effective against forces that may act in any horizontal or vertical direction as applicable. In addition, the attachment hardware used must be seismically qualified components (e.g., anchors), installed in accordance with seismically qualified procedures.

1.12 EXAMPLES

The following examples are provided to assist in the design of equipment anchorage to resist seismic forces. For Examples 1 through 4, assume the provisions contained in ASCE 7-05 apply, $I_p = 1.5$, $S_s = 0.85$, site soil class is C, and the equipment is located at the top of a 50 ft building. Also include an uplift force component $F_{pv} = 0.2S_{DS}D$ where D is the dead load for all examples. Examples 1 through 5 are solved using the polar method of analysis while Example 6 is solved by the lump mass method.

Note: These examples assume that $I_p = 1.5$. This assumes that the equipment being considered is essential to the continued function of the building following an earthquake or contains hazardous materials. ASCE 7-05 Section 13.2.2 requires that this equipment be certified as being operable after the design earthquake.

Example 1. Anchorage design for equipment rigidly mounted to the structure (see Figure 7).

From Equations (1) to (4), calculate the lateral seismic force and its vertical component. Note that for post-installed, if the anchor satisfies the requirements of ASCE 7, Section 13.4.2, the value of R_p is the same as the component being considered. Post-installed anchors with current evaluation reports published by ICC or other agencies are deemed to be compliant with the provisions of ACI 355 or 318 Appendix D and thus satisfy Section 13.4.2. For rigidly mounted mechanical equipment (period < 0.06 s or > 16.7 Hz), a_p from Table 2 is 1.0, otherwise $a_p = 2.5$.

ASCE 7 is based on load and resistance factor design (LRFD). In the past, building codes have been based on allowable stress design (ASD). Load factors and load combinations defined in Chapter 2 of ASCE 7

Fig. 7 Equipment Rigidly Mounted to Structure (Example 1)

must be considered in design. If a component is anchored with post-installed anchors, the design can only be accomplished using LRFD.

The first step in the load determination process is to determine S_{DS} using the following equation and $F_a = 1.1$ (from Table 3, site class C):

$$S_{DS} = 2F_a S_s / 3 = 2 \times 1.1 \times 0.85 / 3 = 0.623$$

Using this value for S_{DS} Equation (1) gives

$$F_p = \left[\frac{0.4 \times 1.0 \times 0.623 \times 1000}{\frac{2.5}{1.5}} \right] \left(1 + 2 \times \frac{50}{50} \right) = 450 \text{ lb}$$

Equation (2) shows that F_p need not be greater than

$$1.6 \times 0.623 \times 1.5 \times 1000 = 1495 \text{ lb}$$

Equation (3) shows that F_p must not be less than

$$0.3 \times 0.623 \times 1.5 \times 1000 = 280 \text{ lb}$$

Therefore $F_p = 450$ lb.

When considering provisions of LRFD, a vertical acceleration component must be considered per ASCE 7, Section 12.4.2.2.

$$F_{pv} = 0.2 \times S_{DS} \times D = 0.2 \times 0.623 \times 1000 = 125 \text{ lb}$$

For Allowable Stress Design (ASD)

The load combinations of Section 2.4.1 of ASCE 7 must be considered in the design. For rigidly mounted components, Combination 8 is generally the critical combination to be considered.

Calculate the overturning moment OTM:

$$OTM = F_p h_{cg} = 450 \times 40 = 18,000 \text{ in} \cdot \text{lb} \tag{18}$$

Calculate the resisting moment RM:

$$RM = W_p \left(\frac{d_{min}}{2} \right) = 1000 \left(\frac{28}{2} \right) = 14,000 \text{ in}\cdot\text{lb} \quad (19)$$

$$T = [18,000(0.7) - 14,000(0.6)]/28 = 150 \text{ lb} \quad (20)$$

Calculate T_{eff} per bolt:

$$T_{eff} = 150/2 = 75 \text{ lb per through-bolt or lag screw} \quad (21)$$

Calculate shear force per bolt:

$$V_{eff} = 450/(4 \times 1.4) = 78 \text{ lb per through-bolt or lag screw} \quad (22)$$

Load and Resistance Factor Design (LRFD)

The load combinations of Section 2.3.2 of ASCE 7 must be considered in the design. For rigidly mounted components, Combination 7 is generally the critical combination to be considered.

$$RM = (W_p - F_{pv})d_{min}/2 = (1000 - 125)28/2 = 12,250 \text{ in}\cdot\text{lb} \quad (23)$$

$$T_{eff} = [18,000 - 0.9(12,250)]/28(2) = 125 \text{ lb} \quad (24)$$

Per ASCE 7 Section 13.4.2, if post-installed anchors are used, an additional 1.3 factor is applied to all E loads. The 1.3 factor applies for projects using ASCE 7-05. This factor is not required for applications using ASCE 7-10.

$$OTM = 18,000(1.3) = 23,400 \text{ in}\cdot\text{lb} \quad (25)$$

$$T_{eff} = [23,400 - 12,250(0.9)]/28(2) = 221 \text{ lb} \quad (26)$$

Case 1. Equipment attached to a timber structure

Before computing interaction forces, the computed loads must be reduced by a factor of 1.4 to make them compatible with the capacity data listed in the *National Design Specification® (NDS®) for Wood Construction* (AWC 1997). The lateral load V_{eff} becomes 112.5/1.4 or 80.4 lb per bolt and the pullout load T_{eff} becomes 103/1.4 = 73.5 lb per bolt. For the capacity of the connection, a resulting combined load and angle relative to the mounting surface must be computed. The combined load is

$$T\alpha_{eff} = \sqrt{(T_{eff})^2 + (V_{eff})^2} = \sqrt{(80.4)^2 + (73.5)^2} = 109 \text{ lb}$$

The angle $\alpha = \arcsin (T_{eff}/Z'\alpha) = 42.5^\circ$, where $Z'\alpha$ is the allowable lag screw load multiplied by applicable factors and $Z'\alpha$ is the factored allowable lag screw load at angle α from the mounting surface.

Selected fasteners must be secured to solid lumber, not to plywood or other similar material. The following calculations are made to determine whether a 1/2 in. diameter, 4 in. long lag screw in redwood will hold the required load. For this computation, it is assumed that bolt spacing, edge distance, temperature, and other factors do not reduce the bolt capacity (see NDS for further details) and that the load allowable factor for short-term wind or seismic loads is 1.6.

From Table 9.3A in the NDS, for redwood, $G = 0.37$, and Z perpendicular to the grain is 512 lb.

From Table 9.2A in the NDS, for $G = 0.37$ and 3.5 in. full thread, $W = 385 \times 3.5 = 1350 \text{ lb}$.

Substituting into the combined load for lag bolts [Equation (9)] gives

$$Z'\alpha = \frac{(385 \times 3.5)512}{(385 \times 3.5)42.5 + 512 \sin^2 42.5} = 714 \text{ lb}$$

Therefore, a 1/2 in. diameter, 4 in. long lag screw can be used at each corner of the equipment.

Case 2. Equipment attached to steel

For equipment attached directly to a steel member, analysis is the same as that shown in case 1. Capacities for the attaching bolts are given in the *Manual of Steel Construction* (AISC 1989). See Chapter J of the AISC Specification for design provisions.

For this example $T_{eff}/T_{ASD} = 125/4410 = 0.02 < 0.2$; therefore a combined tension shear check need not be performed on the connection.

Therefore, 1/2 in. diameter bolts can be used.

Example 2. Anchorage design for equipment supported by external spring mounts (Figure 8) and attached to concrete using nonshallow post-installed anchors.

A mechanical or acoustical consultant should choose the type of isolator or snubber or combination of the two. Then the product vendor should select the actual spring snubber.

Using ASCE 7, the lateral force F_p must be recalculated using new factors. S_{DS} remains as in Example 1. For expansion anchors, $R_p = 1.5$, and for resiliently mounted mechanical equipment, a_p from Table 2 is 2.5.

The basic force equation is then (Note: using $R_p = 1.5$ is conservative, because the anchors must comply with 13.4.2 of ASCE 7. The numbers could be modified)

$$F_p = \left(\frac{0.4 \times 2.5 \times 0.623 \times 1000}{1.5} \right) \left(1 + 2 \times \frac{50}{50} \right) = 1869 \text{ lb}$$

Equation (2) indicates that F_p need not be greater than

$$1.6 \times 0.623 \times 1.5 \times 1000 = 1495 \text{ lb}$$

Equation (3) indicates that F_p must not be less than

$$0.3 \times 0.623 \times 1.5 \times 1000 = 280 \text{ lb}$$

The vertical force F_{pv} equals

$$F_{pv} = 0.2S_{DS}D = 0.2 \times 0.623 \times 1000 = 125 \text{ lb}$$

Because the equipment is resiliently supported, footnote b to Table 13.6-1 of ASCE 7 indicates that the computed forces may need to be doubled. Therefore, F_p is $1495 \times 2 = 2990 \text{ lb}$ and F_{pv} is $125 \times 2 = 250 \text{ lb}$.

Assume that the center of gravity cg of the equipment coincides with the center of gravity of the isolator group.

If T = maximum tension on isolator and C = maximum compression on isolator, then

$$T, C = \frac{-W_p + F_{pv}}{4} \pm F_p h_{cg} \frac{\cos \theta}{2b} + F_p h_{cg} \frac{\sin \theta}{2a} \quad (27)$$

$$= \frac{-W_p + F_{pv}}{4} \pm \frac{F_p h_{cg}}{2} \left(\frac{\cos \theta}{b} + \frac{\sin \theta}{a} \right)$$

To find maximum T or C , set $dT/d\theta = 0$:

$$\frac{dT}{d\theta} = \frac{F_p h_{cg}}{2} \left(\frac{\cos \theta}{b} + \frac{\sin \theta}{a} \right) = 0 \quad (28)$$

$$\theta_{max} = \tan^{-1}(b/a) = \tan^{-1}(28/48) = 30.26^\circ \quad (29)$$

$$T = \frac{-W_p + F_{pv}}{4} + \frac{F_p h_{cg}}{2} \left(\frac{\cos \theta_{max}}{b} + \frac{\sin \theta_{max}}{a} \right) \quad (30)$$

Fig. 8 Equipment Supported by External Spring Mounts

$$C = \frac{-W_p + F_{PV}}{4} - \frac{F_p h_{cg}}{2} \left(\frac{\cos \theta_{max}}{b} + \frac{\sin \theta_{max}}{a} \right) \quad (31)$$

$$T = \frac{-1000 + 250}{4} + \frac{2990 \times 40}{2} \left(\frac{\cos 30.26}{28} + \frac{\sin 30.26}{48} \right) = 2285 \text{ lb}$$

$$C = \frac{-1000 + 250}{4} + \frac{2990 \times 40}{2} \left(\frac{\cos 30.26}{28} + \frac{\sin 30.26}{48} \right) = -2660 \text{ lb}$$

Calculate the shear force per isolator:

$$V = (F_p / N_{iso}) = 2990 / 4 = 748 \text{ lb} \quad (32)$$

This shear force is applied at the operating height of the isolator. Uplift tension T on the vibration isolator is the worst condition for the design of the anchor bolts. The compression force C must be evaluated to check the adequacy of the structure to resist the loads.

$$(T_1)_{eff} \text{ per bolt} = T/2 = 2285/2 = 1143 \text{ lb} \quad (33)$$

The value of $(T_2)_{eff}$ per bolt due to overturning on the isolator is

$$(T_2)_{eff} = V \times \text{operating height} / dN_{bolt} \quad (34)$$

where d is the distance from edge of isolator base plate to center of bolt hole.

$$(T_2)_{eff} = (748 \times 8) / (3 \times 2) = 997 \text{ lb} \quad (35)$$

$$(T_{max})_{eff} = (T_1)_{eff} + (T_2)_{eff} = 1143 + 997 = 2140 \text{ lb} \quad (36)$$

$$V_{eff} = 748 / 2 = 374 \text{ lb} \quad (37)$$

See Example 1 for the design of the connections to the structural system.

Example 3. Anchorage design for equipment with a center of gravity different from that of the isolator group (Figure 10).

Anchor properties

$$I_x = 4B^2 \quad I_y = 4L^2 \quad (38)$$

Angles:

$$\theta = \tan^{-1}(B/L) \quad (39)$$

$$\alpha = \tan^{-1}(e_x/e_y) \quad (40)$$

$$\beta = 180 |\alpha - \theta| \quad (41)$$

$$\phi = \tan^{-1}(LI_x/BI_y) \quad (42)$$

Vertical reactions

$$(W_n)_{max/min} = W_p \pm F_{pv} \quad (43)$$

Vertical reaction caused by overturning moment

$$T_m = \pm F_p \left(\frac{B h_{cg}}{I_x} \cos \theta + \frac{L h_{cg}}{I_y} \sin \theta \right) \quad (44)$$

Fig. 9 Spring Mount Detail (Example 2)

Vertical reaction caused by eccentricity

$$(T_e)_{max/min} = (W_n)_{max/min} \left(\frac{B e_y}{I_x} + \frac{L e_y}{I_y} \right) \quad (45)$$

Vertical reaction caused by W_p

$$(T_w)_{max/min} = (W_n)_{max/min} / 4 \quad (46)$$

$$T_{eff} = T_m + (T_e)_{max} + (T_w)_{max} \text{ (always compression)} \quad (47)$$

$$T_{eff} = -T_m + (T_e)_{min} + (T_w)_{min} \text{ (tension if negative)} \quad (48)$$

Horizontal reactions

Horizontal reaction caused by rotation

$$V_{rot} = F_p \left(\frac{e_x^2 + e_y^2}{16(B^2 + L^2)} \right)^{0.5} \quad (49)$$

$$V_{dir} = F_p / 4 \quad (50)$$

$$V_{max} = (V_{rot}^2 + V_{dir}^2 - 2V_{rot}V_{dir} \cos \beta)^{0.5} \quad (51)$$

See Example 1 for the design of the connections to the structural system.

The values of T_{min} and V_{max} are used to design the anchorage of the isolators and/or snubbers, and T_{max} is used to verify the structure's adequacy to resist the vertical loads.

Example 4. Anchorage design for equipment with supports and bracing for suspended equipment (Figure 11). Equipment weight $W_p = 500$ lb.

Because post-installed anchors may not withstand published allowable static loads when subjected to vibratory loads, vibration isolators should be used between the equipment and the structure to damp vibrations generated by the equipment.

Anchor properties

$$I_x = 4B^2 \quad I_y = 4L^2 \quad (52)$$

Angle

$$\phi = \tan^{-1}(LI_x/BI_y) = 36.86^\circ \quad (53)$$

From Equation (43),

$$(W_n)_{max/min} = 500 \pm 124 = 624 \text{ lb or } 376 \text{ lb}$$

From Equation (44),

$$T_m = \pm 1122(0.132 + 0.075) = \pm 233 \text{ lb}$$

Fig. 10 Equipment with Center of Gravity Different from Isolator Group (in Plan View)

From Equation (45),

$$T_e = 0$$

From Equation (46),

$$(T_w)_{\max/\min} = 156 \text{ lb or } 94 \text{ lb}$$

From Equation (47),

$$(T_{\text{eff}})_{\max} = 233 + 0 + 156 = 389 \text{ lb (downward)}$$

From Equation (48),

$$(T_{\text{eff}})_{\max} = -233 + 0 + 94 = -139 \text{ lb (upward)}$$

Forces in the hanger rods:

Maximum tensile = 389 lb

Maximum compression = 139 lb

Force in the splay brace = $F_p \sqrt{2} = 1587 \text{ lb}$ at a 1:1 slope.

Because of the force being applied at the critical angle, as in Example 2, only one splay brace is effective in resisting the lateral load F_p .

Design of hanger rod/vibration isolator and connection to structure

When post-installed anchors are mounted to the underside of a concrete beam or slab, the allowable tension loads on the anchors must be reduced to account for cracking of the concrete. A general rule is to use half the allowable load. Some manufacturers have ICC reports that provide allowable values for anchors installed under the slab.

Determine whether a 1/2 in. wedge anchor with special inspection provisions will hold the required load.

$$T_{\text{allow}} = 600 \times 0.5 \times 2 = 600 \text{ lb} > T_{\text{eff}} = 389 \text{ lb}$$

Note: Splay braces are prestretched aircraft cables with enough slack so that isolators can fully function vertically.

Fig. 11 Supports and Bracing for Suspended Equipment

Therefore, a 1/2 in. rod and post drill-in anchor should be used at each corner of the unit.

For anchors installed without special inspection,

$$T_{\text{allow}} = 600 \times 0.5 = 300 \text{ lb} > T_{\text{eff}} = 389 \text{ lb}$$

Therefore, a larger anchor should be chosen.

Determine if the 1/2 in. hanger rod would require a stiffener if it is 36 in. long.

Design of splay brace and connection to structure

Force in the slack cable = 1587 lb.

Because all of the load must be resisted by a single cable, the forces in the connection to the structure are

$$V_{\text{max}} = 1122 \text{ lb} \quad T_{\text{max}} = F_p = 1122 \text{ lb}$$

Because the cable forces are relatively small, a 3/8 in. aircraft cable attached to clips with cable clamps should be used. The clips, in turn, may be attached to either the structure or the equipment.

The design of a post-installed anchor installation is similar to that shown in Example 1. Anchors installed through a metal deck will have lower capacities than anchors installed in a flat slab because of limited embedment depths. Take care to ensure that the design also satisfies the requirements contained in the evaluation report for the anchor specified.

Prescriptive provisions of ASCE 7 can be summarized as follows:

- Formulas for relative displacement of floor and ceiling can be conservatively estimated at 1% of the floor-to-ceiling height. This displacement must be used to determine the required horizontal flexibility of the pipe, duct, or electrical connections at the equipment interface.
- In ASCE 7, using all-directional snubbers with clearance of more than 1/4 in. increases F_p by a factor of 2.
- Component supports must be designed to accommodate component movement to prevent pounding on the structure or other components. This affects internal isolators and snubbers.
- Equipment components exposed to seismic impact forces and using nonductile housings must be designed using 25% of material yield stresses.
- Nonessential equipment, failure of which can cause essential equipment failure, must be designed as essential equipment.
- If the structure's site class is not provided in the contract documents, assume site class D, subject to change by the building official.
- For pipe or duct on any given run, if the distance from the bottom of the structure to the top of the support is 12 in. or less for all supports in that run, then that run does not need sway braces.
- Pipe and ducts may not be required to have sway braces, depending on size, material content, and importance factor. These conditions are defined in Chapter 13 of ASCE 7.

1.13 INSTALLATION PROBLEMS

The following should be considered when installing seismic restraints.

- Anchor location affects the required strengths. Concrete anchors should be located away from edges, stress joints, or existing fractures. The evaluation report for the chosen anchor should be followed as a guide for edge distances and center-to-center spacing.
- Supplementary steel bases and frames, concrete bases, or equipment modifications may void some manufacturers' warranties. Snubbers, for example, should be properly attached to a subbase. Bumpers may be used with springs.
- Static analysis does not account for the effects of resonant conditions within a piece of equipment or its components. Because all equipment has different resonant frequencies during operation and nonoperation, the equipment itself might fail even if the restraints do not. Equipment mounted inside a housing should be

seismically restrained to meet the same criteria as the exterior restraints.

- Snubbers used with spring mounts should withstand motion in all directions. Some snubbers are only designed for restraint in one direction; sets of snubbers or snubbers designed for multidirectional purposes should be used.
- Equipment must be strong enough to withstand the high deceleration forces developed by resilient restraints.
- Flexible connections should be provided between equipment that is braced and piping and ductwork that need not be braced.
- Flexible connections should be provided between isolated equipment and braced piping and ductwork.
- Bumpers installed to limit horizontal motion should be outfitted with resilient neoprene pads to soften the potential impact loads of the equipment.
- Anchor installations must be inspected (usually required for anchors resisting seismic forces); in many cases, damage occurs because bolts were not properly installed. To develop the rated restraint, bolts should be installed according to manufacturer's recommendations.
- Brackets in structural steel attachments should be matched to reduce bending and internal stresses at the joint.
- With the exception of heavy-duty clamps used to attach longitudinal restraints to piping systems, friction must not be relied on to resist any load. All connections should be positive and all holes should be tight-fitting or grouted to ensure minimal clearance at the attachment points.

2. WIND-RESISTANT DESIGN

Damage done to HVAC&R equipment by both sustained and gusting wind forces has increased concern about the adequacy of equipment protection defined in design documents. Two main areas of the HVAC&R system are exposed to wind events: the HVAC&R equipment and the exterior wall-mounted cladding components, such as intake and exhaust louvers. For HVAC&R equipment, the following calculative procedure generates the same type of total design lateral force used in static analysis of the seismic restraint. The value determined for the design wind force F_w can be substituted for the total design lateral seismic force F_p when evaluating and choosing restraint devices. For wall-mounted components, a

Table 7 Definition of Exposure Categories

Exposure B. Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions the size of single-family dwellings or larger. Use of this exposure category is limited to those areas for which terrain representative of Exposure B prevails upwind for at least 2600 ft or 20 times the height of the building or structure, whichever is greater.

Exception: For buildings with mean roof height less than or equal to 30 ft, the upwind distance may be reduced to 1500 ft.

Exposure C. Open terrain with scattered obstructions having heights generally less than 30 ft. This category includes flat open country, grasslands, and all water surfaces in hurricane-prone areas. Exposure C applies for all cases where Exposure B or D do not apply.

Exposure D. Flat, unobstructed areas exposed to wind and flowing over open water outside of hurricane-prone regions for a distance of at least 1 mile. This exposure applies to structures exposed to the wind coming from over the water as well as smooth mud flats, salt flats, and unbroken ice.

Reprinted with permission from ASCE (2005).

Notes:

1. For a site located in a transition zone between exposure categories, the exposure resulting in the largest wind forces must be used.
2. Exposure Category D extends into downwind areas of Exposures B or C for a distance of 600 ft or 20 times the height of the building, whichever is greater.
3. The responsibility for determining the exposure category for a given new building project falls on the structural engineer of record. This value is documented in the structural notes drawing (the first of the structural drawings) for the project.

design wind pressure P is determined, which can be used to specify equipment performance levels and design anchors to adequately brace wall-mounted cladding components to the building structure.

The American Society of Civil Engineers' (ASCE) *Standard 7-05* includes design guidelines for wind, snow, rain, and earthquake loads. Note that the equations, guidelines, and data presented here only cover nonstructural components. The current standard (2005) includes more comprehensive and rigorous procedures for evaluating wind forces and wind restraint. Refer to the latest version of ASCE *Standard 7* adopted by the local jurisdiction.

2.1 TERMINOLOGY

Classification. Buildings and other structures are classified for wind load design exposure according to Table 7.

Basic wind speed. The fastest mile-per-hour wind speed at 33 ft above the ground of Terrain Exposure C (see Table 7) having an annual probability of occurrence of 0.02. Data in ASCE *Standard 7* or regional climatic data may be used to determine basic wind speeds. ASCE data do not include all special wind regions (such as mountainous terrains, gorges, and ocean promontories) where records or experience indicate that the wind speeds are higher than what is shown in appropriate wind data tables. For these circumstances, regional climatic data may be used provided that both acceptable extreme-value statistical analysis procedures were used in reducing the data and that due regard was given to the length of record, averaging time, anemometer height, data quality, and terrain exposure. One final exclusion is that tornadoes were not considered in developing the basic wind speed distributions.

Components and Cladding. Elements of the building envelope that do not qualify as part of the main wind-force resisting system.

Corner Zone. Areas of building walls and roofs adjacent to building corners that experience increased external pressure from wind.

Design wind force. Equivalent static force that is assumed to act on a component in a direction parallel to the wind and not necessarily normal to the surface area of the component. This force varies with respect to height above ground level.

Importance factor I . A factor that accounts for the degree of hazard to human life and damage to HVAC components (Table 8). For hurricanes, the value of the importance factor can be linearly interpolated between the ocean line and 100 miles inland because wind effects are assumed negligible at this distance inland.

Gust response factor G . A factor that accounts for the fluctuating nature of wind and the corresponding additional loading effects on HVAC components.

Table 8 Wind Importance Factor I (Wind Loads)

Category	I
I	0.87
II	1
III	1.15
IV	1.15

Note: See Table 9 for categories.

Table 9 Exposure Category Constants

Exposure Category	α	Z_g , ft	Gust Factor G
B	7	1200	0.85
C	9.5	900	0.85
D	11.5	700	0.85

Reprinted with permission from ASCE (2005).

Note: See Table 7 for definitions of exposure categories.

Table 10 Force Coefficients for HVAC Components, Tanks, and Similar Structures

Shape	Type of Surface	C_f for h/D Values of		
		1	7	25
Square (wind normal to face)	All	1.3	1.4	2.0
Square (wind along diagonal)	All	1.0	1.1	1.5
Hexagonal or octagonal $D\sqrt{Q_z} > 2.5$	All	1.0	1.2	1.4
Round $D\sqrt{Q_z} > 2.5$	Moderately smooth	0.5	0.6	0.7
	Rough ($D'/D = 0.02$)	0.7	0.8	0.9
	Very rough ($D'/D = 0.08$)	0.8	1.0	1.2
Round $D\sqrt{Q_z} \leq 2.5$	All	0.7	0.8	1.2

Notes:

- Design wind force calculated based on area of structure projected on a plane normal to the wind direction. Force is assumed to act parallel to wind direction.
- Linear interpolation may be used for h/D values other than shown.
- Nomenclature:

- D = diameter or least horizontal dimension, ft
- D' = depth of protruding elements such as ribs and spoilers, ft
- h = structure (top of equipment) height (above ground), ft
- Q_z = velocity pressure evaluated at height z above ground level, lb/ft²

Minimum design wind load. The wind load may not be less than 10 lb/ft² multiplied by the area of the HVAC component projected on a vertical plane that is normal to the wind direction.

2.2 CALCULATIONS

Two procedures are used to determine the design wind load on HVAC components. The **analytical procedure**, described here, is the most common method for standard component shapes, based on the requirements in ASCE 7. The second method, the **wind-tunnel procedure**, is used in the analysis of complex and unusually shaped components or equipment located on sites that produce wind channeling or buffeting because of upwind obstructions. The analytical procedure produces design wind forces that are expected to act on HVAC components for durations of 1 to 10 s. The various factors, pressure, and force coefficients incorporated in this procedure are based on a mean wind speed that corresponds to the fastest wind speed.

Analytical Procedure

The design wind force is determined by the following equation:

$$F_w = Q_z G C_f A_f \quad (54)$$

where

- F_w = design wind force, lb
- Q_z = velocity pressure evaluated at height z above ground level, lb/ft²
- G = gust response factor for HVAC components evaluated at height z above ground level
- C_f = force coefficient (Table 10)
- A_f = area of HVAC component projected on a plane normal to wind direction, ft²

Certain of the preceding factors must be calculated from equations that incorporate site-specific conditions that are defined as follows:

Velocity Pressure. The design wind speed must be converted to a velocity pressure that is acting on an HVAC component at a height z above the ground. The equation is

$$Q_z = 0.00256 K_z K_{zt} K_d V^2 I \quad (55)$$

where

- K_z = velocity pressure exposure coefficient from Table 12
- K_{zt} = topographic factor = 1.0
- K_d = wind directionality factor = 1.0
- V = velocity from Figure 12, mph
- I = importance factor from Table 8

The force generated by the wind is calculated by

$$F_w = Q_z G C_f A_f \quad (56)$$

where

- F_w = design wind force, lb
- Q_z = velocity pressure evaluated at height z above ground level, lb/ft²
- G = gust response factor for HVAC components evaluated at height z above ground level
- C_f = force coefficient (Table 10)
- A_f = area of HVAC component projected on a plane normal to wind direction, ft²

The following example calculations are for a 400 ton cooling tower:

- Tower height $h = 10$ ft
- Tower width $D = 10$ ft
- Tower length $l = 20$ ft
- Tower operating weight $W_p = 19,080$ lb
- Tower diagonal dimension = $\sqrt{10^2 + 20^2} = 22.4$ ft
- Area normal to wind direction $A_f = 10 \times 22.4 = 224$ ft²

From Table 10, $C_f = 1.0$ for wind acting along diagonal with $h/D = 10/10 = 1$.

Example 5. Suburban hospital in Omaha, Nebraska. The top of the cooling tower is 100 ft above ground level. Building width normal to the wind $B = 3000$ ft, and building height $H = 90$ ft.

Solution:

- From Figure 12, the design wind speed is found to be 90 mph.
- From Table 9, use Category IV.
- From Table 7, use Exposure B.
- From Table 8, $I = 1.15$.
- From Table 12, $K_z = 0.99$.
- From Figure 13, $K_d = 0.9$.
- From Table 9, $G = 0.85$.

Substitution into Equation (58) yields

$$Q_z = 0.00256 \times 0.99 \times 1.0 \times 0.9 \times (90)^2 \times 1.15 = 21.25 \text{ lb/ft}^2 = 2881 \text{ psi}$$

Building height is greater than 60 ft; therefore, $E_f = 1.0$.

Substitution into Equation (54) yields the design wind force as

$$F_w = 21.25 \times 0.85 \times 1.0 \times 224 \times 1.0 = 4046 \text{ lb}$$

Example 6. Office building in New York City. Top of tower is 600 ft above ground level. Building wall normal to the wind $B = 600$ ft and building height $H = 590$ ft.

Solution:

- From Figure 12, the design wind speed is 120 mph.
- From Table 9, use Category II.
- From Table 7, use Exposure B.
- From Table 8, $I = 1.0$.
- From Figure 13, $K_d = 0.9$.
- Because $z > 500$ ft, K_z must be determined from Note 2 of Table 12.
- From Table 9, $\alpha = 7.0$, $z_g = 1200$, and $G = 0.85$.

Substituting into the first equation in Note 2 yields

$$K_z = 2.10(Z/Z_g)^{2/\alpha} = 1.72$$

Substituting into Equation (55) yields

$$Q_z = 0.00256 \times 1.72 \times 1.0 \times 0.9 \times (120)^2 \times 1.15 = 65.6 \text{ lb/ft}^2$$

Building height is greater than 60 ft, therefore $E_f = 1.0$.

Substituting into Equation (56) yields the design force wind as

$$F_w = 65.6 \times 0.85 \times 1.0 \times 224 \times 1.0 = 12,490 \text{ lb}$$

Example 7. Church in Key West, Florida. The top of the tower is 50 ft above ground level. Building wall normal to the wind $B = 300$ ft and building height $H = 40$ ft.

Solution:

- From Figure 12, the design speed is found to be 150 mph.
- From Table 9, use Category III.
- From Table 5, use Exposure C (as this is a hurricane-prone region).
- From Table 16, $I = 1.15$.
- From Table 17, $G = 0.85$.
- From Table 13, $K_d = 0.9$.
- From Table 12, $K_z = 1.09$ (for exp category C).
- From Equation (55):

$$Q_z = 0.00256 \times 1.09 \times 1.0 \times 0.9 \times (150)^2 \times 1.15 = 65 \text{ lb/ft}^2$$

Building height is less than 60 ft, $A_f / (B \times H) = 224 / (300 \times 40) = 0.02$, therefore, $E_f = 1.9$

Substituting into Equation (56) gives the design wind force as

$$F_w = 65 \times 0.85 \times 1.0 \times 224 \times 1.9 = 23,514 \text{ lb}$$

2.3 WALL-MOUNTED HVAC&R COMPONENT CALCULATIONS (LOUVERS)

For many projects, the structural engineer of record will determine the components and cladding wind pressures provided on the structural notes drawing. If these wind pressures are not provided, the two following procedures (described previously) are used to determine the design wind load on HVAC cladding components.

Analytical Procedure

Velocity Pressure. The design wind speed must be converted to a velocity pressure that is acting on an HVAC component at height z above the ground. This is done using Equation (54). Once the velocity pressure has been determined, the design wind pressure can be calculated.

Low-Rise Buildings and Buildings with $h \leq 60$ ft

The design wind pressure for cladding is determined by the following equation:

$$P_w = Q_h(GC_p - GC_{pi}) \tag{57}$$

where

P_w = design wind pressure, lb/ft²

Fig. 12 Wind Speed Data
Reprinted with permission from ASCE (2005)

Q_h = velocity pressure evaluated at mean roof height h above ground level, lb/ft²

GC_p = external pressure coefficient given in Figure 13

GC_{pi} = internal pressure coefficient given in Table 14

Buildings with $h > 60$ ft

The design wind pressure is determined by the following equation:

$$P_w = Q(GC_p) - q_i(GC_{pi}) \quad (58)$$

where

P_w = design wind pressure, lb/ft²

Q_z = velocity pressure for windward walls calculated at height z above the ground of the component being examined

Q_h = velocity pressure for leeward walls, side walls and roofs, evaluated at height h of the roof

Q_i = velocity pressure for windward walls, side walls, leeward walls, and roofs, evaluated at height h of the roof

GC_p = external pressure coefficient given in Figure 14

GC_{pi} = internal pressure coefficient given in Table 14

Example 8. Office building in Houston, Texas. The top of the building is 30 ft above grade located in a newly developed suburban area. It is necessary to determine the wind pressures on louver 1 and louver 2 shown on the building elevation in Figure 15.

Solution:

From Figure 12, the design speed is found to be 120 mph.

From Table 9, use Category II.

From Table 7, use Exposure C.

From Table 8, $I = 1.0$.

From Table 12, $K_z = 0.98$, at roof height, $h = 30$ ft.

From Table 13, $K_d = 0.85$.

K_{zt} assumed to be 1.0.

Determine GC_p : Building height h is less than 60 ft; therefore, Equation (55) is used for the pressure evaluations. GC_p must be determined from Figure 15 for each of the louvers.

- NOTES:**
- Vertical scale denotes GC_p to be used with q_h .
 - Horizontal scale denotes effective wind area, in square feet.
 - Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
 - Each component shall be designed for maximum positive and negative pressures.
 - Values of GC_p for walls shall be reduced by 10% when $\theta \leq 10^\circ$.
 - Notation:
 - a : 10% of least horizontal dimension or $0.4h$, whichever is smaller, but not less than either 4% of least horizontal dimension or 3 ft.
 - h : Mean roof height, in feet, except that eave height shall be used for $\theta \leq 10^\circ$.
 - θ : Angle of plane of roof from horizontal, in degrees.

Louver 1: from the notes on Figure 15, it is necessary to determine the a dimension, which establishes the corner zone 5. The least horizontal dimension coming into the corner is 32 ft from the plan view. Ten percent of this value is 3.2 ft. The minimum value for the corner dimension is 3 ft. Louver 1 is located 1 ft 2 11/16 in. from the corner and is therefore in corner zone 5.

From Figure 15, $GC_p = +0.95$ or -1.3 for a 20 ft² wind area. A positive GC_p indicates a positive pressure on the windward side of the building. A negative GC_p indicates a suction pressure on the leeward side of the building. Both cases must be evaluated.

Louver 2: based on the corner calculation, louver 2 is in noncorner zone 4. From Figure 15, $GC_p = +0.9$ or -1.0 for a 30 ft² wind area.

Determine GC_{pi} : See Figure 14. Most buildings without significant wall openings are enclosed buildings. For the purposes of this example, an enclosed building is assumed. $GC_{pi} = +0.18$ or -0.18 . A positive sign indicates pressure outward on all structure walls. A negative sign indicates pressure inward on all structure walls.

Determine velocity pressure at roof elevation h from Equation (55):

$$Q_h = 0.00256 \times 0.98 \times 1.0 \times 0.85 \times (120)^2 \times 1.0 = 30.7 \text{ lb/ft}^2$$

Determine design wind pressure P from Equation (56):

Louver 1, case 1: positive external, positive internal

$$P = 30.7 \times (0.95 - 0.18) = 23.6 \text{ lb/ft}^2$$

Louver 1, case 2: positive external, negative internal

$$P = 30.7 \times [0.95 - (-0.18)] = 34.7 \text{ lb/ft}^2$$

Louver 1, case 3: negative external, positive internal

$$P = 30.7 \times [(-1.3) - 0.18] = -45.4 \text{ lb/ft}^2$$

Louver 1, case 4: negative external, negative internal

$$P = 30.7 \times [(-1.3) - (-0.18)] = -34.4 \text{ lb/ft}^2$$

The controlling values for P for louver 1 are 34.7 lb/ft², -45.4 lb/ft² and should be used to specify equipment performance levels.

Louver 2, case 1: positive external, positive internal

$$P = 30.7 \times (0.90 - 0.18) = 22.1 \text{ lb/ft}^2$$

Fig. 13 External Pressure Coefficient GC_p for Walls for $h \leq 60$ ft

Reprinted with permission from ASCE (2005)

Louver 2, case 2: positive external, negative internal

$$P = 30.7 \times [0.90 - (-0.18)] = 33.2 \text{ lb/ft}^2$$

Louver 2, case 3: negative external, positive internal

$$P = 30.7 \times [(-1.0) - 0.18] = -36.2 \text{ lb/ft}^2$$

Louver 2, case 4: negative external, negative internal

$$P = 30.7 \times [(-1.0) - (-0.18)] = -25.2 \text{ lb/ft}^2$$

The controlling values for P for louver 2 are 33.2 lb/ft^2 , -36.2 lb/ft^2 and should be used to specify equipment performance levels.

- NOTES:**
- Vertical scale denotes GC_p to be used with appropriate q_z or q_h .
 - Horizontal scale denotes effective wind area A , in square feet.
 - Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
 - Use q_z with positive values of GC_p and q_h with negative values of GC_p .
 - Each component shall be designed for maximum positive and negative pressures.
 - Coefficients are for roofs with angle $\theta \leq 10^\circ$. For other roof angles and geometry, use GC_p values from Figure 6-11 and attendant q_h based on exposure defined in 6.5.6.
 - If a parapet equal to or higher than 3 ft is provided around the perimeter of the roof with $\theta \leq 10^\circ$, Zone 3 shall be treated as Zone 2.
 - Notation:
 a: 10% of least horizontal dimension, but not less than 3 ft.
 h: Mean roof height, in feet, except that eave height shall be used for $\theta \leq 10^\circ$.
 z: Height above ground, in feet.
 θ : Angle of plane of roof from horizontal, in degrees.

2.4 CERTIFICATION OF HVAC&R COMPONENTS FOR WIND

Some jurisdictions require certifications of performance of HVAC&R components for wind resistance. These certifications focus on (1) the equipment’s ability to remain intact and/or (2) the equipment restraints and anchors to keep the item in place during a wind event.

In the United States, the State of Florida and the Building Code Compliance Office of Miami-Dade County have certification requirements that affect HVAC&R system designers. The HVAC products may have special requirements for wind performance and may need approval of the State of Florida. In addition to wind performance, the Florida Building Code (ICC 2007) requires impact resistance and wind-pressure resistance for items that protect openings in buildings in windborne debris regions. The windborne debris regions can be viewed in Figure 16. HVAC products provided for projects located in these regions may be required to have testing and product certification from the State of Florida before installation. Other states, such as Texas, also have requirements for wind-pressure and impact testing. To ensure that the HVAC&R equipment

Table 12 Velocity Pressure Exposure Coefficient K_z

50015	1.29	1.56	1.77	1.89

Reprinted with permission from ASCE (2005).

Notes:

1. Linear interpolation for intermediate values of height z is acceptable.
2. For values of height z greater than 500 ft, K_z must be calculated using the following equations:

$$K_z = 2.01(z/z_g)^{2/\alpha} \quad \text{For } 15 \text{ ft} \leq z \leq z_g$$

or

$$K_z = 2.01(15/z_g)^{2/\alpha} \quad \text{For } z < 15 \text{ ft}$$

3. Exposure categories are defined in Table 7.

4. Values for alpha (α) and z_g are found in Table 9.

Table 13 Directionality Factor K_d

CHAPTER 56

ELECTRICAL CONSIDERATIONS

<i>Terminology</i>	56.1
<i>Safety</i>	56.1
<i>Performance</i>	56.2
<i>Electrical System Components and Concepts</i>	56.2
<i>Power Quality Variations</i>	56.7
<i>Billing Rates</i>	56.13
<i>Codes and Standards</i>	56.15

PRODUCTION, delivery, and use of electricity involve countless decisions made along the way, by hundreds of people and companies. This chapter focuses on the decisions to be made about the building and equipment. Creating a building that works means including the best designs available, communicating needs and capabilities, and planning ahead.

For an owner-occupied building, the benefits of a properly designed building return to the owner throughout the building's life. For tenant-occupied spaces, good design means fewer problems with tenant and building system interference (e.g., lighting or appliances in one suite disrupting computers in a neighboring suite).

Because HVAC&R equipment can have a large effect on buildings, it is necessary to address electrical issues in buildings that specifically are caused by or have an effect on HVAC&R equipment.

1. TERMINOLOGY

Electricity: fundamental form of energy found in positive and negative forms and expressed in terms of the movement and interaction of electrons.

Volt (V): practical unit of electric pressure; the pressure that will produce a current of 1 A against a resistance of 1 Ω ; equal to 1 J/s. Also called the **electromotive force (emf)**.

Current (I): movement of electrons through a conductor; measured in amperes.

Ampere (A): practical unit of electric current flow. If a 1 Ω resistance is connected to a 1 V source, 1 A will flow.

Alternating current (ac): a current that reverses at regular, recurring intervals of time and that has alternately positive and negative values. The values vary over time in a sinusoidal manner.

Direct current (dc): a current where electrons move steadily in one direction.

Watt (W): unit of real electrical power, equal to the power developed in a circuit by a current of 1 A flowing through a potential difference of 1 V.

Volt-ampere (VA): amount of apparent power in an alternating current circuit equal to a current of 1 A at an emf of 1 V. It is dimensionally equivalent to watts. Volt-ampere is equal to watts when voltage and current are in phase.

Volt-ampere-reactive (VAR): unit for reactive power. The symbols Q and sometimes N are used for the quantity measured in VARs. VARs represent the power consumed by a reactive load (i.e., when there is a phase difference between applied voltage and current).

Power factor: for an ac electric power system, the ratio of the real power to the apparent power, or W/VA .

Three-phase power: supplied by three conductors, with the currents (or voltages) of any two 120° out of phase with each other.

Fig. 1 Fundamental Voltage Wave

Y (or “wye”) connection: a configuration of wiring so that each winding of a polyphase transformer (or three single-phase transformers) is connected to a common point, the “neutral.”

Delta-connected circuit: a three-phase circuit that is mesh connected, so the windings of each phase of a three-phase transformer are connected in a series for a closed circuit (i.e., in a triangle or “delta” configuration).

Fundamental voltage: produced by an electric ac generator and has a sinusoidal waveform with a frequency of 60 cycles per second, or 60 Hz (in the United States). Other countries may have a similar waveform but at 50 cycles per second of 50 Hz.

Cycle: the part of the fundamental waveform where the electrical potential goes from zero to a maximum to zero to a minimum, and back to zero again (i.e., one complete wave; see Figure 1). At 60 Hz, there are 60 cycles in 1 second.

RMS (root-mean-squared) voltage: an effective way to compare ac to dc value. For a pure sinusoidal waveform, RMS value is equal to 0.707 times the peak magnitude.

System voltage: the RMS phase-to-phase voltage of a portion of an ac electric utility system. Each system voltage pertains to a part of the system bounded by transformers or end-use equipment.

Service voltage: the voltage at the point where the electric systems of the supplier and the user are connected.

Utilization voltage: the voltage at the terminals of the utilization equipment.

Nominal system voltage: the rated system voltage level (i.e., 480 volts) at which the electrical system normally operates. To allow for operating contingencies, utility systems generally operate at voltage levels within -5% to +5% of nominal system voltage.

2. SAFETY

The greatest danger from electricity is that it is taken for granted and not taken seriously as a hazardous energy source. Electricity can produce bodily harm and property damage, and shut down entire operations. The type of damage from electricity ranges from a mild shock to the body to a major electrical fire. Electrical safety is important in all occupational settings. See information on safety codes in the Electrical Codes section.

The preparation of this chapter is assigned to TC 1.9, Electrical Systems.

3. PERFORMANCE

In the United States, the *National Electrical Code*® (NEC; NFPA *Standard 70*) is generally accepted as the minimum safety requirements for wiring and grounding in a structure. Other countries have similar requirements. The NEC ensures building design is safe, but may not provide the performance that a modern building requires. Rapid changes in electronic technologies have rendered many traditional electrical distribution practices obsolete and must be replaced with new designs. Electrical power distribution decisions made during design affect occupants' productivity for the life of the building. Many improvements over the minimum requirements are relatively inexpensive to implement during building construction.

Power quality, like quality in other goods and services, is difficult to define. There are standards for voltage and waveshape, but the final measure of power quality is determined by the performance and productivity of the building occupant's equipment. If the electric power is inadequate for those needs, then the quality is lacking.

Specifications for electric power are set down in recognized national standards. These are voltage levels and tolerances that should be met, on the average, over a long period of time. Electric utilities and building distribution systems generally meet such specifications. Voltage drop in a building is a fundamental reason for calculating the size of electrical conductors. Brief disturbances on the power line are not addressed in these time-averaged specifications; new standards are being developed to address these concerns.

Interaction between tenants' electrical equipment is an ongoing problem. Often, a large load in one tenant's space can disrupt a small appliance or computer in another part of the building. Voltage drop along building wiring and harmonic distortion are often the causes of the problem. **Dedicated circuits** usually solve the voltage drop problem, but harmonic distortion must be solved at the contributing loads. By eliminating much of the wiring common to both pieces of equipment, the original performance of each is restored. With modern electronic loads, the interaction might easily involve a large load that interferes with smaller, more sensitive equipment. Disturbances might travel greater distances or through nondirect paths, so diagnostics are more difficult.

For tenants of a building with ordinary power distribution, lost productivity associated with power quality problems is an additional operating expense. The disturbance may last only milliseconds, but the disruption to business may require hours of recovery. This multiplication of lost time makes power quality a significant business problem.

Lost productivity may be the time it takes to restart a chiller, to repair a critical piece of equipment, or to retype a document. Another aspect of lost productivity is the stress on employees whose work is lost. The building owner may suffer loss, as well. Certainly the building equipment itself may suffer from the same damage or losses as tenant equipment. Sophisticated energy management systems, security systems, elevator controls, HVAC&R systems, and communications facilities are susceptible to disruption and vulnerable to damage.

4. ELECTRICAL SYSTEM COMPONENTS AND CONCEPTS

Voltage differential causes electrons to flow. In a direct current (dc) electrical system, electrons flow in only one direction. In an alternating current (ac) electrical system, electrons continually alternate or change direction at a prescribed number of times per second. The main disadvantage of dc voltage is its inability to be boosted or attenuated easily and efficiently. The alternating magnetic fields of ac make boosting or decreasing voltage with transformers feasible, which is why ac has been widely adopted. Electrons flow more efficiently at lower currents because I^2R losses are minimized. For the

same load, raising the voltage level reduces the current while delivering the same power. When long distances are involved, electric utility companies step up voltages to very high levels for transmission. However, these voltages are extremely dangerous, so they must be stepped down to a safer, lower, usable voltage before use. Transformers offer an efficient way to change voltage levels (step-up or step-down) for an alternating current power source.

Electrical Wiring (Conductors for General Wiring)

Just because a conductor is insulated does not mean it is suited for a specific application. NFPA *Standard 70* list designations of wires and cables that meet minimum fire, electrical, and physical requirements of relevant standards. Unless otherwise specified by codes, conductors must be aluminum, copper-clad aluminum, or copper.

To find allowable ampacities for insulated conductors at various temperatures, consult Tables 310.15(B)(16) to 310.15(B)(20) of NFPA *Standard 70-2014*. Tables 310.15(B)(2)(a) and 310.15(B)(2)(b) of that standard have correction factors for ambient temperatures other than 86 or 104°F. If more than one ampacity could apply for a given circuit, use the lowest value.

Transformers

Transformers are used to change one voltage to another voltage, typically to step up voltage levels from generators. Power can then be transmitted at a low current (with less loss). At the end of the transmission line, a step-down transformer reduces the voltage to a usable level.

A transformer consists of a ferromagnetic core wrapped with multiple coils, or windings, of wire. The input line is connected to the primary coil, and the output line is connected to the secondary coil. Alternating current I_1 in the primary coil induces an alternating magnetic flux ϕ that flows through the ferromagnetic core, changing direction during each electrical cycle. This flux in turn induces alternating current I_2 in the secondary coil. The voltage V_2 at the secondary coil is directly related to the primary voltage by the turns ratio (i.e., the number of turns N_1 in the primary coil divided by the number turns N_2 in the secondary coil).

An **ideal transformer** with two windings wrapped around a magnetized core is shown in Figure 2. The ideal model for a transformer assumes I^2R losses, core losses, leakage flux, and core reluctance are insignificant. A practical model includes these losses.

Transformer **losses** can be divided into core (or iron) losses, copper losses, and stray losses. Core losses include hysteresis losses and eddy current losses. All ferromagnetic materials tend to retain some degree of magnetization after exposure to an external magnetic field. This tendency to stay magnetized is called hysteresis, and it takes energy to overcome this opposition to change every time the magnetic field produced by the primary winding changes polarity. Eddy current losses result from induced currents circulating in the

Fig. 2 Ideal Transformer

magnetic core perpendicular to the flux. Because iron conducts both electricity and magnetic flux, eddy currents are induced in the iron just as in the secondary windings from the alternating magnetic field.

Three identical single-phase, two-winding transformers may be connected to form a **three-phase bank**. The four possible connections are Y-Y, Y-Δ, Δ-Y, and Δ-Δ. The U.S. standard for marking three-phase transformers uses $H_1, H_2,$ and H_3 on the high-voltage terminals and $X_1, X_2,$ and X_3 on the low-voltage terminals; $A, B,$ and C identify phases on the high-voltage side of the transformer, and $a, b,$ and c identify phases on the low-voltage side. Typically, three-phase voltages present the higher voltage (phase-to-phase) first, followed by the lower voltage (phase-to-neutral). Single-phase voltages typically present the lower voltage (phase-to-neutral) first, followed by the higher voltage (phase-to-phase). For example, 208/120 V is three-phase and 120/240 V is single-phase.

Y-Y connections (Figure 3) are rarely used because of balancing and harmonics problems.

Y-Δ connections (Figure 4) are typically used for stepping down from high to medium voltage.

The Δ-Y transformer (Figure 5) is commonly used as a generator step-up transformer, where the Δ winding is connected to the generator terminals and the Y winding is connected to the transmission line. One advantage of the high-voltage Y winding is that a neutral point N is provided for grounding on the high-voltage side.

The Δ-Δ transformer (Figure 6) has the advantage that one phase can be removed for repair or maintenance while the remaining

phases continue to operate as a three-phase bank. The open Δ connection allows balanced three-phase operation with the kVA rating reduced to 58% of the original bank. These Δ-Δ connections are typically used in distribution networks.

An **autotransformer** has two windings connected in series (Figure 7). Whereas a typical transformer's windings are only coupled magnetically via the mutual core flux, an autotransformer's windings are both electrically and magnetically coupled.

An autotransformer has smaller per-unit leakage impedances than a two-winding transformer; this results in both smaller series

Fig. 3 Three-Phase Y-Y Transformer

Fig. 4 Three-Phase Y-Δ Transformer

Fig. 5 Three-Phase Δ-Y Transformer

Fig. 6 Three-Phase Δ-Δ Transformer

Fig. 7 Typical Autotransformer

voltage drops and higher short-circuit currents. It also has lower per-unit losses, lower excitation current, and lower cost, if the turns ratio is not large. An autotransformer is not isolated as well as a typical two-winding transformer; transient overvoltages pass through the autotransformer more easily because the windings are connected electrically.

Transformer Coolants and Insulators. Because heat is created by the flow of electrical current through the windings, a liquid (e.g., oil or silicone) is often used as a coolant inside the transformer. Such liquids are also good electrical insulators for the wire windings and iron core. **Dry transformers** do not require a liquid for cooling, instead using ambient air for cooling as well as insulation. Dust, dirt, moisture, and other contaminants in the air can reduce its insulating capabilities and deteriorate exposed parts, and may cause premature failure of the transformer.

Emergency and Standby Power Systems

Emergency Power Systems. IEEE *Standard 446-1995* defines these systems as independent reserves of electrical power that automatically take over if the usual supply experiences an outage or failure, and sustain mission-critical systems (i.e., those that, if inoperable, could present a danger to health and safety, or to property). Local or national codes may also mandate specific systems as required emergency power systems.

Standby Power Systems. Generally, these systems provide power back-up for loads that may be critical to production or product preservation, but do not present a danger to life or safety. They allow facilities to carry on with satisfactory operation during failure or outage of the usual supply source. NFPA *Standard 70* distinguishes between those that are legally required and those that are optional.

Emergency and Standby Power Supplies. Diesel generators are still the dominant source of emergency power, particularly for emergency loads such as fire pumps or elevators that require large starting currents and must meet the outage's full capacity at start-up. Some natural gas engines meet the start-up requirements for emergency systems, and are popular for smaller standby applications such as homes, communication towers, and other operations where diesel fuel is undesirable and/or impractical. Some turbines are also used for standby service, but most turbines are dedicated to combined heat and power (CHP) applications (see Chapter 7 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*).

The use and constraints of emergency and standby power systems must be understood to ensure proper safety and operation of the electrical equipment they support. This is especially true with emergency systems and with standby systems that are expanded to carry the full facility load, including HVAC&R systems. Starting and load step capabilities also must be understood when replacing diesel engines with natural gas engines and turbines, which have very different acceptable load step characteristics.

Most codes require emergency generators used for life-safety loads to be online within 10 s. However, age, battery wear, and even improper exercising of the engine can cause delays and even failures to start. Even if the engine does start within 10 s, some type of ride-through device may be required to support electronic loads (including computers and energy management systems) until the generator starts and picks up the load.

National mandates on emissions, and state and local implementation of those mandates, also influence the generator type specified. In the United States, Environmental Protection Agency (EPA) tier ratings are required for off-road engine permits, including for generators. U.S. EPA (2012) addresses emissions of oxides of nitrogen (NO_x), hydrocarbons (HC), particulate matter (PM), and carbon monoxide (CO). Earlier tier ratings limited diesel use to emergency applications in most cases, but the new tier 4 ratings allow their use for standby and CHP applications.

Another variable that must be considered with all generation equipment are the potential derates caused by elevation and weather. Combustion air has a direct effect, but of varying degrees, on the energy that can be generated during combustion. Ways to overcome these derates include precooling or humidifying the combustion air. It is important to find out from a manufacturer what the derating characteristics are and the cost in equipment and consumables for any correction system selected.

Uninterruptible power supply (UPS) units are most commonly used to keep computers and controls running during the transition from outage to generator operation. Batteries are sized to meet the load requirement for a specified period of time (frequently about 15 min). The UPS provides power through the interruption and, if generators fail to start, provides enough time for orderly system shutdown.

Flywheel technology is gaining ground where larger (e.g., whole-building) loads are supported. The flywheels are also sized for time and load, but may be cost prohibitive for orderly shutdown and even for engines that do not start until the second or third try (20 to 30 s). They are only rarely used to support a natural gas engine that may take between 1 to 3 min to start.

Impedance of emergency and standby power supplies is usually higher than that of utility electric service. Thus, power quality of a circuit typically deteriorates when it is switched from regular utility power to emergency power.

A key component of the emergency generator system is the automatic transfer switch (ATS) used to switch from the primary source (usually the utility) to the secondary source (usually the generator). The type of switch selected has important ramifications to the overall electrical system. The types of automatic transfer switches are as follows:

Standard ATS (Figure 8)

- *Break-* (from one source) *before-make* (to another source) design.
- Mechanically interlocked electrical contactors move loads from one power source to another.
- Most can optionally be equipped for delayed transition (switch delays in the neutral position for a preset number of seconds). This allows larger (>50 hp) motors' residual voltage to decay before connection to the other source. Other timers are usually available to provide ride-through for one or two recloser operations (used by utilities to keep their system operational during momentary faults caused by falling limbs, high winds, etc.).
- An *in-phase monitor* can be preset and used in conjunction with or in place of the delayed transition to protect large motors during the transfer process.
- Can be two-, three- or four-pole, depending on phase and grounding scenario.
- Results in at least two momentary power outages: when utility service is lost and when the system switches back to the utility.

Closed-Transition ATS (Figure 9)

- Provides momentary (less than six cycles) connection of load to both power sources within acceptable phase angle for seamless transfer when both sources are available.

Fig. 8 Break-Before-Make Design for Standard ATS

Fig. 9 Closed-Transition ATS

Fig. 10 Parallel-Transfer Switch

- Eliminates the second outage associated with a standard ATS and, in some cases, can be used to operate the generator as a peaking power source.

Bypass-Isolation ATS

- Same as a standard ATS except for its separate bypass mechanism to allow continuation of power to the load from either source while isolating the automatic switch device for maintenance or repair. Typically, the automatic portion of the switch can be mechanically isolated from the frame during this process.
- All other features of the standard ATS apply.
- Closed-transition and bypass-isolation can be combined to provide the capabilities of both.

Service-Entrance-Rated ATS

- Transfer switch includes a circuit breaker or fused device ahead of the transfer mechanism, allowing the device to act as the service-entrance point for building load.
- Fused protection can also be provided ahead of the secondary (generator) entrance point, but is normally omitted in lieu of locating the protection (circuit breaker) at the generator set.
- Can include any or all of the other ATS features listed in standard, closed-transition, or bypass-isolation types.

Parallel-Transfer (PT) Switch (Figure 10)

- Parallel switchgear in a simple one- or two-breaker design allows for parallel connection of the load to both power sources for an indefinite time period.
- Should include all protective relay devices as required by the local utility and generator supplier.
- Can include some of the features of a standard ATS, because most can also be operated as an open-transfer (break-before-make) switch.

Switch selection can profoundly affect the electrical system, especially if an existing back-up system is upgraded for an expanded role. For example, it may be necessary to completely replace the existing switchgear of a building if an original generator system with a small generator and a standard ATS is replaced with a larger generator and a closed-transition ATS.

If the emergency power system is being expanded to include large motor loads, such as chillers, then

- Set delay to account for chiller motor back current to dissipate.
- Size the generator set large enough to handle the motor loads' starting current requirements. The electrical engineer needs to know the starting requirements and maximum allowable voltage drop that the overall electrical system can handle, especially computer and control loads. Most major generator manufacturers can provide sizing software.

If a standard ATS is being replaced with a closed-transition or parallel-transfer switch,

- Verify that the existing switchgear can handle the added potential fault current of the generator set. For instance, if the available fault current from the utility is 65,000 A and the generator fault current is 30,000 A, then the system only has to be braced for 65,000 A with a standard ATS. It has to be braced for 95,000 A with either of the other two switches because fault current is additive with multiple sources connected at the same time.

If the emergency power system is being converted from diesel to natural gas, then

- Check the acceptable load steps of the new engine: the diesel likely accepted 100% load, but the natural gas engine may be limited to as low as 20% load. Chillers and other large loads frequently exceed the acceptable load increase.
- Determine whether large-motor-load starting systems can be changed to reduce starting requirements and meet acceptable load steps.

If the emergency system is being modified for peaking or curtailment uses, then

- Obtain the specific utilities' interconnection requirements; these tend to be utility-specific and may exceed normal NEC or local codes.
- Check the existing system for closed-transition or parallel-transfer switch issues and compatibility.
- Investigate emissions issues; standby emissions permit requirements are almost always less stringent than peaking requirements.

If the emergency system includes a UPS or flywheel system, then

- Size the UPS or flywheel for the maximum required load for a specific time; remember that capacity of these systems is x kW for y min.
- Avoid motor loads as much as possible.

Motors

Motor Control and Protection. Chapter 45 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* addresses motor control and protection in detail, but is summarized and simplified here. Motor control must be effective without damaging the motor or its associated equipment. Control must be designed to prevent inadvertent motor starting caused by a fault in the control device. The control should be able to sense motor conditions to keep the motor windings from getting too warm.

Motor protection involves sensing motor current and line voltage, and can include bearing vibration, winding temperature, bearing temperature, etc. Motor temperature increase has two basic sources. Heating occurs when dirt or debris blocks airflow over or through the motor, or it comes from the motor current and is commonly referred to as I^2R , where I is motor current and R is motor winding resistance. Because the current is squared, its contribution is exponential. R is quite small and contributes a linear function to heating (and therefore temperature rise) in the motor. Motor windings can withstand temperature rise, depending on the motor winding temperature rating. The second source of motor temperature increase is lack of motor cooling. The primary source of cooling is moving air, usually from a shaft-driven fan. As a motor slows down, the fan runs more slowly; therefore, the less air movement, the less cooling. Because fan loads are also exponential, a small decrease in motor speed greatly reduces airflow on the motor, reducing cooling. To compound the issue, the slower the motor runs, the greater the slip, and the greater the motor current. This then becomes a vicious circle.

Motor Starters and Thermal Overloads. Motor starters energize (start), deenergize (stop), protect, and control the motor. They sense

motor current based on a time curve: the shorter the time, the more current they let through. They may also limit the number of motor starts in a given period of time so the motor does not exceed its ANSI rating. Another cause for concern is the starter's ambient temperature: if it is different from the ambient temperature around the motor controller, the thermal overloads need to be sized accordingly.

Several motor starter types are available, and they can function several different ways. The **across-the-line** starter is the simplest but may disturb electric service because of high motor-starting current requirements. Other starters reduce and may eliminate troublesome electrical disturbance; for instance, the **part-winding**, **reduced-voltage**, and **wye-delta** starters all act by reducing the starting voltage on the motor. Fan and pump loads can usually be started this way; this reduces starting current draw and demand, but sacrifices motor starting speed. **Soft-start** starters also reduce the voltage and limit demand during starting, thereby easing stress on the electric system during motor starting. **Variable-frequency drives (VFDs)** are also used to soft-start a motor, and are designed to control acceleration during starting as well as optimize motor speed to its load. See the section Motor-Starting Methods for more information.

A VFD converts ac to dc and then back to variable-frequency, variable-voltage ac. Motor speed is varied by varying the frequency of the ac output voltage, typically using pulse-width modulation (PWM). This power conversion process results in distorted input current and may contribute to building power system voltage distortion. When motors and other loads are supplied from a distorted voltage source, their operating temperatures may rise.

Phase Loss Protection. Phase loss can be detected by sensing either voltage loss or current loss on one of the phases. Motor overloads often are set based on the nameplate data of the motor, but the real motor current draw is less because the motor may not be fully loaded. If one of three phases is lost, the current increases in the other two phases, but not by enough to trip the overloads. However, it will overheat and possibly damage the motor. Some phase loss detectors also check phase current to be sure that it is balanced within 10%. This protects the motor and makes the operator aware of potential motor or line problems.

Motor-Starting Effects. The following effects do not occur with all motors. For instance, brushless dc and inverter-driven motors, which are electronically controlled, do not have inrush currents that cause light dimming or sags.

Light Dimming or Voltage Sags. Light dimming or voltage sag associated with motor starts can be more than a nuisance. Motors have the undesirable effect of drawing several times their full-load current while starting. This large current, by flowing through system impedances, may cause voltage sag that can dim lights, cause contactors to drop out, and disrupt sensitive equipment. The situation is worsened by an extremely poor starting displacement factor, usually in the range of 15 to 30%. If the motor-starting-induced voltage sag deepens, the time required for the motor to accelerate to rated speed increases. Excessive sag may prevent the motor from starting successfully. Motor-starting sags can persist for many seconds.

The Illuminating Engineering Society of North America (IESNA) is precise in describing lighting reactions. *Dimming* is an intentional technique to enhance the ambiance of surroundings by varying the perceived lighting levels. It is also used to reduce the electrical power used by lamps when adequate natural lighting is available; the controller electronically follows the natural variations in a way that will not be optically perceived. Similarly, *flicker* is deliberately selected in some lamps to resemble a candle's flame. In contrast, this chapter discusses possible causes of *undesirable, perceptible* reductions of a lamp's lumen output.

Momentary undesirable lighting reductions from voltage sags, often caused by motor starting, were common with incandescent

lamps. More efficient lamps (especially fluorescent and electronic ballasts) are now the most common for most applications. For fluorescent lamps, electronic ballasts convert the 60 Hz electrical service to much higher frequencies, which eliminates perception of irritating flicker, and provides greater lumens per watt than the former magnetic ballasts. Similar improvements have occurred for mercury, metal halide, and sodium lamps, typically found in large stores, sports, and industrial applications. Including electronic circuitry in the lamps and lighting systems makes power quality even more important for building owners: electronic components are sensitive to both lower and upper threshold voltages, and the building's voltage may experience momentary voltage sag as large motors start. Specific product literature for lamps, lamp ballasts, and lighting controls should be reviewed to ensure client satisfaction with expected operations (starts, stops, and speed changes) of the HVAC system's motors and controls.

Motor-Starting Methods. The following motor-starting methods can reduce voltage sag from motor starts.

An **across-the-line start**, energizing the motor in a single step (full-voltage starting), provides low cost and allows the most rapid acceleration. It is the preferred method unless the resulting voltage sag or mechanical stress is excessive.

Autotransformer starters have two autotransformers connected to open delta (similar to a delta connection using three single-phase transformers, but with one transformer removed; carries 57.7% of a full delta load). Taps provide a motor voltage of 80, 65, or 50% of system voltage during start-up. Starting torque varies with the square of the voltage applied to the motor, so the 50% tap delivers only 25% of the full-voltage starting torque. The lowest tap that will supply the required starting torque is selected. Motor current varies as the voltage applied to the motor, but line current varies with the square of the tap used, plus transformer losses of ~3%.

Resistance and reactance starts initially insert impedance in series with the motor. After a time delay, this impedance is shorted out. Starting resistors may be shorted out over several steps; starting reactors are shorted out in a single step. Line current and starting torque vary directly with the voltage applied to the motor, so for a given starting voltage, these starters draw more current than the line with autotransformer starts, but provide higher starting torque. Reactors are typically provided with 50, 45, and 37.5% taps.

Part-winding starters are attractive for use with dual-rated motors (220/440 V or 230/460 V). The stator of a dual-rated motor consists of two windings connected in parallel at the lower voltage rating, or in series at the higher voltage rating. When operated with a part-winding starter at the lower voltage rating, only one winding is energized initially, limiting starting current and torque to 50% of the values seen when both windings are energized simultaneously.

Delta-wye starters connect the stator in wye for starting, then after a time delay, reconnect the windings in delta. The wye connection reduces the starting voltage to 57% of the system line-line voltage, starting current and starting torque are reduced to 33% of their values for full voltage start.

Utilization Equipment Voltage Ratings

Utilization equipment is electrical equipment that converts electric power into some other form of energy, such as light, heat, or mechanical motion. Every item of utilization equipment should have a nameplate listing, which includes, among other things, the rated voltage for which the equipment is designed. In some cases, the nameplate also indicates the maximum and minimum voltage for proper operation. With one major exception, most utilization equipment carries a nameplate rating that is the same as the voltage system on which it is to be used: that is, equipment to be used on 120 V systems is rated 120 V. The major exception is motors and equipment containing motors, where performance peaks in the middle of the

Fig. 11 Utilization Voltages Versus Nameplate Ratings

tolerance range of the equipment: better performance can be obtained over the tolerance range specified in ANSI *Standard* C84.1 by selecting a nameplate rating closer to the middle of this tolerance range. The difference between the nameplate rating of utilization equipment and the system nominal voltage is necessary because the performance guarantee for utilization equipment is based on the nameplate rating and not on the system nominal voltage.

The voltage tolerance limits in ANSI *Standard* C84.1 are based on ANSI/NEMA *Standard* MG 1, Motors and Generators edition, which establishes voltage tolerance limits of the standard low-voltage induction motor at $\pm 10\%$ of nameplate voltage ratings of 230 and 460 V. Because motors represent the major component of utilization equipment, they were given primary consideration in the establishment of this voltage standard. Figure 11 compares utilization voltages to nameplate ratings.

Voltage Level Variation Effects

Whenever voltage at the terminals of utilization equipment varies from its nameplate rating, equipment performance and life expectancy change. The effect may be minor or serious, depending on the equipment characteristics and the amount of voltage deviation from the nameplate rating. NEMA standards provide tolerance limits within which performance will normally be acceptable. In precise operations, however, closer voltage control may be required. In general, a change in the applied voltage causes a proportional change in the current. Because the effect on the load equipment is proportional to the product of the voltage and the current, and because the current is proportional to the voltage, the total effect is approximately proportional to the square of the voltage.

However, the change is only approximately proportional and not exact: the change in the current affects the operation of the equipment, so the current continues to change until a new equilibrium position is established. For example, when the load is a resistance heater, the increase in current increases the heater temperature, which increases its resistance and, in turn, reduces the current. This effect continues until a new equilibrium current and temperature are established. In the case of an induction motor, a voltage reduction reduces the current flowing to the motor, causing the motor to slow down. This reduces the impedance of the motor, increasing the current until a new equilibrium position is established between the current and motor speed.

Voltage Selection

Generally, the preferred utilization voltage for large commercial buildings is 480Y/277 V, three-phase. The three-phase power load is connected directly to the system at 480 V, and fluorescent ceiling lighting is connected phase-to-neutral at 277 V. Dry-type transformers rated 480 V/208Y/120 V are used to provide 120 V single phase for convenience outlets and 208 V three phase for other building equipment. Single-phase transformers with secondary ratings of 120/240 V may also be used to supply lighting and small office equipment. However, single-phase transformers should be

connected in sequence on the primary phases to maintain balanced load on all phases of the primary system.

Where the supplying utility furnishes the distribution transformers, the choice of voltages is limited to those the utility provides. For tall buildings, space will be required on upper floors for transformer installations and the primary distribution cables supplying the transformers. Apartment buildings generally have the option of using either 208Y/120 V three-phase/four-wire systems, or 120/240 V single-phase systems, because the major load in residential occupancies consists of 120 V lighting fixtures and appliances. The 208Y/120 V systems are often more economical for large apartment buildings. Single-phase 120/240 V systems should be satisfactory for small apartment buildings and other small buildings.

However, large single-phase appliances, such as electric ranges and water heaters rated for use on 120/240 V single-phase systems, will not perform to the rated wattage on a 208Y/120 V systems, because the line-to-line voltage is appreciably below the rated voltage of the appliance.

5. POWER QUALITY VARIATIONS

Power quality refers to varied parameters that characterize the voltage and current for a given time and at a given point on the electric system. A power quality problem is usually any variation in the voltage or current that actually results in failure or misoperation of equipment in the facility. Therefore, power quality evaluations are a function of both the power system characteristics and the sensitivity of equipment connected to the power system.

This section defines the different kinds of power quality variations that may affect equipment operation. Important reasons for categorizing power anomalies include the following:

- Identifying the cause of the power anomalies. Understanding the characteristics of a power quality variation can often help identify the cause.
- Identifying the possible effects on equipment operation. A transient voltage can cause failure of equipment insulation; a sag in voltage may result in dropout of sensitive controls based on an undervoltage setting.
- Determining the requirements for measurement. Some power quality variations can be characterized with simple voltmeters, ammeters, or strip chart recorders. Other conditions require special-purpose disturbance monitors or harmonic analyzers.
- Identifying methods to improve the power quality. Solutions depend on the type of power quality variation. Transient disturbances can be controlled with surge arrestors, whereas momentary interruptions could require an uninterruptible power supply (UPS) system for equipment protection. Harmonic distortion may require special-purpose harmonic filters.

Power quality can be described in terms of *disturbances* and *steady-state variations*.

Disturbances. Disturbances are one-time, momentary events. Measurement equipment can characterize these events by using thresholds and triggering when disturbance characteristics exceed specified thresholds. Examples include transients, voltage sags and swells, and interruptions.

Steady-State Variations. Changes in long-term or steady-state conditions can also result in equipment misoperation. High harmonic distortion levels can cause equipment heating and failure, as can long-term overvoltages or unbalanced voltages. These are variations best characterized by monitoring over a longer period of time with periodic sampling of the voltages and currents. Steady-state variations are best analyzed by plotting trends of the important quantities (e.g., RMS voltages, currents, distortion levels).

These two types of power quality are further defined in seven major categories and numerous subcategories. There are three primary

attributes used to differentiate among subcategories within a power quality category: frequency components, magnitude, and duration. These attributes are not equally applicable to all categories. For instance, it is difficult to assign a time duration to a voltage flicker, and it is not useful to assign a spectral frequency content to variations in the fundamental frequency magnitude (sags, swells, overvoltages, undervoltages, interruptions).

Each category is defined by its most important attributes for that particular power quality condition. These attributes are useful for evaluating measurement equipment requirements, system characteristics affecting power quality variations, and possible measures to correct problems. The terminology has been selected to agree as much as possible with existing terminology used in technical papers and standards.

The following descriptions focus on causes of the power quality variations, important parameters describing the variation, and effects on equipment.

Transients

Transients are probably the most common disturbance on distribution systems in buildings and can be the most damaging. Transients can be classified as impulsive or oscillatory. These terms reflect the waveshape of a current or voltage transient.

Impulsive Transient. An impulsive transient (spikes or notches) is considered unidirectional; that is, the transient voltage or current wave is primarily of a single polarity (Figures 12 and 13). Impulsive transients are often characterized simply by magnitude and duration. Another important component that strongly influences the effect on many types of electronic equipment is the **rate of rise**, or rise time of the impulse. This rate of rise can be quite steep, and can be as fast as several nanoseconds. Repetitive subtractive transients (Figure 13), often caused by thyristors such as silicon controlled rectifiers (SCRs), are referred to as voltage notches.

The high-frequency components and high rate of rise are important considerations for monitoring impulses. Very fast sampling rates are required to characterize impulses with actual waveforms. In many power quality monitors, simple circuits are used to detect the transient's peak magnitude and duration (or volt-seconds). If

Fig. 12 Example of Spike

Fig. 13 Example of Notch

impulse waveshapes are recorded, they usually do not include the fundamental frequency (60 Hz) component. When evaluating these disturbances, it is important to remember that stress on equipment is based on the impulse magnitude plus the magnitude of the fundamental component at the instant of the impulse. The voltage, current available, and pulse width determine the amount of energy available in a transient.

Oscillatory Transient. An oscillatory transient (Figure 14) is a voltage or current that changes polarity rapidly. Because the term “rapidly” is nebulous, the frequency content is used to divide oscillatory transients into three subcategories: high, medium, and low frequency. Frequency ranges from these classifications are chosen to coincide with common types of power system oscillatory transient phenomena.

As with impulsive transients, oscillatory transients can be measured with or without including the fundamental frequency. One way to trigger on transients is to continually test for deviation in the waveform from one cycle to the next. This method records any deviation exceeding the set threshold. When characterizing the transient, it is important to indicate the magnitude with and without the 60 Hz fundamental component.

Transients are generally caused by a switching event or by system response to a lightning strike or fault. The oscillations result from interactions between system capacitances and inductances, and occur at the natural frequencies of the system excited by the switching event or fault.

High-frequency transients can occur at locations very close to the initiating switching event. Rise times created by closing a switch can be as fast as a few tens of nanoseconds. Short lengths of circuit have very high natural oscillation frequencies that can be excited by a step change in system conditions (e.g., operating a switch). Power electronic devices such as transistors and thyristors/SCRs can cause high-frequency transients many times during each cycle of the fundamental frequency. The transients can be in the tens or hundreds of kilohertz, and occasionally higher.

Because of the high frequencies involved, circuit resistance typically damps transients out; thus, they only occur close (within hundreds of feet) to the site of the switching event that generates them. Characterizing these transients with measurements is often difficult because high sampling rates are required.

Medium-frequency transients are associated with switching events with somewhat longer circuit lengths (resulting in lower natural frequencies). Switching events on most 480 V distribution systems in a facility cause transient oscillations within this frequency range, which can propagate over a significant portion of the low-voltage system. Motor interruption (definite interruption) is a good example of a common switching event that can excite transients in this frequency range.

Transients coupled from the primary power system (e.g., coupled through the step down transformer) can also cause medium-frequency transients. The most common cause of transients on the primary power system is capacitor switching.

Fig. 14 Example of Oscillatory Transient

Capacitor energizing results in an initial step change in the voltage, which gets coupled through stepdown transformers by the transformer capacitance and then excites natural frequencies of the low-voltage system (typically 2 to 10 kHz). **Low-frequency transients** are usually caused by capacitor switching, either on the primary distribution system or within the customer facility. Lower-frequency transients result from capacitance of the switched capacitor bank oscillating with the inductance of the power system. The natural frequencies excited by these switching operations are much lower than those of the low-voltage system without the capacitor bank, because of the large capacitance of the capacitor bank itself.

Capacitor switching operations are common on most distribution systems and many transmission systems. Energizing a capacitor results in an oscillatory transient with a natural frequency in the range of 300 to 2000 Hz (depending on the capacitor size and the system inductance). The peak magnitude of the transient can approach twice the normal peak voltage (per unit), and lasts between 0.5 and 3 cycles, depending on system damping.

Isolation transformers, voltage arresters, and/or filters can reduce transients.

Short-Duration Variations

Short-duration voltage variations are momentary changes in the fundamental voltage magnitude. Common causes are faults on the power system (short circuits between phases or from phase to ground). Depending on the fault location and system conditions, the fault can cause either momentary voltage rises (swells) or momentary voltage drops (sags). The fault condition can be close to or remote from the point of interest.

Sags. Sags (Figure 15) are often associated with system faults but can also be caused by switching heavy loads or starting large motors (usually a longer-duration variation). Figure 15 shows a typical voltage sag that can be associated with a remote fault condition. For instance, a fault on a parallel feeder circuit (on the primary distribution system) results in a voltage drop at the substation bus that affects all of the other feeders until the fault is cleared by opening a fuse or circuit breaker.

The percent drop in the RMS voltage magnitude and duration of the low-voltage condition are used to characterize sags. Voltage sags are influenced by system characteristics, system protection practices, fault location, and system grounding. The most common problem caused by voltage sags is tripping sensitive controls (e.g., adjustable-speed drives or process controllers), relays or contactors dropping out, and failure of power supplies to ride through the sag. Many types of voltage regulators are not fast enough to provide voltage support during sags, but ferroresonant transformers and some other line conditioners can provide some ride-through capability or can quickly compensate for deep sags.

In practice, sags are the type of power quality variation that most frequently causes problems. Fault conditions remote from a particular customer can still cause voltage sags that can cause equipment problems. Because there are no easy ways to eliminate faults on the power system, it is always necessary for customers to consider the effects of sags.

Fig. 15 Example of Sag

Swells. Swells or **surges** can also be associated with faults on the primary distribution system (Figure 16). They can occur on non-faulted phases when there is a single-line-to-ground fault.

Swells are characterized by their magnitude (RMS value) and duration. The severity of a voltage swell is a function of fault location, system impedance, and grounding. On a three-phase ungrounded system (delta), the line-to-ground voltages on the ground phases are 1.73 per unit (i.e., 1.73 times the normal line-to-ground voltage) during a single-line-to-ground fault condition. Close to the substation on a grounded system, there is no voltage rise on the ground phases because the substation transformer is usually delta-wye, providing a low-impedance path for the fault current.

Long-Duration Variations

Long-duration RMS voltage deviations generally do not result from system faults. They are caused by load changes on the system and system switching operations. The duration of these voltage variations depends on the operation of voltage regulators and other types of voltage control on the power system (e.g., capacitor controls, generator exciter controls). The time required for these voltage controllers to respond to system changes ranges from large fractions of a second to seconds. Long-duration variations can be overvoltages or undervoltages, depending on the cause of the variation. Voltage unbalance should be considered when evaluating steady-state or long-duration voltage variations. Unbalanced voltages can be one of the major causes of motor overheating and failure. With increasing emphasis on energy-efficient motors, requirements for voltage balance (i.e., limitations on negative sequence voltage magnitudes) may become even more important.

Overvoltages. Overvoltages (Figure 17) can result from load switching (e.g., switching off a large load), variations in system generation, or variations in reactive compensation on the system (e.g., switching a capacitor bank on). These voltages must be evaluated against the long-duration voltage capability of loads and equipment on the system. For instance, most equipment on the power system is only rated to withstand a voltage 10% above nominal for any length of time. Many sensitive loads can have even more stringent voltage requirements.

Long-duration overvoltages must also be evaluated with respect to the long-time overvoltage capability of surge arresters. Metal oxide variation (MOV) arresters in particular can overheat and fail due to high voltages for long durations (e.g., seconds).

Fig. 16 Example of Swell (Surge)

Fig. 17 Example of Overvoltage

Fig. 18 Example of Undervoltage

Overvoltages can be controlled with voltage regulation equipment either on the power system or in a customer's facility. This can include various tap-changing regulators, ferroresonant regulators, line power conditioners, motor-generator sets, and uninterruptible power supplies.

Undervoltages. Undervoltages (Figure 18) have the opposite causes of overvoltages. Adding a load or removing a capacitor bank will cause an undervoltage until voltage regulation equipment on the system can bring the voltage back to within tolerances.

Motor starting is one of the most common causes of undervoltages. An induction motor draws 6 to 10 times its full load current during starting. This lagging current causes voltage drops in the system impedance. If the started motor is large relative to the system strength, these voltage drops can result in a significant system undervoltage. The magnitude of this starting current decreases over a period ranging from 1 s to minutes, depending on the inertia of the motor and the load, until the motor reaches full speed. This type of undervoltage can be mitigated by using various starting techniques to limit the starting current and is largely self-corrected when the starting is completed. For more information, see the section on Motor-Starting Effects.

Voltage Unbalance. Ideally, all phase-to-phase voltages to a three-phase motor should be equal or balanced. Unbalance between the individual phase voltages is caused by unbalanced loading on the system and by unbalances in the system impedances. Voltage unbalance is an important parameter for customers with motors because most three-phase motors have fairly stringent limitations on negative-sequence voltage (a measure of voltage unbalance), which is generated in the motor by unbalances in supplied voltages. Negative sequence currents heat the motor significantly. Voltage unbalance limitations (and steady-state voltage requirements in general) are discussed in ANSI *Standard* C84.1. The National Electrical Manufacturers Association (NEMA) developed standards and methods for evaluating and calculating voltage unbalance. Unbalance, as defined by NEMA, is calculated by the following equation:

$$\% \text{ Voltage unbalance} = 100 \times \frac{\text{Maximum deviation from average voltage}}{\text{Average voltage}}$$

The motor derating factor caused by the unbalanced voltage curve from NEMA *Standard* MG 1 shows the nonlinear relationship between the percent of voltage unbalance and the associated derating factor for motors (Figure 19). A balanced-voltage three-phase power supply to the motor is essential for efficient system operation. For example, a voltage unbalance of 3.5% can increase motor losses by approximately 15%.

Interruptions and Outages

Interruptions can result from power system faults, equipment failures, generation shortages, control malfunctions, or scheduled maintenance. They are measured by their duration (because the voltage magnitude is always zero), which is affected by utility

Fig. 19 Derating Factor Curve

Fig. 20 Example of Momentary Interruption

protection system design and the particular event causing the interruption.

Interruptions of any significant duration can potentially cause problems with a wide variety of different loads. Computers, controllers, relays, motors, and many other loads are sensitive to interruptions. The only protection for these loads during an interruption is a back-up power supply, a back-up generator (requires time to get started), or a UPS system (can constantly be online).

Momentary Interruption. A typical momentary interruption (Figure 20) lasts less than 3 s and occurs during a temporary fault, when a circuit breaker successfully recloses after the fault has been cleared. Lightning-induced faults usually fall into this category unless they cause a piece of equipment (e.g., transformer) to fail.

Temporary Interruption. Temporary interruptions that last between 3 s and 1 min result from faults that require multiple recloser operations to clear, or require time for back-up switching to reenergize portions of the interrupted circuit (e.g., automatic throwover switches).

Power Failure/Blackout. Outages lasting at least 1 min (Figure 21) are severe enough to be included in utility companies' reliability statistics. These failures are caused by fault conditions, maintenance operations that require repair crews, and emergency situations called blackouts.

Solutions involve using either UPS systems or back-up generators, depending on the critical nature of the load. UPS systems typically can provide uninterrupted supply for at least 15 min (based on battery capacity). This covers all momentary and temporary interruptions and provides sufficient time for an orderly shutdown. A UPS can be used in conjunction with a switching scheme involving multiple feeds from the utility to provide an even higher level of reliability. If back-up power is required beyond the capability of a UPS system, and multiple feeds are not realistic or adequate, then back-up generators are needed. On-site generators are typically used in these applications.

Brownout. A brownout is a long-term voltage reduction, usually of 3 to 5%. This is an intentional reduction to reduce load under emergency system conditions.

Harmonic Distortion

Harmonic distortion of the voltage waveform occurs because of the nonlinear characteristics of devices and loads on the power system. These nonlinear devices fall into one of three categories:

- Power electronics
- Ferromagnetic devices (e.g., transformers)
- Arcing devices

These devices usually generate harmonic currents, and voltage distortion on the system results from these harmonics interacting with the system impedance characteristics. Harmonic distortion is a growing concern for many customers and for the overall power system because of the increasing applications of power electronic equipment. In many commercial buildings, electronic (nonlinear) loads, such as variable-frequency drives, computers, and UPS systems, may be dominant in the facility, especially as more buildings switch to electronic ballasts for fluorescent lighting.

Harmonic distortion levels can be characterized by the complete harmonic spectrum with magnitudes and phase angles of each individual harmonic component. However, it is more common to use a single quantity, the **total harmonic distortion (THD)**, to characterize harmonic distortion of a particular waveform. It is important in general to distinguish between voltage distortion and current distortion because these quantities are handled differently in the standards and should be handled differently when performing measurements and interpreting data.

Voltage distortion is caused by the harmonic current emissions of nonlinear devices interacting with the impedance characteristics of the power system. Harmonic current distortion results in elevated true RMS current, which increases I^2R losses and elevated peak current. Because harmonics flow at frequencies higher than the fundamental frequency (e.g., 180 Hz, 300 Hz, 420 Hz), additional losses are experienced because of the reduction of conductor effective cross-sectional area, a phenomenon known as **skin effect**. These losses are attributed to I^2X_L at each harmonic frequency.

A particular concern is when resonance conditions on the power system magnify harmonic currents and high-voltage distortion levels. The natural resonance of the power system varies based on system inductance and capacitance and should be evaluated when adding nonlinear devices (equipment) or power factor capacitors to the system. Capacitors offer a low-impedance path to harmonic frequencies and can therefore attract harmonics, often resulting in reduced life, fuse blowing, or capacitor failure. Figure 22 illustrates the voltage waveform with harmonic content. Figures 23 and 24 illustrate distorted current waveforms.

Harmonic distortion can be reduced by adding an ac line reactor or harmonic filter at the input of individual nonlinear loads (Figure 25). A 5% impedance line reactor typically reduces

Fig. 21 Example of Blackout or Power Failure Waveform

harmonic distortion for three-phase nonlinear loads to about 35% of the fundamental current.

Harmonic current distortion can be reduced to levels of 5 to 8% total harmonic current distortion, at the individual load, using a typical low-pass harmonic filter (Figure 26). The benefit of reducing harmonics right at the contributing load is that the entire upstream power system benefits from reduced levels of current and voltage distortion.

Voltage Notches. A voltage waveform with notches (see Figure 13) caused by operating power electronics, especially where SCRs are involved [e.g., adjustable-speed drives (ASDs)], can be considered a special case that falls in between transients and harmonic distortion. Because notching occurs continuously (steady state), it can be characterized by the harmonic spectrum of the affected voltage. However, frequency components associated with the notching can be quite high, and it may not be possible to characterize them with measurement equipment normally used for harmonic analysis. It is usually easier to measure with an oscilloscope or transient disturbance monitor.

Three-phase SCR rectifiers (those typically in dc drives, UPS systems, ASDs, etc.) with continuous dc current are the most common cause of voltage notching. The notches occur when the current

Fig. 22 Example of Harmonic Voltage Distortion

Fig. 23 Example of Harmonic Current Distortion for Six-Pulse Rectifier with 5% Impedance Reactor

Fig. 24 Example of Harmonic Current Distortion for One-Phase Input Current for Single Personal Computer

Fig. 25 Example of VFD with ac Line Reactor

Fig. 26 Example of VFD with Low-Pass Harmonic Filter

commutates from one phase to another on the ac side of the rectifier. During this period, there is a momentary short circuit between two phases. The severity of the notch at any point in the system is determined by the source of inductance and the inductance between the rectifier and the point being monitored.

Often, an isolation transformer or 3% impedance ac line reactor (inductor) can be used in the circuit to reduce the effect of notching on the source side. The additional inductance increases the severity of voltage notches at the rectifier terminals (commutation time, or width of the notch, increases with increased commutation reactance); however, most of the notching voltage appears across the ac inductor and notching is less severe on the source side, where other equipment shares a common voltage source.

Steep voltage changes caused by notching can also result in ringing (oscillation) because of capacitances and inductances in the supply circuit. This oscillation can disturb sensitive controls connected to the affected circuit. The high frequencies involved can also cause noise to be capacitively coupled to adjacent electrical or communication circuits.

Voltage Flicker

Loads that vary with time, especially in the reactive component, can cause voltage flicker; the varying voltage magnitudes can affect lighting intensity. Arc furnaces are the most common cause of

Fig. 27 Example of Flicker

Fig. 28 Example of Electrical Noise

voltage flicker. The envelope of the 60 Hz variations is defined as the flicker signal V , and its RMS magnitude is expressed as a percentage of the fundamental. Voltage flicker is measured with respect to sensitivity of the human eye. A typical plot of the 60 Hz voltage envelope characterizing voltage flicker is shown in Figure 27.

The characteristics of voltage flicker are mainly determined by load characteristics and the system short-circuit capacity. For a critical load, it may be necessary to provide a dedicated feed so that it is not on the same circuit with a major load that causes voltage flicker. Using fast switching compensation, such as a static volt-ampere-reactive (VAR) system or dynamic VAR compensation system, can mitigate the problem. Another method is to effectively increase the short-circuit capacity at the point of common coupling with other loads by using a series capacitor. Protecting the series capacitor during fault conditions requires careful design.

Voltage flicker appears as a modulation of the fundamental frequency (similar to amplitude modulation of an AM radio signal). Therefore, it is easiest to define a magnitude for voltage flicker as the RMS magnitude of the modulation signal, which can be found by demodulating the waveform to remove the fundamental frequency and then measuring the magnitude of the modulation. Typically, magnitudes as low as 0.5% can result in perceptible light flicker if frequencies are in the range of 1 to 10 Hz. Flicker limitations are discussed in ANSI/IEEE *Standard 146*.

Light dimming, another type of light flicker, is caused by starting motors. Large single- or three-phase motors, as used in air conditioners, have the undesirable effect of drawing 6 to 10 times their full load current while starting. This large current, by flowing through system impedances, causes voltage sag that may dim lights.

Noise

Noise, a continuous, unwanted signal on the power circuits (Figure 28), can have a wide variety of different causes (e.g., switching, arcing, electric fields, magnetic fields, radio waves) and can be coupled onto the power circuit in a number of different ways. The noise source and susceptible circuit can be coupled by electric or magnetic fields or by electromagnetic interference (EMI).

The frequency range and magnitude of noise depend on the source that produces the noise. A typical magnitude of noise measured in the voltage is less than 1% of the RMS voltage magnitude.

Noise with enough amplitude disturbs electronic equipment such as microcomputers and programmable controllers. Some noise can be eliminated by using an isolation transformer with an electrostatic shield; other noise requires EMI filtering or line conditioners. Wiring and grounding practices also significantly affect the noise levels at particular loads. The appropriate method for controlling noise depends on the methods of coupling, frequency range of the noise, and susceptibility of the equipment being protected.

Inductive (Magnetic) Coupling. Magnetic fields induce currents in conductors. The magnetic fields are caused by current flowing in nearby power conductors, parts of circuits, data lines, or even building structure, and can be temporary or steady state. The actual coupled currents in power conductors and equipment conductors depend on exposure (length of conductor in the field), angle between conductor and field, and magnetic field strength. Conductors carrying large currents and/or with large spacing between conductors can create strong 60 Hz magnetic fields that do not decay quickly with distance from the source. These fields can cause distortion on CRT or TV screens, and may interfere with sensitive electronic (especially analog) devices such as radio-controlled equipment, energy and building automation systems, photoelectric sensors, test and measurement equipment, and data processing equipment. During building design, take steps to minimize generation of strong magnetic fields, and to keep sensitive equipment well separated from these areas.

Current flow in the power system ground can be an important cause of magnetic fields because the loop area between the supply conductor and the return path through the ground can be very large. Therefore, grounding techniques to minimize noise levels can help reduce magnetic field problems. To minimize interference, power conductors should always be physically separated from control circuit conductors. Magnetic shielding can also help.

Capacitive (Electrostatic) Coupling. Capacitive coupling between conductors results in coupling of transient voltage signals between circuits. Transient voltages with high-frequency components or high rates of rise are the most likely to be capacitively coupled between circuits (the coupling capability of a capacitor increases with frequency). Switch operations, arcing, lightning, or electrostatic discharge can cause these transients. Electric fields capacitively couple voltage between conductors. Strength is measured in volts per metre and may range from very slight to many kilovolts per metre.

High magnitudes of capacitively coupled voltages can affect normal operations of various types of electronic devices, or even cause discharges and damage. Possible solutions include applying shielding and coating, and improving design of power equipment to reduce the generation of high-transient-voltage conditions. To minimize interference, power conductors should always be physically separated from control circuit conductors.

Electromagnetic Interference (EMI). EMI refers to interference caused by electromagnetic waves over a wide range of frequencies. Many interference sources start out as either strongly magnetic or strongly electric, but within about half a wavelength the fields convert to a balanced ratio of electric and magnetic fields (an electromagnetic field). Transients such as electrostatic discharge, arcing, contacts, power electronic switching, fluorescent lighting, and lightning cause electromagnetic waves. Steady-state EMI can occur in the form of radio frequency interference (RFI) from microwave and radar transmissions, radio and TV broadcasts, corona of high-voltage transmission line, arc welding, and other sources that generate radio-frequency electromagnetic waves. Although RFI is not destructive, it can cause a variety of malfunctions of susceptible electronic equipment and can disturb microcomputers and programmable controllers; the level of disturbance depends on the amount of RFI. Solutions include using appropriate shielding or filtering techniques.

6. BILLING RATES

Equipment specifications state how much electricity is used, but the cost of that electricity is usually the determining factor in HVAC&R system design and equipment selection. Electricity tariffs or rates set prices for

- How much electricity is used; energy (kWh)
- Rate at which electricity is used; demand (kW)
- Quality of electricity used; power factor (VAR or kVAR)

Electric rates are contracts defining what the electricity user will pay for the amounts consumed. Rates may be based on cost, policy, market, or a combination of cost/policy and market. Additionally, rates may be based on either kW or kVA demand. Designers should not assume that the types of rates will remain the same over the life of a building, and owner/operators should review with their utility about potential rate changes that might lower cost or improve reliability.

Cost-Based Rates

Cost-based rates are designed to charge each class of consumer based on the utility's cost to serve that class. Costs depend on kilowatt-hours used, maximum demand, and time of day at which electricity is used. A customer class is a group of electricity consumers whose use characteristics are similar; each customer class has a different rate or tariff. Typical customer classes are residential, multifamily, small commercial, large commercial, small industrial, large industrial, electric water heating, electric space heating, street lighting, etc. Cost-based rates are usually predicated on the following assumptions:

- The more electricity a customer uses the less it costs, per kilowatt-hour, to serve that customer.
- The higher a customer's demand, the more it costs to serve that customer.
- It costs less per kilowatt-hour to serve a customer with a higher load factor. Load factor LF is defined as the customer's average demand divided by the peak demand, or the energy consumed in the billing period divided by the peak demand times the number of hours in the billing period. [LF = kWh used in the billing period/(peak demand × hours in billing period)]
- It costs less for a utility to deliver electricity at times of low system load than at times of high system load.

Energy Charge. The consumer pays the utility a fixed amount for every kilowatt-hour used. Small customers, especially residential, often simply pay for energy used. Certain loads may have usage profiles that allow the utility to provide electricity at times of low production costs (e.g., street lighting) or cost less per kilowatt-hour because the customer uses significantly more than a typical customer (e.g., electric space heating). These loads are often metered separately and are charged a lower cost per kilowatt-hour than general-service usage.

Fuel Adjustment Clause (FAC). A significant part of the cost of electricity is the fuel needed to generate it. In the 1970s, the price of primary energy sources (especially oil) became extremely volatile, and the fuel adjustment clause was designed to accommodate this without requiring frequent rate adjustments. Energy charges with FACs consist of two parts: a fixed charge per kilowatt-hour and a variable charge per kilowatt-hour that depends on the average price of fuel purchased by the power generator. During periods of low fossil fuel prices or high hydro runoff, for example, the FAC results in lower prices to the consumer. Many utilities embed part of the fuel cost in the rate tariffs and include the remaining variable portion in the FAC.

Demand Charge. "Demand" is the maximum rate of use of electricity. It is expressed in kilowatts (kW) or kilovolt-amps (kVA) and is

typically measured over 15, 30, or 60 min periods. For example, 1 kWh used in 15 min is equal to 4 kW demand (1 kWh/0.25 h). Demand charges are designed to cover the system capacity cost to deliver energy to a customer and/or the marginal generation cost to produce electricity at time of highest usage. To deliver electricity to a consumer, a utility must install wires, transformers, and meters; the higher the customer's projected demand, the larger the capacity of wires and transformers serving the customer must be. From a system-wide perspective, the utility must also build enough generation and transmission capacity to serve the system load at its highest peak level. A **noncoincident demand (NCD) charge** is a charge per kilowatt for the customer's maximum demand for electricity (in any 15, 30, or 60 min period) during the billing cycle. Noncoincident demand charges are generally imposed to cover the cost to transform and deliver energy to the consumer. A **coincident demand (CD) charge** (also known as a **peak or on-peak demand charge**) is a charge per kilowatt for the customer's maximum demand for electricity in any 15, 30, or 60 min period occurring during times of high system load. For example, in a summer-peaking utility, the demand charge may be applied only to the maximum demand occurring between 11:30 AM and 6:00 PM on weekdays from May to September. CD charges are designed to pay for additional generation and other system reinforcement costs needed to meet peak demands.

Ratcheted Demand Charge. Demand charges may be calculated based on the customer's maximum demand during each billing cycle, or the maximum demand during the current or previous 11 months preceding the electricity bill. A high demand in one month "ratchets" the demand charge up for some or all of the following 11 months.

Seasonal Rate. Some utilities' generation costs vary significantly from one season to another. For example, spring runoff may yield more low-cost hydroelectric energy, or high summer air-conditioning loads may result in more power generation by less efficient peaking plants. A seasonally adjusted rate reflects this by setting different kilowatt and/or kilowatt-hour charges for different seasons.

Time of Use (TOU) Rate. A utility's average production cost for electricity usually varies with the total system load. As demand increases, less efficient (i.e., more costly) generators are used. Increasing peak loads also require that a utility invest in greater generation, transmission, and distribution capacity to meet the peak. A TOU rate is designed to recover the increased production or capacity costs during times of system peak. Electricity use is recorded by multiregister meters and priced at different levels, depending on whether the peak/off-peak or peak/shoulder/off-peak model is used. TOU rates are usually designed not only to "recover" time-differentiated production costs, but also to induce consumers to shift their electricity usage from peak periods to times of lower system load. In this way, TOU rates are both cost-based and policy-based. Thermal energy storage (TES) systems are one method for consumers to reduce their on-peak demand or energy charges and to consume electricity during lower-cost, off-peak times. With TES, a consumer may use the same or more total electricity but will pay less for it.

Declining Block Rate. In designing cost-based rates, the cost to serve is usually inversely proportional to the amount consumed. To reflect this, energy may be priced according to a declining block rate, where the cost per kilowatt-hour decreases as usage increases. For example, a residential customer may pay \$0.12/kWh for the first 800 kWh used in a month, \$0.10/kWh for the next 550 kWh, and \$0.08/kWh for all electricity above 1350 kWh.

Demand-Dependent Block Rate. For larger customers, the size of the blocks of a block rate may depend on the measured demand. For example, a commercial consumer may pay \$0.12/kWh for the first 75 kWh per kilowatt of billing demand, \$0.10/kWh for the next 150 kWh per kilowatt of billing demand, and \$0.08/kWh for every kWh above 225 kWh per kilowatt of billing demand.

Load Factor Penalty. Utilities recover their fixed costs (e.g., capital cost of a transformer) as well as production costs through energy (kWh) charges as well as demand charges. If a consumer's load factor is less than expected, then the utility's kilowatt-hour revenues may not be sufficient to recover its fixed costs. This may occur for a customer with self-owned on-site generation who relies on the utility mainly when the on-site generator is being maintained. In this case, the utility may impose a load factor penalty or surcharge.

Power Factor Penalty. A power system is more efficient and stable when all three phases are equally loaded (balanced) and serving pure resistive load (100% power factor). Some inductive loads, such as most lighting and motors, require reactive power, which may be more difficult and expensive for the utility to supply. Moreover, reactive power (kVAR) is not always measured, and therefore not billed, by typical kilowatt-hour meters. Therefore, utilities often impose a power factor penalty or surcharge on customers with very reactive or inductive loads (power factor not close to 100%) to pay for the VARs that it must supply.

Customer Charge. This is a monthly, usually fixed charge that a consumer must pay, regardless of whether any electricity is used, for being a customer of a utility. This charge typically covers customer services such as the costs of billing, metering, and customer support services, such as call centers.

Connection Fee. When electric service is initiated, especially when construction (additional distribution lines, substations, distribution transformers, etc.) is required, the utility may charge a connection fee. For example, a utility may charge a residential customer a fixed cost per foot of distribution line that must be constructed beyond an initial 500 ft of line. Some customers may require redundant facilities to ensure reliable service (e.g., a second feeder and load transfer switch for a hospital). The utility would probably include such costs in its connection fee.

Policy-Based Rates

Policy-based rates are designed to encourage consumers to modify their energy use to better conform with the objectives of the utility or legislative or regulatory body (e.g., using nonpolluting or renewable energy sources, deferring grid expansion or generator construction by shifting electricity demand from peak periods, better using waste heat from industrial processes, etc.). It can be argued that some policy-based rates are in fact cost-based, but they incorporate "externalities," or external costs that cannot be directly allocated to a consumer's electricity use. The time of use rate could fall under either category.

Inverted Block Rate. The marginal cost to provide an existing customer with additional energy decreases as energy use per kilowatt of connected load increases. However, additional energy use often hastens the need to construct new generation facilities. An inverted block rate motivates the consumer to reduce energy use by charging less for the first kilowatt-hour used. For example, a residential consumer may pay \$0.08 for the first 850 kWh per month, \$0.10 for the next 500 kWh, and \$0.12 for all usage above 1350 kWh. As with the declining block rate, the break points between "blocks" may be based on demand for that billing cycle.

Lifeline Rate. Lifeline rates are designed so lower-income consumers will still be able to afford necessary electricity (e.g., enough for refrigeration, lights, adequate heat in winter, etc.). For example, a consumer pays a subsidized price per kilowatt-hour for a minimal amount of electricity and the market rate for any usage above the minimum (e.g., \$0.04/kWh for the first 675 kWh and \$0.12/kWh for usage above 675 kWh/month).

Net Metering. This is applicable for consumers who own their own on-site generation, still buy electricity from the grid, but sometimes can generate more electricity than is needed in their facility. Net metering is a contract in which the customer pays the utility for

the net electricity purchased (i.e., excess on-site generation is sold to the grid and offsets what the customer owes the utility for purchases from the grid).

Green Power Rate. Customers may sign up for blocks of electricity produced by renewable sources, such as solar photovoltaic (PV) or wind turbines. Because electricity from such sources usually costs more than electricity produced by conventional generation, the green energy is sold at a premium.

Surcharges. Government agencies may add special surcharges to electric bills to provide funding for specific energy-related or general-purpose programs. For example, in the United States, many state governments collect public benefit funds through electric bills to provide money for energy efficiency, renewable energy, low-income weatherization, and research programs. Other surcharges may be for power plant upgrades or putting electric distribution lines underground. Surcharges can be fixed or charged on a per-kWh basis. Some surcharges may be capped at a specific dollar amount per type of customer.

Taxes. Government agencies may collect sales and other specific taxes through utility bills. The taxes may be calculated as a percentage total of the entire bill, or on a per-kWh basis (such as \$0.001 per kWh). For some customers, taxes and surcharges may comprise a significant portion of the total bill.

Market-Based Rates

Electric utilities are restructuring to disaggregate electricity production, transmission, and distribution and open the market to competition. The theory is that a competitive electricity sector, governed by market rules, is more efficient, lower cost, and more congruent with consumer needs than regulated electric utilities. Market-based rates are not new, but they are becoming more prevalent. Rates tend to be volatile, and are structured as a contract between the consumer and energy supplier, rather than as a traditional tariff. As a result, they tend to be more customer specific than uniform over a customer class.

Real-Time Pricing (RTP). Under this scheme, the cost of electricity varies with each hour. The supplier sets a price for electricity based on its forecasted cost to produce or provide the electricity. Hour-by-hour prices are communicated to the customer from 1 to 24 h in advance, and the consumer decides what, if any, action to take in response to the forecasted prices. The most common RTP programs send prices to consumers each evening, to cover the next day. Some programs send prices 4 h in advance, and several also allow 1 h alerts for “surprise” prices during system emergencies or forced outages. Consumers who were on a demand (kilowatt) and energy (kilowatt-hour) rate often are billed only for energy use (kilowatt-hour) on RTP, because the hourly energy cost incorporates the demand charge. The RTP may only apply to the generation portion of the electric bill if transmission and distribution charges are still regulated.

Fixed Pricing. Some consumers in a deregulated market may opt for fixed prices for their electric supply. In these situations, the consumer may pay a price that is higher or lower than the RTP or spot prices. With this type of pricing, the burden of price risk goes to the supplier, who may charge a risk premium to the customer.

Spot Pricing. Consumers in some regions may purchase some or all of their electricity on the spot market, based on the current marginal cost of electricity. This is done through a power exchange, with the consumer either contracting directly with the exchange or going through a third-party electricity broker. Consumers may also purchase electricity through a combination of long-term contracts and spot market purchases.

Interruptible Rates and Responsive Loads. At times of high marginal electricity costs, it may be more cost effective for a utility to pay its customers to reduce electricity consumption than to

contract for additional electricity supplies. With interruptible rates, a consumer agrees to reduce power consumption to or below an agreed-upon level (or go off-line) when requested to do so by the utility, in return for a lower price. The utility’s requests may be limited in number of times per year (or month) the consumer can be asked to reduce load, maximum duration of the load reduction, and minimum notice required (typically 1 to 4 h) before electric load is reduced. In other cases, there is no limit to the number or length of utility requests.

Direct Load Control. This is similar to interruptible load, but instead of the consumer’s complying with the utility’s request, the utility can exercise direct control over the consumer’s appliances. Appliances commonly contracted for load control programs are water heaters, swimming pool pumps, air conditioners, heat pumps, resistance space heat, and controllable thermostats for HVAC&R systems. The tariff usually is in the form of a monthly rebate or fixed bill credit for each controllable appliance.

Performance-Based Rates. These are designed to ensure that the consumer receives acceptable quality and reliability of electric supply. The utility and consumer agree on a minimum standard for service quality in terms of number and duration of outages, voltage sags and swells, harmonic levels, or other transient phenomena. If these minimum service quality levels are not met, the utility must rebate money to the consumer; the amount rapidly increases as performance or service quality declines. In some cases, the rate, or type of rate charged, may not change, but customers receive bill credits or rebates based on a reduction in the electric company’s rate of return.

Performance Contracting. In performance contracting, a consumer contracts with a third party to pay for the end-use applications of electricity. This usually involves an agreement where the performance contractor [often called an energy service company (ESCO)] installs and sometimes operates and maintains improved equipment for HVAC&R systems, lighting, building or process energy management, etc. The consumer’s payments are indexed to successful equipment performance, which is often evaluated in terms of the facility’s utility bills and calculated cost savings comparing the actual energy costs with estimates of what the costs would have been without the ESCO’s intervention. A more detailed explanation of performance contracting is presented in *ASHRAE Guideline 14-2002*.

7. CODES AND STANDARDS

NEC®

The *National Electrical Code*® (NEC; NFPA *Standard 70*) is devised and published by the National Fire Protection Association, a consensus standards writing industry group. It is revised every three years. The code exists in several versions: the full text, an abridged edition, and the NEC Handbook (which contains the authorized commentary on the code, as well as the full text). It sets minimum electrical safety standards, and is widely adopted.

UL Listing

Underwriters Laboratories (UL), formerly an insurance industry organization, is now independent and nonprofit. It tests electrical components and equipment for potential hazards. When a device is UL-listed, UL has tested the device, and it meets their requirements for safety (i.e., fire or shock hazard). It does not necessarily mean that the device actually does what it is supposed to do. The UL does not have power of law in the United States; non-UL-listed devices are legal to install. However, insurance policies may have clauses that limit their liability in a claim related to failure of a non-UL-listed device. The NEC requires that a wiring component used for a specific purpose is UL-listed for that purpose. Thus, certain components

must be UL-listed before inspector approval and/or issuance of occupancy permits.

CSA Approved

The Canadian Standards Association (CSA) is made up of various government agencies, power utilities, insurance companies, electrical manufacturers, and other organizations. They update CSA *Standard* C22.1, the *Canadian Electrical Code* (CEC), every two or three years.

The Canadian Standards Association (or recognized equivalent) must certify every electrical device or component before it can be sold in Canada. Implicit in this is that all wiring must be done with CSA-approved materials. Testing is similar to UL testing (a bit more stringent), except that CSA approval is required by law. Like the UL, if a fire is caused by non-CSA-approved equipment, the insurance company may not pay the claim.

ULC

Underwriters Laboratory of Canada (ULC) is an independent organization that undertakes the quarterly inspection of manufacturers to ensure continued compliance of UL listed/recognized products to agency reports and safety standards. This work is done under contract to UL, Inc.; they are not a branch or subsidiary of UL.

NAFTA Wiring Standards

Since the North America Free Trade Agreement (NAFTA) came into effect on January 1, 1994, CSA approval of a device is legally considered equivalent to UL approval in the United States, and UL listing is accepted as equivalent to CSA approval in Canada. Devices marked only with UL approval are acceptable in the CEC, and CSA approval by itself of a device is accepted by the NEC. This allows much freer trade in electrical materials between the two countries. This does not affect the electrical codes themselves, so differences in practice between the NEC and CEC remain.

IEEE

The Institute of Electrical and Electronic Engineers' *Standard* 519 suggests limits for both harmonic current and voltage distortion, based on electrical system conditions.

CHAPTER 57

ROOM AIR DISTRIBUTION

<i>Indoor Air Quality and Sustainability</i>	57.1
<i>Application Guidelines</i>	57.2
<i>Mixed Air Distribution</i>	57.2
<i>Fully Stratified Air Distribution</i>	57.6
<i>Partially Mixed Air Distribution</i>	57.9
<i>Terminal Units</i>	57.10
<i>Fan Selection</i>	57.15
<i>Chilled Beams</i>	57.18

ROOM air distribution systems, like other HVAC systems, are intended to achieve required thermal comfort and ventilation for space occupants and processes. Although air terminals (inlets and outlets), terminal units, local ducts, and the rooms themselves may affect room air distribution, this chapter addresses only air terminals and their effect on occupant comfort. This chapter is intended to help HVAC designers apply air distribution systems to occupied spaces, providing information on characteristics of various air distribution strategies, and tools and guidelines for applications and system design. Naturally ventilated spaces are not addressed; see Chapter 16 of the 2013 *ASHRAE Handbook—Fundamentals* for details. Also see Chapter 20 of the 2013 *ASHRAE Handbook—Fundamentals* for more information on space air diffusion; Chapter 20 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for information on room air distribution equipment; and Chapter 48 of this volume for sound and vibration control guidance.

Room air distribution systems can be classified by (1) their primary objective and (2) the method by which they attempt to accomplish that objective. The objective of any air distribution system can be classified as one of the following:

- Conditioning and/or ventilation of the space for occupant thermal comfort
- Conditioning and/or ventilation to support processes within the space
- A combination of these

As a general guideline, the **occupied zone** in a space is any location where occupants normally reside, and may differ from project to project; it is application-specific, and should be carefully defined by the designer. The occupied zone is generally considered to be the room volume between the floor level and 6 ft above the floor. Standards and guidelines, such as ANSI/ASHRAE *Standards* 55 and 62.1, further define the occupied zone (e.g., *Standard* 55 exempts areas near walls).

Occupant comfort is defined in detail in ANSI/ASHRAE *Standard* 55-2004. Figure 5.2.1.1 of the standard shows acceptable ranges of temperature and humidity for spaces. As a general guide, 80% of occupants in typical office spaces can be satisfied with thermal environments over a wide range of temperatures and relative humidities. Designers often target indoor dry-bulb temperatures between 73 and 77°F, relative humidities between 25 and 60%, and occupied zone air velocities below 50 fpm. ANSI/ASHRAE *Standard* 113 describes a method for evaluating effectiveness of various room air distribution systems in achieving thermal comfort.

Room air distribution methods can be classified as one of the following:

- **Mixed systems** (e.g., overhead distribution) have little or no thermal stratification of air in the occupied and/or process space.
- **Full thermal stratification systems** (e.g., thermal displacement ventilation) have little or no air mixing in the occupied and/or process space.

- **Partially mixed systems** (e.g., most underfloor air distribution designs) provide limited air mixing in the occupied and/or process space.
- **Task/ambient air distribution** (e.g., personally controlled desk outlets, spot conditioning systems) focuses on conditioning only part of the space for thermal comfort and/or process control.

Because task/ambient design requires a high degree of individual control, it is not covered in this chapter; see Chapter 20 of the 2013 *ASHRAE Handbook—Fundamentals* for details. Limited design guidance is also provided by Bauman and Daly (2003).

Figure 1 illustrates the spectrum between the two extremes (full mixing and full stratification) of room air distribution strategies.

1. INDOOR AIR QUALITY AND SUSTAINABILITY

Air distribution systems affect not only indoor air quality (IAQ) and thermal comfort, but also energy consumption over the entire life of the project. Choices made early in the design process are important. ANSI/ASHRAE/IESNA *Standard* 90.1 provides energy efficiency requirements that affect supply air characteristics.

The U.S. Green Building Council's (USGBC) Leadership in Energy and Environmental Design (LEED®) Green Building Rating System™ was originally created in response to indoor air quality concerns, and has evolved to include prerequisites and credits for increasing ventilation effectiveness and improving thermal comfort (USGBC 2009). These requirements and optional points are relatively easy to achieve if good room air distribution design principles, methods, and standards are followed.

Environmental tobacco smoke (ETS) control is a LEED prerequisite. Banning indoor smoking is a common approach, but if indoor smoking is to be allowed, ANSI/ASHRAE *Standard* 62.1-2010 requires that more than the base non-ETS ventilation air be provided where ETS is present in all or part of a building. Rock (2006) provides additional advice on dealing with ETS.

Ventilation effectiveness is affected directly by the room air distribution system's design, construction, and operation, but is very difficult to predict. Many attempts have been made to quantify ventilation effectiveness, including ASHRAE *Standard* 129. However, this standard is only for experimental tests in well-controlled laboratories and should not be applied directly to real buildings.

Because of the difficulty in predicting ventilation effectiveness, ASHRAE *Standard* 62.1 provides a table of typical values that were determined through the experiences of its Standard Project Committee and reviewers or extracted from research literature; for example, well-designed ceiling-based air diffusion systems produce near-perfect air mixing in cooling mode, and yield an air change effectiveness of almost 1.0. More information on ASHRAE *Standard* 62.1 is available in its user's manual (ASHRAE 2011).

Displacement and underfloor air distribution (UFAD) systems have the potential for values greater than 1.0. More information on ceiling- and wall-mounted air inlets and outlets can be found in Rock and Zhu (2002). Performance of displacement systems is described by Chen and Glicksman (2003), and UFAD is discussed in detail by Bauman and Daly (2003).

The preparation of this chapter is assigned to TC 5.3, Room Air Distribution.

Fig. 1 Classification of Air Distribution Strategies

Air terminals, such as diffusers or grilles, may become unsightly over time because of accumulation of dirt on their faces (smudging). Instead of replacing air terminals, and thus requiring new materials and energy for manufacturing, they can often be cleaned in place to restore their appearance. Those that cannot be cleaned and must be replaced should be recycled, not discarded, to recover the various metals and other desirable materials of construction.

2. APPLICATION GUIDELINES

Design Constraints

Space design constraints affect room air distribution system choices and how air inlets and outlets are used. Space constraints may include the following:

- Dimensions
- Heat gain and loss characteristics
- Use
- Acoustical requirements
- Available locations for air inlets and outlets

Inlet and outlet characteristics are discussed in Chapter 20 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*. This chapter discusses more specific application considerations for air inlets and outlets.

Sound

Sound emitted from inlets and outlets is directly related to the airflow quantity and free area velocity. The airflow sound intensity in a space also depends on the room's acoustical absorption and the observer's distance from air distribution devices. For more information, see Chapter 48 of this volume and Chapter 8 in the 2013 *ASHRAE Handbook—Fundamentals*.

Inlet Conditions to Air Outlets

The way an airstream approaches an outlet is important. For good air diffusion, the inlet configuration should create a uniform discharge velocity profile from the outlet, or the outlet may not perform as intended.

The outlet usually cannot correct effects of improper duct approach. Many sidewall outlets are installed either at the end of

Table 1 Recommended Return Inlet Face Velocities

Inlet Location	Velocity Across Gross Area, fpm
Above occupied zone	>800
In occupied zone, not near seats	600 to 800
In occupied zone, near seats	400 to 600
Door or wall louvers	200 to 300
Through undercut area of doors	200 to 300

vertical ducts or in the side of horizontal ducts, and most ceiling outlets are attached either directly to the bottom of horizontal ducts or to special vertical takeoff ducts that connect the outlet with the horizontal duct. In all these cases, devices for directing and equalizing the airflow may be necessary for proper direction and diffusion of the air.

Return Air Inlets

The success of a mixed air distribution system depends primarily on supply diffuser location. Return grille location is far less critical than with outlets. In fact, the return air intake affects room air motion only immediately around the grille. Measurements of velocity near a return air grille show a rapid decrease in magnitude as the measuring device is moved away from the grille face. Table 1 shows recommended maximum return air grille velocities as a function of grille location. Every enclosed space should have return/transfer inlets of adequate size per this table.

For stratified and partially mixed air distribution systems, there are advantageous locations for return air inlets. For example, an intake can be located to return the warmest air in cooling season.

If the outlet is selected to provide adequate throw and directed away from returns or exhausts, supply short-circuiting is normally not a problem. The success of this practice is confirmed by the availability and use of combination supply and return diffusers.

3. MIXED AIR DISTRIBUTION

In mixed air systems, high-velocity supply jets from air outlets maintain comfort by mixing room air with supply air. This air mixing, heat transfer, and resultant velocity reduction should occur outside the occupied zone. Occupant comfort is maintained not directly by motion of air from outlets, but from secondary air

motion from mixing in the unoccupied zone. Comfort is maximized when uniform temperature distribution and room air velocities of less than 50 fpm are maintained in the occupied zone.

Maintaining velocities less than 50 fpm in the occupied zone is often overlooked by designers, but is critical to maintaining comfort. The outlet's selection, location, supply air volume, discharge velocity, and air temperature differential determine the resulting air motion in the occupied zone.

Principles of Operation

Mixed systems generally provide comfort by entraining room air into discharge jets located outside occupied zones, mixing supply and room air. Ideally, these systems generate low-velocity air motion (less than 50 fpm) throughout the occupied zone to provide uniform temperature gradients and velocities. Proper selection of an air outlet is critical for proper air distribution; improper selection can result in room air stagnation, unacceptable temperature gradients, and unacceptable velocities in the occupied zone that may lead to occupant discomfort.

The location of a discharge jet relative to surrounding surfaces is important. Discharge jets attach to parallel surfaces, given sufficient velocity and proximity. When a jet is attached, the throw increases by about 40% over a jet discharged in an open area. This difference is important when selecting an air outlet. For detailed discussion of the surface effect on discharge jets, see Chapter 20 of the 2013 *ASHRAE Handbook—Fundamentals*.

Space Ventilation and Contaminant Removal

These systems are intended to maintain acceptable indoor air quality by mixing supply and room air (dilution ventilation). Supply air is typically a conditioned mixture of ventilation and recirculated air. Outlet type and discharge velocity determine the mixing rate of the space and should be a design consideration. The room's return or exhaust air carries away diluted air contaminants. Space air ventilation rates are mandated under ASHRAE *Standard* 62.1-2010, but supply airflow rates are often higher because of thermal loads.

Benefits and Limitations

Benefits of fully mixed systems include the following:

- Most office applications can use lower supply dry-bulb temperatures, for smaller ductwork and lower supply air quantities.
- Air can be supplied at a lower moisture content, possibly eliminating the need for a more complex humidity control system.
- Vertical temperature gradients are lower for cooling applications with high internal heat gains, which may improve thermal comfort.
- Mixed systems are the most common design for distribution systems, because designers and installers are familiar with the required system components and installation.

Limitations of mixed systems include the following:

- Partial-load operation in variable-air-volume (VAV) systems may reduce outlet velocities, reducing room air mixing and compromising thermal comfort. Designers should consider this when selecting outlets.
- Cooling and heating with the same ceiling or high-sidewall diffuser may cause inadequate performance in heating mode and/or excessive velocity in cooling mode.
- Ceilings more than 12 ft high may require special design considerations to provide acceptable comfort in the occupied zone. Care should be taken to select the proper outlet for these applications.
- Because mixed systems typically use high-velocity jets of air, any obstructions in the space (e.g., bookshelves, wall partitions, furniture) can reduce comfort.
- Lighter-than-air contaminants are uniformly mixed in the space and typically result in higher contaminant concentrations, which may compromise indoor air quality.

Fig. 2 Air Supplied at Ceiling Induces Room Air into Supply Jet

Mixed air systems typically use either ceiling or sidewall outlets discharging air horizontally, or floor- or sill-mounted outlets discharging air vertically. They are the most common method of air distribution in North America.

Horizontal Discharge Cooling with Ceiling-Mounted Outlets

Ceiling-mounted outlets typically use the surface effect to transport supply air in the unoccupied zone. The supply air projects across the ceiling and, with sufficient velocity, can continue down wall surfaces and across floors, as shown in Figure 2. In this application, supply air should remain outside the occupied zone until it is adequately mixed and tempered with room air. Air motion in the occupied zone is generated by room air entrainment into the supply air (Nevins 1976).

Overhead outlets may also be installed on exposed ducts, in which case the surface effect does not apply. Typically, if the outlet is mounted 1 ft or more below a ceiling surface, discharge air will not attach to the surface. The unattached supply air has a shorter throw and can project downward, resulting in high air velocities in the occupied zone. Some outlets are designed for use in exposed duct applications. Typical outlet performance data presented by manufacturers are for outlets with surface effect; consult manufacturers for information on exposed duct applications.

Vertical-Discharge Cooling or Heating with Ceiling-Mounted Outlets

Vertically projected outlets are typically selected for high-ceiling applications that require forcing supply air down to the occupied zone. It is important to keep cooling supply air velocity below 50 fpm in the occupied zone. For heating, supply air should reach the floor.

There are outlets specifically designed for vertical projection and it is important to review the manufacturer's performance data notes to understand how to apply catalog data. Throws for heating and cooling differ and also vary depending on the difference between supply and room air temperatures.

Cooling with Sidewall Outlets

Sidewall outlets are usually selected when access to the ceiling plenum is restricted. Sidewall outlets within 1 ft of a ceiling and set for horizontal or a slightly upward projection the sidewall outlet provide a discharge pattern that attaches to the ceiling and travels in the unoccupied zone. This pattern entrains air from the occupied zone to provide mixing.

In some applications, the outlet must be located 2 to 4 ft below the ceiling. When set for horizontal projection, the discharge at some distance from the outlet may drop into the occupied zone. Most devices used for sidewall application can be adjusted to project the

air pattern upwards toward the ceiling. This allows the discharge air to attach to the ceiling, increasing throw distance and minimizing drop. This application provides occupant comfort by inducing air from the occupied zone into the supply air.

Some outlets may be more than 4 ft below the ceiling (e.g., in high-ceiling applications, the outlet may be located closer to the occupied zone to minimize the volume of the conditioned space). Most devices used for sidewall applications can be adjusted to project the air pattern upward or downward, which allows the device's throw distance to be adjusted to maximize performance.

When selecting sidewall outlets, it is important to understand the manufacturer's data. Most manufacturers offer data for outlets tested with surface effect, so they only apply if the device is set to direct supply air toward the ceiling. When the device is 4 ft or more below a ceiling, or supply air is directed horizontally or downward, the actual throw distance of the device is typically shorter. Many sidewall outlets can be adjusted to change the spread of supply air, which can significantly change throw distance. Manufacturers usually publish throw distances based on specific spread angles.

Cooling with Floor-Mounted Air Outlets

Although not typically selected for nonresidential buildings, floor-mounted outlets can be used for mixed system cooling applications. In this configuration, room air from the occupied zone is induced into the supply air, providing mixing. When cooling, the device should be selected to discharge vertically along windows, walls, or other vertical surfaces. Typical nonresidential applications include lobbies, long corridors, and houses of worship.

It is important to select a device that is specially designed for floor applications. It must be able to withstand both the required dynamic and static structural loads (e.g., people walking on them, loaded carts rolling across them). Also, many manufacturers offer devices designed to reduce the possibility of objects falling into the device. It is strongly recommended that obstructions are not located above these in-floor air terminals, to avoid restricting their air jets.

Long floor-mounted grilles generally have both functioning and nonfunctioning segments. When selecting air outlets for floor mounting, it is important to note that the throw distance and sound generated depend on the length of the active section. Most manufacturers' catalog data include correction factors for length's effects on both throw and sound. These corrections can be significant and should be evaluated. Understanding manufacturers' performance data and corresponding notes is imperative.

Cooling with Sill-Mounted Air Outlets

Sill-mounted air outlets are commonly used in applications that include unit ventilators and fan coil units. The outlet should be selected to discharge vertically along windows, walls, or other vertical surfaces, and project supply air above the occupied zone.

As with floor-mounted grilles, when selecting and locating sill grilles, consider selecting devices designed to reduce the nuisance of objects falling inside them. It is also recommended that sills be designed to prevent them from being used as shelves.

Heating and Cooling with Perimeter Ceiling-Mounted Outlets

When air outlets are used at the perimeter with vertical projection for heating and/or cooling, they should be located near the perimeter surface, and selected so that the published 150 fpm isothermal throw extends at least halfway down the surface or 5 ft above the floor, whichever is lower. In this manner, during heating, warm air mixes with the cool downdraft on the perimeter surface, to reduce or even eliminate drafts in the occupied space.

If a ceiling-mounted air outlet is located away from the perimeter wall, in cooling mode, the high-velocity cool air reduces or overcomes the thermal updrafts on the perimeter surface. To accomplish

this, the outlet should be selected for horizontal discharge toward the wall. Outlet selection should be such that isothermal throw to the terminal velocity of 150 fpm should include the distance from the outlet to the perimeter surface. For heating, the supply air temperature should not exceed 15°F above the room air temperature.

Space Temperature Gradients and Airflow Rates

A fully mixed system creates homogeneous thermal conditions throughout the space. As such, thermal gradients should not be expected to exist in the occupied zone. Improper selection, sizing, or placement may prevent full mixing and can result in stagnant areas, or having high-velocity air entering the occupied zone.

Supply airflow requirements to satisfy space sensible heat gains or losses are inversely proportional to the temperature difference between supply and return air. The following equation can be used to calculate space airflow requirements (at standard conditions):

$$Q = \frac{q_s}{1.08(t_r - t_s)} \quad (1)$$

where

Q = required supply airflow rate to meet sensible load, cfm

q_s = net sensible heat gain in the space, Btu/h

t_r = return or exhaust air temperature, °F

t_s = supply air temperature, °F

For fully mixed systems with conventional ceiling heights, the return (or exhaust) and room air temperatures are the same; for example, a room with a set-point temperature of 75°F has, on average, a 75°F return or exhaust air temperature.

Methods for Evaluation

The objective of air diffusion is to create the proper combination of room air temperature, humidity, and air motion in the occupied zone to provide thermal comfort and acceptable indoor environmental quality. There are three recommended methods of selecting outlets for mixed air systems using manufacturers' data:

- By appearance, flow rate, and sound data
- By isovels (lines of constant velocity) and mapping
- By comfort criteria

These selection methods are not meant to be independent. It is the designer's choice as to which to start with, but it is recommended that at least two methods be used for any design.

Variation from accepted thermal limits (ASHRAE *Standard 55*), lack of uniform thermal conditions in the space, or excessive fluctuation of conditions in one part of the space may produce discomfort. Thermal discomfort also can arise from any of the following conditions:

- Excessive air motion (draft)
- Excessive room air temperature stratification (horizontal, vertical, or both)
- Failure to deliver or distribute air according to load requirements at different locations
- Rapid fluctuation of room temperature

Selection

By Appearance, Flow Rate, and Sound Data. For a given appearance, flow rate, pressure drop, and sound level criteria, designers can select outlets from manufacturers' catalogs, using the following steps:

1. Determine air volumetric flow requirements based on load and room size. For VAV systems, evaluation should include the range of flow rates from minimum occupied to design load.

2. Determine acceptable outlet noise criterion (NC); consult Chapter 48 of this volume, or Chapter 8 in the 2013 *ASHRAE Handbook—Fundamentals*.
3. Locate a range of products from manufacturers' catalogs that meet the airflow and NC requirements. Multiple outlets in a space at the same cataloged NC, and other design considerations, may result in actual sound levels greater than cataloged values. Manufacturers' data are obtained using ideal inlet conditions, and may vary from field installations. From experience,
 - For identical outlets 10 ft or more apart, the cataloged NC rating applies.
 - Identical outlets within 10 ft of each other add no more than 3 dB to the sound pressure level.
 - For continuous linear outlets, only the sound produced by the closest 10 ft need be considered.
 - A wide-open damper installed in the neck of a diffuser can add 4 to 5 NC to the cataloged NC value.
 - Significantly closed balancing dampers can add more than 10 NC, depending on duct pressure and how far upstream it is installed. Table 2 gives an example.
4. Select air terminals from manufacturers' catalogs that meet aesthetic and physical needs.

Although these selections may meet the sound requirements for a project, the results do not fully address occupant comfort. Without evaluating the throw of the outlets or room air mixing, this selection method may result in excessive air velocities in the occupied zone, or limited mixing and resultant stagnation. It is recommended that the designer consider selection by isovel mapping or by comfort criteria in addition to selection by appearance, flow rate, and sound data. Either of these methods addresses resulting air motion in the occupied zone and occupant comfort.

By Isovels and Mapping. Using manufacturers' catalog throw data, a designer can predict the path of an outlet's discharge jet. Most manufacturers' catalogs list the distance a jet travels to reach a terminal velocity of 150 to 50 fpm. With this information, the designer can map the path of the discharge jet for a given outlet. This evaluation can prevent problems such as excessively high air velocities in the occupied zone, or stagnation in a given area. Note that most manufacturers' throw data are based on isothermal supply air; the supply jet temperature is equal to the room air temperature. When using this mapping method, consider the positive or negative buoyancy of non-isothermal (heated or cooled) supply air. In both heating and cooling, a discharge jet should travel the distance shown in the catalog to a terminal velocity of 150 fpm without much influence from buoyancy. When evaluating a jet at lower terminal velocities (e.g., 100 or 50 fpm), consider buoyancy's effect on the distance the jet will travel.

A cool air jet travels less far along a horizontal surface than an isothermal jet does. If an outlet is selected so that the horizontal jet does not have enough velocity to reach a vertical surface, the jet can separate from the horizontal surface and project down into the occupied zone, causing drafts and discomfort. Manufacturers' tables show the drop of a cool air jet so the designer can predict the resulting path.

When evaluating heated air, the designer should consider the positive buoyancy of the discharge jet. A heated jet projecting along a horizontal surface or in an upward vertical pattern travels farther than an isothermal jet. In downward vertical discharge, a heated jet travels a shorter distance than an isothermal jet.

Table 2 Effect of Neck-Mounted Damper on Air Outlet NC

Total Pressure Ratio*	100%	150%	200%	400%
dB Increase	0	4.5	8	16

*Ratio of air pressure before and after damper.

Combining selection by isovels and mapping with acoustical selection allows discharge jet location and intensity in a space to be predicted. Outlet selection should be evaluated at the space's typical operating points (i.e., maximum heating and cooling, and minimum heating and cooling). The following steps may be used:

1. Identify the occupied zone for the space.
2. Select outlet(s) that meet design NC, pressure drop, and flow rate requirements. Identify the supply jet location using cataloged throw data.
3. Evaluate air jet mapping to ensure terminal velocities in the occupied zone do not exceed 50 fpm.
4. For overhead heating applications, $\Delta t < 15^\circ\text{F}$ (see Chapter 20 of the 2013 *ASHRAE Handbook—Fundamentals*), evaluate the diagram to ensure that jet velocities 5 ft from the floor are at least 150 fpm.

Other design considerations include the following:

- In multiple-outlet applications, jets should not collide to cause a downward projection of air resulting in velocities greater than 50 fpm in the occupied zone.
- For VAV applications, consider both minimum and maximum flow conditions.

Selection by Comfort Criteria T_{50}/L . Selection by isovels and mapping is effective at predicting the path of the discharge jet from an outlet and evaluating resultant occupant comfort. However, there is an established method to quantify occupant comfort during cooling conditions, based on space dimensions and isothermal catalog throw data. This method can be used to predict a space's resulting air diffusion performance index (ADPI).

The comfort criteria T_{50}/L method was developed to predict occupant comfort during cooling conditions, using manufacturers' isothermal catalog throw data (T , usually for 50 fpm terminal velocity) and the dimensions available for throw (L) on the plan view of a mechanical drawing. By using the ratio of T_{50}/L , the designer can predict the level of comfort with a single rating number: ADPI. ADPI can provide further information about the comfort level in a space for results obtained from the NC and mapping selection methods.

Air Distribution Performance Index (ADPI). The air distribution performance index was developed as a way to quantify the comfort level for a space conditioned by a mixed air system in cooling. ADPI uses the effective draft temperature collected at an array of points taken within the occupied zone to predict comfort. ADPI is the percentage of points in a space where the effective draft temperature is between -3 and $+2^\circ\text{F}$ and the air velocity is less than 70 fpm. A high percentage of people have been found to be comfortable in cooling applications for office-type occupations where these conditions are met. High ADPI values generally correlate to high space thermal comfort levels with the maximum obtainable value of 100. Select outlets to provide a minimum ADPI value of 80.

The effective draft temperature provides a quantifiable indication of comfort at a discrete point in a space by combining the physiological effects of air temperature and air motion on a human body. The effective draft temperature t_{ed} (the difference in temperature between any point in the occupied zone and the control condition) can be calculated using the following equation proposed by Rydberg and Norback (1949) and modified by Straub (Straub and Chen 1957; Straub et al. 1956) in discussion of a paper by Koestel and Tuve (1955):

$$t_{ed} = (t_x - t_c) - 0.07(V_x - 30) \tag{2}$$

where

- t_{ed} = effective draft temperature, °F
- t_x = local airstream dry-bulb temperature, °F

t_c = average (control) room dry-bulb temperature, °F
 V_x = local airstream centerline velocity, fpm

T_{50}/L *Selection Method.* This method uses the ratio of cataloged isothermal throw data at 50 fpm to the characteristic length for a given device (Table 3).

Each type of diffuser has different performance characteristics and therefore may provide a different ADPI value for the same cooling application at the same conditions. Calculating T_{50}/L for a given outlet can predict the level of cooling comfort for a space. Using Table 4, the designer can optimize not only the type of diffuser to select but also the size and capacity.

Using T_{50}/L helps designers maximize space cooling comfort; however, this method is not meant to, nor may it be practical to, evaluate T_{50}/L values for each outlet on a project.

Design Procedures. T_{50}/L can be used as a general tool to evaluate cooling comfort levels in a space, at the beginning of design to optimize outlet selection (as shown in the following steps), or at the end of the process to predict cooling comfort levels in spaces designed using NC and mapping methods:

Table 3 Characteristic Room Length for Several Diffusers (Measured from Center of Air Outlet)

Diffuser Type	Characteristic Length L
High sidewall grille	Distance to wall perpendicular to jet
Circular ceiling diffuser	Distance to closest wall or intersecting air jet
Sill grille	Length of room in direction of jet flow
Ceiling slot diffuser	Distance to wall or midplane between outlets
Light troffer diffusers	Distance to midplane between outlets plus distance from ceiling to top of occupied zone
Perforated, louvered ceiling diffusers	Distance to wall or midplane between outlets

Table 4 Air Diffusion Performance Index (ADPI) Selection Guide

Terminal Device	Room Load, Btu/h·ft ²	T_{50}/L for Maximum ADPI	For ADPI Maximum Greater Than	Range of T_{50}/L
High sidewall grilles	80	1.8	68	—
	60	1.8	72	1.5 to 2.2
	40	1.6	78	1.2 to 2.3
Circular ceiling diffusers	20	1.5	85	1.0 to 1.9
	80	0.8	76	0.7 to 1.3
	60	0.8	83	0.7 to 1.2
	40	0.8	88	0.5 to 1.5
Sill grille, straight vanes	20	0.8	93	0.7 to 1.3
	80	1.7	61	1.5 to 1.7
	60	1.7	72	1.4 to 1.7
	40	1.3	86	1.2 to 1.8
Sill grille, spread vanes	20	0.9	95	0.8 to 1.3
	80	0.7	94	0.6 to 1.5
	60	0.7	94	0.6 to 1.7
	40	0.7	94	—
Ceiling slot diffusers for T_{100}/L	20	0.7	94	—
	80	0.3	85	0.3 to 0.7
	60	0.3	88	0.3 to 0.8
	40	0.3	91	0.3 to 1.1
Light troffer diffusers	20	0.3	92	0.3 to 1.5
	60	2.5	86	<3.8
	40	1.0	92	<3.0
Perforated, louvered ceiling diffusers	20	1.0	95	<4.5
	11 to 50	2.0	96	1.4 to 2.7
				80 1.0 to 3.4

1. Determine air volumetric flow requirements based on load and room size. For VAV systems, evaluation should include both minimum occupied and maximum design flow rates.
2. Select tentative diffuser type and location in room.
3. Determine room's characteristic length L (Table 3).
4. Select recommended T_{50}/L (or T_{100}/L) ratio from Table 4.
5. Calculate throw distance T_{50} by multiplying recommended T_{50}/L (T_{100}/L for linear slots) ratio from Table 4 by available length L .
6. Locate appropriate outlet size from manufacturer's catalog.
7. Ensure that this outlet meets other imposed specifications (e.g., noise, static pressure loss).

Example 1. For a 20 by 12 ft room, with 9 ft ceiling, with uniform loading of 10 Btu/h·ft² or 2400 Btu/h, and air volumetric flow of 1 cfm/ft² or 240 cfm for one outlet, find the size for a high sidewall grille located at the center of 12 ft end wall, 9 in. from ceiling.

Solution:

Characteristic length $L = 20$ ft (length of room: Table 3)

Recommended $T_{50}/L = 1.5$ Table 4

Throw to 50 fpm $T_{50} = 1.5 \times 20 = 30$ ft

Refer to the manufacturer's catalog for a size that gives this isothermal throw to 50 fpm. One manufacturer recommends the following sizes, when vanes are straight, discharging at 240 cfm: 16 by 4 in., 12 by 5 in., or 10 by 6 in.

More information on conventional mixing systems, and many more design examples, can be found in Rock and Zhu (2002).

4. FULLY STRATIFIED AIR DISTRIBUTION

Systems that discharge cool air at low sidewall or floor locations with very little entrainment of (and thus mixing with) room air create (vertical) thermal stratification throughout the space. These **displacement ventilation** systems have been popular in northern Europe for some time. Floor-based outlets in underfloor applications may also be used to provide fully stratified air distribution.

Principles of Operation

Thermal displacement ventilation (TDV) systems (Figure 3) use very low discharge velocities, typically 50 to 70 fpm, to deliver cool supply air to the space. The discharge temperature of the supply air is generally above 60°F, although lower temperatures may be used in industrial applications, exercise or sports facilities, and transient areas. The cool air is negatively buoyant compared to ambient air and drops to the floor after discharge. It then spreads across the lower level of the space.

As convective heat sources (Figure 3) in the space transfer heat to the cooler air around them, natural convection currents form and rise along the heat transfer boundary. Without significant room air movement, these currents rise to form a convective heat plume around and above the heat source. As the plume rises, it expands by entraining surrounding air. Its growth and ascent are proportional to the heat source's size and intensity and temperature of ambient air above it. Ambient air from below and around the heat source fills the void created by the rising plume. If the heat source is near the floor (e.g., an occupant), the plume entrains cool, conditioned air from the floor level, which is drawn to the respiration level, and serves as the source of inhaled air. Exhaled air rises with the escaping heat plume, because it is warmer and more humid than the ambient air. Convective heat from sources located above the occupied zone has little effect on occupied-zone air temperature.

At a certain height, where plume temperature equals ambient temperature, the plume disintegrates and spills horizontally. Two distinct zones are thus formed in the room: a lower occupied zone with little or no recirculation flow (close to displacement flow), and an upper zone with recirculation flow. The boundary between these two zones is called **shift zone**. The shift zone height is calculated as the height above the floor where the total amount of air carried in

convective plumes above heat sources equals the supply airflow distributed through displacement diffusers. Actual and simplified representations of the temperature gradient in the space are shown in Figure 4.

Thermal displacement ventilation systems can be modeled as shown in Figure 4. A thin layer of conditioned supply air lies adjacent to the floor. Next is a lower zone in which both ambient air temperature and contaminant concentration levels increase with height. Finally, a pool of warm used or contaminated air (the upper zone) may form next to the ceiling, depending on the supplied airflow rate in proportion to the volume of thermal plumes rising through the space.

Space Ventilation and Contaminant Removal

Thermal displacement ventilation is very effective at removing airborne contaminants that are equal to or lighter than the ambient air (e.g., respiratory-produced contaminants, tobacco smoke). According to ASHRAE *Standard* 62.1-2010, these systems have zone air distribution effectiveness E_z values of 1.2, compared to maximum values of 1.0 for mixed air systems.

Fig. 3 Displacement Ventilation System Characteristics

Fig. 4 Temperature Profile of Displacement Ventilation System

Typical Applications

Thermal displacement ventilation systems typically have higher return air temperatures than mixed systems. Thus, they may allow extended periods of air- or water-side economizer operation, especially in mild, relatively dry climates.

Thermal displacement ventilation systems are commonly used in applications such as

- Restaurants
- Casinos
- Large open-plan offices, classrooms, lecture halls, and meeting rooms
- Theaters and auditoriums
- Hospitals and clean rooms
- Other spaces with high ceilings

Benefits and Limitations

Benefits of displacement ventilation systems include the following:

- Removal of airborne contaminants is more effective.
- In mild climates, significantly less energy may be used to maintain the same space occupied zone air temperature in cooling mode.
- Air distribution effectiveness is high: less outdoor air is required to meet ASHRAE *Standard* 62.1-2010 requirements.
- Diffuser noise level is lower.
- Lower turbulence intensity can reduce draft-related complaints.

Some applications do not favor use of thermal displacement ventilation. Small offices, especially with perimeter exposures, often do not have room for the large outlets that may be required. The following types of areas may be better served by a mixed system:

- Spaces with ceiling heights less than 9 ft
- Spaces with exceptionally high occupied zone heat loads (Bauman and Daly 2003)
- Spaces with ceiling heights below 10 ft that are subjected to significant room air disturbances
- Applications where contaminants are heavier and/or colder than ambient air

When thermal displacement systems are used in humid climates, it may be necessary to dehumidify and possibly reheat supply air to maintain desired space conditions. As with all HVAC air systems' design, a psychrometric analysis is advised.

Outlet Characteristics

Displacement outlets are designed for average face velocities between 50 and 70 fpm, and are typically in a low sidewall or floor location. Return or exhaust air intakes should always be located above the occupied zone for human thermal comfort applications.

Displacement outlets are available in a number of configurations and sizes. Some models are designed to fit in corners or along sidewalls, or stand freely as columns. It is important to consider the degree of flow equalization the outlet achieves, because use of the entire outlet surface for air discharge is paramount to minimizing clear zones and maintaining acceptable temperatures at the lower levels of the space.

Stationary occupants should not be subjected to discharge velocities exceeding about 40 fpm because air at the ankle level within this velocity envelope tends to be quite cool. As such, most outlet manufacturers define a **clear zone** in which location of stationary, low-activity occupants is strongly discouraged, but transient occupancy, such as in corridors or aisles, is possible. Occupants with high activity levels may also find the clear zone acceptable.

Fig. 5 Temperature Gradient Relationships for Thermal Displacement Ventilation System in Typical Classroom or Office with 10 ft Ceiling

Space Temperature Gradients and Airflow Rates

Figure 5 illustrates thermal temperature gradients that might be expected for a classroom with a 10 ft ceiling, served by thermal displacement ventilation. If loads are typical to the application and proper space airflow is supplied, Skistad et al. (2002) indicate that approximately 50% of the total temperature difference between supply air and return or exhaust air is dissipated in clear zone(s) next to the outlet(s). The other half of the temperature gradient is the **space temperature gradient (STG)**, assumed to be linear with air temperature, increasing gradually from floor to ceiling.

For stationary, low-activity occupants, keep supply air temperatures above 60°F. When occupants are very near outlets (e.g., in underseat delivery), keep supply air temperatures at or above 64°F.

Methods of Evaluation

Unlike mixed systems, outlets in thermal displacement systems discharge air at very low velocities, resulting in very little mixing. As such, design of these systems primarily involves determining a supply airflow rate to manage the thermal gradients in the space in accordance with ASHRAE comfort guidelines. ASHRAE *Standard 55* recommends that the vertical temperature difference between the ankle and head levels of space occupants be limited to no more than 5.4°F to maintain a high degree (>95%) of occupant satisfaction.

Design Procedures

Displacement ventilation system design is somewhat different than for mixing ventilation. For mixing ventilation systems, where air is mixed relatively evenly throughout the space, the return/exhaust air temperature is assumed to equal the space temperature. In displacement ventilation systems, the space is divided into two vertical zones. The desired space air temperature is maintained only in the lower zone and is always higher in the upper zone because of the temperature stratification created by natural convection.

Depending on space requirements, two types of design methods are used. The most common is temperature-based, and is used when heat removal is the main objective of the air-conditioning system design (e.g., in schools, offices, auditoriums, sport facilities). The other, the shift-zone method, is used when contaminant removal

should be considered (e.g., smoking rooms and other facilities with emissions of gaseous, equal- or lighter-than-air contaminants). The objective of the temperature-based method is satisfying thermal comfort in the occupied zone; the shift-zone design addresses this concern and also ensures that contaminants rise above the occupants' breathing level.

Space temperature gradient (STG) is affected by the strength and location of heat sources in the space, heat exchange by radiation between surfaces in the space, and supply airflow. The design procedure presented in this section is based on Skistad et al.'s (2002) simplified method of estimating temperature gradient (Figure 5). This method is applicable for typical spaces with a ceiling height up to 12 ft, such as classrooms, office spaces, and meeting rooms. When designing more complex spaces, computational fluid dynamics (CFD) software programs may be used (see Chapter 13 of the 2013 *ASHRAE Handbook—Fundamentals* for more information).

The thermal gradient relationships illustrated in Figure 5 can be used to establish an acceptable supply-to-return air temperature differential Δt_{SR} from which the supply airflow rate is calculated. Because the space temperature gradient is assumed to be linear, the occupied gradient in the occupied zone is proportional to the volume of the space it represents. For example, if return height is 10 ft and the occupied zone is 5 ft high, its gradient comprises 50% of the space temperature gradient, or 25% of Δt_{SR} . The temperature difference between room air at the top of the occupied zone and the supply air is therefore 75% of Δt_{SR} .

Determining an acceptable Δt_{SR} should consider both the room-to-supply temperature differential and the occupied zone temperature gradient (as limited to 5.4°F by ASHRAE *Standard 55*).

In general, high-ceiling applications allow larger supply-to-return air temperature differentials, because the occupied zone is a smaller percentage of total room air volume. However, the differential may be reduced by limitations on the supply air temperature, as shown in Example 2.

The supply airflow rate Q to achieve Δt_{SR} is calculated from Equation (1).

Example 2. A classroom with a 10 ft ceiling is to be cooled by thermal displacement ventilation. The supply air temperature is 62°F and room temperature is maintained at 76°F at 5 ft level. The total sensible heat gain of the space is 28,000 Btu/h.

Calculate the (1) overall temperature differential between supply and return airflow and (2) required space airflow. Identify return air temperature and temperature at occupants' ankle level.

Solution: Using the relationships in Figure 5, the supply-to-return temperature differential Δt_{SR} and return air temperature can be predicted as follows:

$$\Delta t_{SR} = (t_{room} - t_{supply})/0.75 = (76 - 62)/0.75 = 18.7^\circ\text{F}$$

$$t_{return} = t_{supply} + \Delta t_{SR} = 62 + 18.7 = 80.7^\circ\text{F}$$

To ensure a high level of thermal comfort, the occupied-zone temperature gradient Δt_{oz} should not exceed 5.4°F. For this application, the occupied zone gradient is acceptable:

$$\Delta t_{oz} = \Delta t_{SR} \times 0.25 = 18.7 \times 0.25 = 4.7^\circ\text{F}$$

From Equation (1), the airflow required to maintain this gradient is

$$Q = 28,000/(1.08 \times 18.7) = 1386 \text{ cfm}$$

Application Considerations

Displacement ventilation is a cooling-only method of room air distribution. For heating, a separate system is generally recommended. Displacement ventilation can be used successfully in combination with radiators and convectors installed at the exterior walls to offset space heat losses. Radiant heating panels and heated floors also can be used with displacement ventilation. To maintain

displacement ventilation, outlets should supply ventilation air about 4°F lower than the desired room temperature.

Thermal displacement ventilation systems can be either constant or variable air volume. A thermostat in a representative location in the space or return plenum should determine the delivered air volume or temperature. If the time-averaged requirements of ASHRAE *Standard* 62.1-2004 are met, intermittent on/off airflow control can be used.

Avoid using thermal displacement and mixed air systems in the same space, because mixing destroys the natural stratification that drives the thermal displacement ventilation system. Thermal displacement systems can be complemented by hydronic systems such as chilled floors. Use caution when combining chilled ceilings, beams, or panels with fully stratified systems, because cold surfaces in the upper zone of the space may recirculate contaminants stratified in the upper zone back into the occupied zone.

Chen and Glicksman (2003) provide additional information on fully stratified air distribution systems.

5. PARTIALLY MIXED AIR DISTRIBUTION

A partially mixed system's characteristics fall between a fully mixed system and a fully stratified system. It includes both a high-velocity mixed air zone and a low-velocity stratified zone where room air motion is caused by thermal forces. For example, floor-based outlets, when operating in a cooling mode with relatively high discharge velocities (>150 fpm), create mixing, thus affecting the amount of stratification in the lower portions of the room. In the upper portions of the room, away from the influence of floor outlets, room air often remains thermally stratified in much the same way as displacement ventilation systems.

Principles of Operation

Supply air is discharged, usually vertically, at relatively high velocities and entrains room air in a similar fashion to outlets used in mixed air systems. This entrainment, as shown in Figure 6, reduces the temperature and velocity differentials between supply and ambient room air. This discharge results in a vertical plume that rises until its velocity is reduced to about 50 fpm. At this point, its kinetic energy is insufficient to entrain much more room air, so mixing stops. Because air in the plume is still cooler than the surrounding air, the supply air spreads horizontally across the space, where it is entrained by rising thermal plumes generated by nearby heat sources.

Research and experience have shown that the amount of room air stratification varies depending on design, commissioning, and operation. Control of stratification includes the following considerations:

- By reducing airflow and mixing in the occupied zone, fan energy can be reduced and stratification can be increased, approaching a

Fig. 6 UFAD System in Partially Stratified Application

reasonable target at 3 to 4°F temperature difference from head to ankle height, which satisfies ASHRAE *Standard* 55-2010.

- By increasing airflow and mixing in the occupied zone, excessive stratification can be avoided, thereby improving thermal comfort.

In practice, successful installation requires an optimal balance of these issues (Webster and Bauman 2006).

Figure 6 shows one example of the resulting room air distribution in which the room air is mixed in the **lower mixed zone**, which is bounded by the floor and the elevation (**throw height**) at which the 50 fpm terminal velocity occurs. At this elevation, stratification begins to occur and a linear temperature gradient, similar to that found in thermal displacement systems, forms and extends through the **stratified zone**. As with thermal displacement ventilation, convective heat plumes from space heat sources draw conditioned air from the lower (mixed) level through the stratified zone and to the overhead return location. A third zone, referred to as the **upper mixed zone**, may exist where the volume of rising heat plumes terminate. Although velocities in this area are quite low, the air tends to be mixed.

Space Ventilation and Contaminant Removal

Partially mixed systems' ventilation and contaminant removal efficiencies vary considerably. Restricting mixed conditions to below the breathing level results in most respiratory-associated contaminants being conveyed directly to the overhead return by heat plumes rising from occupants. If the lower mixed zone extends above the breathing level, contaminants are entrained and horizontally transmitted across occupied levels of the space, as occurs in mixed air (dilution ventilation) systems.

According to ASHRAE *Standard* 62.1, these systems may have zone air distribution effectiveness E_z values that exceed those of fully mixed systems.

Typical Applications

Partially mixed systems are commonly used in applications such as the following:

- Office buildings with raised floors
- Call centers
- Libraries
- Casinos
- Other spaces with open or high ceilings

Many underfloor air distribution (UFAD) systems can be classified as partially mixed systems. These systems are popular because of their relocation flexibility when used in conjunction with raised-access flooring systems. Outlet accessibility also allows easy occupant adjustment of space airflow delivery. The cavity beneath the access floor tiles is generally pressurized and used as a supply air plenum. Supply outlets placed in access floor tiles are commonly tapped directly into the pressurized plenum, but may be ducted from a fan-assisted terminal unit mounted beneath the floor.

Benefits and Limitations

Benefits of UFAD systems include the following:

- Using a raised floor system may substantially reduce air distribution ductwork and terminal requirements.
- Central fan energy consumption may be lower.
- The space service flexibility of the access floor platform is extended to include HVAC services as well. Nonducted outlets can be easily added or relocated.
- Because most outlets are sized to handle loads typical to an interior single-occupant office or workstation, they can be placed within the workstation to give occupants thermal control over their individual work environment. This makes higher individual occupant comfort levels possible.

- Air- and water-side economizer opportunities are extended, especially in mild and relatively dry climates.

Applications where contaminants are heavier and/or colder than ambient air may be better served by a mixed air system. As with thermal displacement systems, partially stratified systems in humid climates require that the outdoor air be sufficiently dehumidified to satisfy space latent requirements. The temperature of dehumidified air must often be increased before introduction to the occupied space.

Outlet Characteristics

One outlet type is a swirl diffuser with a high-induction core, which induces large amounts of room air to quickly reduce supply to ambient air velocity and temperature differentials. Supply air is injected into the room as a swirling vertical plume close to the outlet. Properly selected, these outlets produce a limited vertical projection of the supply air plume, restricting mixing to the lower portions of the space. Most of these outlets allow occupants to adjust the outlet airflow rate easily. Other versions incorporate automatically controlled dampers that are repositioned by a signal from the space thermostat and/or central control system.

Another category includes more conventional floor grilles designed for directional discharge of supplied airflow. These grilles may be either linear or modular in design, and may allow occupants to adjust the discharge air pattern by repositioning the core of the outlet. Most floor grilles include an integral actuated damper, or other means, that automatically throttles the volume of air in response to the zone conditioning requirements.

Room air induction allows UFAD diffusers to comfortably deliver supply air a few degrees cooler than possible with outlets used for thermal displacement ventilation outlets. The observance of clear, or adjacent, zones above and around the diffusers, where stationary occupants should not reside, is recommended. Outlet manufacturers typically identify such restrictive areas in their product literature.

Space Temperature Gradients and Airflow Rates

The objective of partially mixed systems is to condition the air in the occupied zone while allowing stratification to naturally occur. By allowing this stratification, some of the space heat gain can be removed by return or exhaust instead of by supply air delivery to the space. If the supply airflow rate and sensible heat gains affecting the lower zone are balanced, an acceptable temperature gradient ($<5^{\circ}\text{F}$) can be achieved in the occupied zone. Supply airflow beyond that required by these heat gains reduces the degree of stratification shown in Figure 6. If the supply airflow rate is insufficient, excessive vertical space temperature gradients may occur.

Accurate calculation of the space design supply airflow rate requires analysis of all space sensible heat gains to determine their contribution to the lower zone. Although there is not yet a single recognized procedure for calculating these airflow rates, most UFAD equipment manufacturers offer guidance.

Methods of Evaluation

As for thermal displacement systems, design involves determining a supply airflow rate that limits thermal gradients in the occupied zone in accordance with ASHRAE *Standard 55* guidelines. ASHRAE *Standard 55* recommends that the vertical temperature difference between the ankle and head level of space occupants be limited to no more than 5.4°F if a high degree ($>95\%$) of occupant comfort is to be maintained.

Design Procedures

The design of partially mixed air distribution systems requires identifying both thermal and contaminant removal objectives:

- The desired space temperature, the elevation to which it applies, and an appropriate supply air temperature must be identified.
- The supply air temperature for UFAD systems served by a pressurized or neutral pressure floor plenum should be limited to that which results in a relative humidity level below 80% in the floor cavity, to minimize the threat of mold or fungus growth.
- Supply air temperatures tend to rise as air moves through the floor cavity; therefore, the supply air temperature varies with its distance traveled. When determining space airflow requirements, supply temperatures should be modified accordingly to avoid undercooling the occupied space. Bauman and Daly (2003) discuss this subject further.
- If the objective is to provide displacement ventilation of respiratory contaminants in the stratified zone, mixing must be limited to below the breathing level of most space occupants.
- Outlets should be located far enough from stationary occupants to ensure that they are not subjected to drafts that might cause thermal discomfort. Outlet manufacturers generally prescribe clear zones that quantify this separation distance.

Application Considerations

ASHRAE's *Underfloor Air Distribution Design Guide* (Bauman and Daly 2003) includes a thorough discussion of issues involved in the design, application, and commissioning of UFAD systems. Some considerations include the following:

- Supply temperatures in the access floor cavity should be kept at 60°F or above, to minimize the risk of condensation and subsequent mold growth.
- Most UFAD outlets can be adjusted automatically by a space thermostat or other control system, or manually by the occupant. In the latter case, outlets should be located within the workstation they serve.
- Use of manually adjusted outlets should be restricted to open office areas where cooling loads do not tend to vary considerably or frequently. Perimeter areas and conference rooms require automatic control of supply air temperatures and/or flow rates because their thermal loads are highly transient.
- Heat transfer to and from the floor slab affects discharge air temperature and should be considered when calculating space airflow requirements. Floor plenums should be well sealed to minimize air leakage, and exterior walls should be well insulated and have good vapor retarders. Night and holiday temperature setbacks should likely be avoided, or at least reduced, to minimize plenum condensation and thermal mass effect problems. With air-side economizers, using enthalpy control rather than dry-bulb control can help reduce hours of admitting high moisture-content air, thus also reducing the potential for condensation in the floor plenums.
- Avoid using stratified and mixed air systems in the same space, because mixing destroys the natural stratification that drives the stratified system.
- Return static pressure drop should be relatively equal throughout the spaces being served by a common UFAD plenum. This reduces the chance of unequal pressurization in the UFAD plenum.

6. TERMINAL UNITS

System Selection

Designers have various systems (terminal units and their associated controls) to choose from when designing a building. The owner's needs must be met for installation, application, and cost of operation. The designer must consider performance, capacity, reliability, energy consumption, sustainability, and spatial requirements and restrictions. The following guidelines describe different types of equipment and their general uses, restrictions, and limitations. Table 5 summarizes the different types of terminal units

Table 5 Suitability of Terminal Units for Various Applications

Terminal Types	Facility Type													
	Office Space, Educational, and Institutional Buildings					Hospitals, Cleanrooms, and Laboratories ^a			Noise-Sensitive Applications ^b			Other Facilities

P = Preferred for this application.

• = Used for this application.

N = Not recommended for this application.

^aSealed lining is recommended to minimize entrainment of airborne fibers from liner to occupied spaces.

^bSpecial consideration should be given to selecting very quiet operating equipment and use of attenuators or silencers.

and their suitability for particular commercial building applications.

Building Use. Before specifying equipment types, the designer must consider the building’s intended use. Office buildings with daily operational schedules frequently use fan-powered terminal units. Usually, fan-powered terminals with auxiliary heaters (supplementary heat) are used in perimeter zones; these units allow the greatest flexibility for individual zones while also allowing the central system to be turned off during unoccupied periods. During unoccupied periods, the fan-powered terminal units maintain the minimum or setback temperature levels without the help of the central air-conditioning equipment.

In institutional, medical, or campus buildings, systems that provide pressurization differences between interior areas may be required.

Buildings with centralized heating and cooling plants sometimes use dual-duct terminal units.

Building Size. In large buildings, central air handlers deliver large quantities of air to many zones with different needs. Interior zones may not require heat; therefore, they can be served either by single duct or fan-powered units with no supplemental heat. Unless the building is located in a tropical climate, the perimeter zones require heat, typically electric or hot water. These are usually included with the terminal units, but sometimes separate heating systems are used, such as dual-duct or baseboard. In buildings where the owner desires low operating costs, the static pressure in the ducts should be lowered in accordance with ASHRAE *Standard* 90.1 to the minimum pressure, which sets at least one VAV damper to near-full open. Interior zones in these buildings can use fan-powered terminal units to keep the static pressure low. Buildings with parallel-type fan-powered terminal units usually use single-duct units in the interior zones and require higher system static pressures.

In small buildings, such as shopping malls and other low-rise buildings where each tenant area is small, it is common to use small packaged air conditioners. If terminal units are used on these systems, usually single duct or bypass units are selected. A variation of this system, variable-volume variable-temperature (VVT), uses pressure-dependent single-duct units with a main bypass damper in the supply duct. The bypass damper is regulated by static pressure in the supply duct. A nearly constant pressure can be maintained, allowing the packaged units to operate at constant volume and the individual zones to be pressure-dependent VAV.

Building Controls. The type of control system to be used is somewhat dependent on the size and type of building. Controls can be electric, pneumatic, analog electronic, or digital electronic.

- Electric controls are pressure dependent where the damper responds to a single control input. For example, the thermostat sends a signal to the damper to open or close based solely on room sensible temperature.
- Pneumatic controls are usually used for building renovation or buildout of existing buildings where the base building already has a pneumatic system installed. They can be pressure dependent or pressure independent. Pneumatic controls require regular system maintenance and may need to be periodically re-balanced.
- Analog controls are often applied to smaller buildings that do not have a building operation staff. Typically, these controls do not communicate with other zones or other equipment in the building.
- Digital controls are typically used on buildings that have a building operation staff. These controls provide individual zone control and communication to the building management system.

Acoustical Considerations. Terminal units and room air distribution devices are typical equipment sound sources for the room.

However, they are not the only sources that affect room acoustics. Refer to Chapter 48 as well as AHRI *Standard* 885 and other standards for guidance on space acoustics. Broadcast studios, theaters, and libraries require very low noise levels. Equipment selection and location is important here, and careful examination of the equipment sound performance is imperative. Radio-frequency interference (RFI) and electromagnetic interference (EMI) should also be considered when designing television studios.

Environmental Factors. Environmental factors play an important role in system selection. They include the climate and air conditions inside as well as outside the building. They also include legislative requirements such as outdoor air ventilation rates and local building codes. When high ventilation rates are required, reheat is often required to maintain human comfort. Fan-powered terminal units are usually used where the thermal load changes significantly and heating is required. Single-duct terminal units are usually applied in the interior where the thermal load is normally stable.

Contamination Considerations. Hospitals, cleanrooms, and laboratories pose special challenges. Protective isolation spaces such as operating rooms, bone marrow transplant patient rooms, AIDS patient areas, and cleanrooms require positively pressurized environments. Infectious isolation spaces such as tuberculosis patient rooms require negatively pressurized environments. See ASHRAE *Standard* 170 for details on room pressurization, Chapter 8 for specifics on health care requirements, and Chapter 18 for details on clean spaces. Hospital rooms and cleanrooms frequently also require constant high ventilation rates, which tend to favor single- or dual-duct terminal units. Pressure-independent, variable-speed motor technology has led to the development of fan-powered pressurization units.

To minimize entrainment of fibers into the airstream, either do not use internal insulation or use special liners in the terminal units and duct systems. Insulations can be isolated from the airstream by metal, foil, or polymer liners inside silencers and terminal units. All of these liners have different thermal, acoustic, and other physical properties and should be evaluated for each job.

Maintenance and Accessibility.

Typical Applications. Terminal units are typically not easily accessible after building occupation; they should be selected and located with consideration for required maintenance. Review the applicable building codes [e.g., ICC (2009)] for required access.

Critical Environments. Some applications, such as cleanrooms and operating theaters, require high levels of reliability from terminal units because of the difficulty and cost associated with servicing or maintaining the equipment. In a cleanroom, for example, if the ceiling must be opened, the space may require disinfection before it can be used again. Associated costs might include lost production time as well as the cost for wipedown and/or disinfecting the room and/or equipment. In cases like these, the designer should consider locating the equipment outside of the clean space or consider highly reliable, very-low-maintenance, very basic equipment and controls. Terminal units may require access to internal components for cleaning in the case of contamination.

Cost Factors. Costs should be considered before system selection is finalized. Installation, operation, and maintenance all contribute to total cost. Often, one of these costs overrides the others. Electric heaters usually have a lower installed cost than hot water coils, but they may have a higher operating cost. Local utility rates and building codes should be researched to arrive at the correct decision before making the final selection.

Applications

Single Duct. The basic single-duct unit consists of an airflow regulator and may also include an actuator, an airflow-measuring

device, and selected controls. Accessory discharge attenuators and multiple outlet attenuators are also frequently used.

Typical applications include

- Where the supply air system is not tasked with the space heating requirements
- With VVT or other auto-changeover controls
- Constant air volume
- Constant pressure control

A **single duct with reheat** has an added heating coil (hot water or electric). They are typically applied in zones where heat losses create a need for heating. The terminal usually reheats at the minimum airflow setting. An auxiliary higher heating setting may be available as an option with additional controls.

Interior zones, where ventilation requirements may be larger than the desired heating airflow, may require additional reheat.

A **single-duct exhaust** consists of an airflow regulator and may also include an actuator, an airflow-measuring device, and selected controls. Accessory inlet attenuators are sometimes used. Specialty materials may need to be considered for corrosion resistance. The designer should consider pressure drop and inlet versus outlet designs.

Single-duct exhaust units are typically used in isolation wards, operating theaters, laboratories, cleanrooms, and systems that require supply and exhaust tracking.

Dual Duct. A **nonmixing dual duct** is effectively two single-duct terminal units side by side. The basic unit incorporates separate cold and hot (sometimes neutral) air inlets. They are usually applied in exterior zones in buildings where overhead heating and cooling are desired but not auxiliary heat, and zero minimum flow is acceptable during changeover between heating and cooling.

A **mixing dual duct** is the same, with an integral mixing/attenuator section on the downstream end of the terminal unit to minimize temperature stratification in the discharge airstream. Interior and exterior zones in buildings (e.g., hospitals) where overhead heating and cooling are desired but an auxiliary heating coil is not, and zero minimum flow is unacceptable during changeover between heating and cooling. Mixing performance should be evaluated to fit the application.

Fan-Powered Parallel Flow. Sometimes called **variable-volume** or **intermittent-fan units**, these consist of a single duct unit, blower/motor, backdraft damper, and selected controls where the motor and primary damper are arranged such that mixing occurs downstream of the blower. Supplemental heating coils (either hot water or electric) are generally required. Electric heaters are typically located on the discharge of the unit. Water coils may be on the discharge or the induction port, although location on the discharge adds to the supply air system's static pressure requirements and increases leakage through the backdraft damper, as shown in ASHRAE research project RP-1292 (Davis et al. 2007). Heating coils on the induction port increase ambient temperature at the motor and decrease motor life.

Fan-powered parallel-flow units are used in exterior zones where heating and cooling loads may vary considerably, and in buildings where heating is needed when the central system is shut down during unoccupied hours.

Fan-Powered Series Flow. The basic unit consists of a single-duct unit, blower/motor, and selected controls where the motor and primary damper are arranged such that mixing occurs upstream of the blower. These units are also called **constant-volume** or **constant-fan**. Supplemental heating coils (either hot water or electric) are generally required. Electric heaters are typically located on the discharge of the unit; water coils may be on the discharge or the induction port. Heating coils on the induction port increase ambient temperature at the motor and decrease motor life.

Fan-powered series-flow units generally are used in the following situations:

- Exterior zones where heating and cooling loads may vary considerably
- Buildings where heating is desired when the central system is shut down during unoccupied hours
- To allow lower central system static pressure
- Where occupant comfort can be optimized, because the high- (sometimes constant-) volume variable-temperature air delivery produces consistent air distribution, acoustics, and ventilation

Low-Profile Fan-Powered Series or Parallel Flow. Similar in construction to the standard series or parallel flow terminal described earlier, these units are typically less than 12 in. high for all sizes, to minimize the depth of ceiling space required. Unlike standard fan-powered terminals, the fan/ motor assembly is installed flat on its side with the wheel rotating in a horizontal plane.

Typical applications are the same as for regular series or parallel units, but low-profile versions are commonly used where zoning requirements limit building height and the architect wishes to maximize the number of floors, because these units fit in a shallow ceiling plenum. Designers should pay special attention to available space and unit heights.

Ventilation Air Inlet Fan-Powered Series Flow. These units are similar in construction to the standard series-flow terminal, but have an added secondary air inlet that provides a direct connection to the terminal unit for ventilation air. They are commonly used in buildings where ventilation air is piped in a dedicated ventilation duct system to each terminal unit; this is generally done where it is desirable to monitor ventilation air quantities to each zone.

Low-Temperature Fan-Powered Series Flow. These units are the same as fan-powered series flow, but have special construction to minimize the potential for condensation. They can be used with cold-water/ice storage systems that provide low-temperature central system air distribution to the zone terminals when there is potential for condensation, or where standard terminals may be exposed to high humidity.

Underfloor Fan-Powered Series Flow. This unit is a fan-powered series flow terminal designed to fit between the pedestal support grids of a raised- or access-floor HVAC system, without modification to the floor. They are available in several unit sizes, but with limited height and width.

Primary and induction ports, if any, to the unit may or may not be ducted. Typically, air under the raised floor is cool air supplied directly to the space, although heated air may also be ducted to the unit. In these cases, a control system is required to select the proper damper sequence to control room air distribution to maintain the proper ambient conditions in the occupied space.

Bypass Terminals. The basic bypass terminal consists of a diverter-type damper, actuator, bypass port, and selected pressure-dependent controls. A balancing damper is recommended ahead of the inlet. Use of reheat coils is discouraged, and electric reheat should be prohibited because of the potential fire hazard.

Bypass terminals are used primarily with packaged rooftop air conditioning (PTAC) equipment with a direct-expansion (DX) coil where zoning is desired, but relatively constant airflows across the system components (e.g., coils, fans) are required to minimize the potential for freeze-up. The system offers an economical VAV supply design with low first cost. It does not provide the energy-saving advantages of variable fan volume, but avoids the expense of a more sophisticated system.

Comparison of Series- and Parallel-Flow Fan-Powered Terminal Units

Series (constant-volume) units have a continuously operating fan during occupied mode, and are typically installed in the ceiling

plenum. Primary air is ducted from a central air handler. Induction air is either from the ceiling plenum or occasionally ducted from the conditioned space. Fan air is a combination of plenum and primary air supplied to the zone.

Parallel (variable-volume) units should have an intermittently operating fan during the occupied mode and are typically installed in the ceiling plenum. Primary air is ducted from the central air handler and should flow directly to the zone in a variable volume cooling mode. Fan air is induced from the ceiling plenum or may be ducted from the conditioned space. The fan should run in the dead band and heating modes. When the fan runs, the zone air is induced air or a combination of primary and induced air:

- **Primary air** is that delivered to the space for the purposes of satisfying ventilation, latent, and all or part of the sensible load.
- **Secondary air** is that circulated from the return air plenum.
- **Supply air** is a mixture of primary and secondary air delivered to the space.

Configuration.

Series. The fan and VAV damper are aligned so that all conditioned air and all induced air independently enter the mixing section and must go through the fan to exit the unit. The mixing section is between the VAV damper and the fan.

Parallel. The fan and VAV damper are arranged so that all induced air enters the fan, and conditioned air bypasses the fan. Any mixing of conditioned air with the induced plenum air occurs on the discharge side of the fan. A backdraft damper inhibits air from exiting the unit through the fan when not running.

Terminal Fan Selection.

Series. In occupied mode, the fan runs continuously, supplying either a constant or modulating volume to the space. Some direct digital controls (DDCs) provide an optional output that may be used for controlling fan airflow using the building management system (BMS). This allows dynamic fan volume control, which may be either modulating or multiple-speed operation from a single speed motor. The fan must be sized to match the maximum airflow to be supplied to the zone. These terminal fan airflows are usually larger than those with parallel units for similar zones. When modeling energy consumption for this unit, it is important to model the energy consumption and heat generated by the fan motor for both unoccupied and occupied periods. The motor heat should also be included in the heating mode calculation (Davis et al. 2007).

Parallel. Typically, the fan runs only in heating or deadband modes, supplying a relatively constant induced air volume to the space. The fan must be sized to supply the required heating airflow to the zone, which requires overcoming the pressure created in the mixing chamber caused by the inclusion of primary air. These units usually have smaller terminal fan airflows than series units for similar zones. When modeling energy consumption for this unit, it is important to model casing and backdraft damper leakage as well as fan energy consumption for both the terminal unit and the air handler during operation. Motor heat should also be included in the heating mode calculation (Davis et al. 2007).

VAV Cooling and Inlet Static Pressure Requirements.

Series. Additional savings above that for the single- or dual-duct units can be realized because of the low inlet static pressure requirement of the series fan powered terminal unit. The pressure at the air handler can be reduced to that required to push the conditioned air through the ducts to the unit and across the VAV damper into the mixing section.

Parallel. Like the single or dual duct unit, the air handler must push the conditioned air through the ducts to the parallel unit, across the VAV damper, into the mixing section, through the discharge duct from the unit and across the diffuser(s) into the room.

Control Sequence.

Series. The fan runs constantly during occupied periods. On a call for cooling, the controls modulate the VAV damper toward maximum airflow, delivering primary air to the mixing chamber. If the fan is set at the same airflow as the primary air, no air is induced from the plenum. If the fan is set at a higher airflow than the primary air (e.g., as in a low-temperature application), air is induced from the plenum to meet the fan's set point. The primary and induced air are blended before they enter the fan. Constant-volume, variable-temperature air is then discharged into the downstream duct and into the conditioned space.

As cooling demand decreases, the VAV damper modulates toward minimum airflow, reducing the primary air into the mixing chamber. This increases the volume of warmer induced air into the mixing chamber. Fan air can also be reduced [typically with an electronically commutated motor (ECM)] as load changes. The increased percentage of plenum air causes the discharge temperature to rise to approach the plenum temperature, taking advantage of recaptured heat from lights, people, and machinery.

After a further decrease in zone temperature, the controls automatically energize the supplemental heat (optional equipment), which can be either electric or hot water coils. The discharge temperature increases as heat is applied. As the temperature increases in the zone, the sequence reverses.

Parallel. On a call for cooling, the controls modulate the VAV damper toward maximum airflow while the fan is off. Variable-volume, constant-temperature air is then discharged into the downstream ducts and into the conditioned space.

On a decreasing call for cooling, the VAV damper modulates toward minimum airflow. The unit delivers variable-volume, constant-temperature air to the zone.

In deadband, the controls energize the fan. Fan air and primary air are blended in the mixing chamber on the fan's discharge side. The increased plenum air causes the discharge temperature to rise. Constant-volume, constant-temperature air is delivered to the zone.

On a call for heating, the heat is energized. The heater may be staged or modulating. Constant-volume, constant- or variable-temperature air can be delivered to the zone.

Because the largest energy-consuming characteristic of parallel boxes is leakage and not motor energy, and because modulating fan air in the heating mode increases reheat, ECMs are not recommended for parallel boxes.

Fan Interlocks.

Series. Typically, series units are designed to run continuously. Usually, they are energized only during occupied periods or when needed for emergency heating during unoccupied periods. Care should be taken to interlock the unit fan with air handlers in the building to ensure that the terminal unit fans start during occupied periods. Series-unit fans should be started ahead of the air handler to prevent backflow into the plenum and backward rotation of the fan.

Parallel. Fans in parallel units are designed to be energized in the deadband and heating modes throughout the day. Primary air enters the mixing chamber at the fan discharge. When the fan is not energized, there is a positive pressure at the fan's discharge. Typically, this would cause the blower and motor to rotate backwards; however, parallel units are equipped with backdraft dampers at the fan, which inhibit backward airflow through the fan into the plenum.

Acoustics.

Series. Series fans are sized to match the maximum airflow required in the zone. The fan runs constantly during occupied periods. There are two sound sources in the unit: the fan motor and the VAV damper. Although both contribute to the overall discharge and

radiated sound emitted from the unit, the fan is primarily responsible for discharge noise, and both the damper and the fan are responsible for radiated sound. Usually, sound radiated into the occupied space is the greater and usually more difficult to attenuate.

Comparing the sound level between a series and a parallel unit in similar zones, the fan in the series unit might generate a slightly higher sound power level. In the series unit, the fan and damper would be at their peak when the unit operates at full cooling capacity, the loudest point in the sequence of operation for sound generation. As the primary air decreases, the sound generated by the fan typically masks the sound from the damper. Sequences that also command the fan to modulate in this condition create lower ambient sound levels.

Series fan power sound levels are more consistent compared to ambient background sound levels than the rapid cyclic nature of the parallel unit.

Parallel. Parallel fans are sized to match the heating airflow required in the zone. The fan runs intermittently when the mode changes from cooling to deadband. There are two sound sources in the unit: the fan/blower and the VAV damper. Both damper and fan are responsible for radiated and discharge sound. Usually, sound radiated into the occupied space is the greater and usually more difficult to attenuate.

Comparing the sound level between a parallel and a series unit in similar zones, the parallel unit may generate slightly less sound. In the parallel unit the fan and damper would normally not peak simultaneously. When the unit operates at full cooling capacity, the damper is at its peak sound generation and the fan is off. In heating mode, the fan peaks while the damper is at minimum sound generation.

Damper sound must be considered as the sound increases with increasing inlet static pressure. Parallel units require significantly higher inlet static pressures at the unit. Fan sound is consistent into the zone when the fan is running; however, the fan is intermittent during much of the day. This rapid fan cycling can create a variation in sound levels and subsequent noise in the space, which can be more annoying than a higher consistent sound level.

Energy Consumption.

Fan-powered VAV terminal units take advantage of typical VAV savings at the air handler and chiller during cooling periods, and even more savings are realized when heating is required. Fan-powered terminals induce warm plenum air from the ceiling and blend it with the primary air at minimum ventilation requirements as required by ASHRAE *Standard* 90.1 during the heating sequence. This recaptures much of the heat created in the zone and plenum by lights, occupants, solar loading, and machinery or equipment such as computers, coffee machines, copiers, etc. The unit returns this heat as free heating rather than losing it at the air handler. If additional heating is required, supplemental heat is added to the sequence, but the unit still saves energy by warming blended air, for example, at 72°F rather than reheating primary cooled air at 55°F, saving the cost of 17°F at the heating airflow. According to ASHRAE research project RP-1292 (Davis et al. 2007), there is very little difference in total building energy use between series and parallel units when equipped with permanent split-capacitor (PSC) motors.

Series. Series fans run constantly during occupied periods, and the fan is sized for the full airflow to the zone. This causes the energy consumption from the fan to be higher than that of a parallel fan in a similar zone. ASHRAE RP-1292 identified the motor as the biggest energy user in a series unit (Davis et al. 2007). The fan energy raises the air temperature across the motor by 1 to 3°F. This means that total energy use can be reduced if the fan energy is reduced. Using electronically commutated motors (ECMs) can significantly increase motor lifetimes and provide significant energy savings in excess of 50%.

Series units are designed for very low inlet static pressures. This saves energy at the air handler compared to a parallel unit for a similar zone.

Casing leakage does not affect energy consumption of series units. All the primary air injected into the unit gets delivered to the occupied zone. This causes ceiling plenum temperatures to be warmer for installations with series units than those with parallel units, and more heat can be reclaimed from the ceiling plenum when the unit is in heating mode.

Because the motor heat is in the airstream, more heat is introduced into the occupied zone during cooling mode when compared to a parallel unit.

Parallel. Parallel unit fans operate only when required during heating and deadband modes. The fan is sized for the induced airflow required in heating mode, which may be much less than the zone's total airflow requirement.

Because the minimum primary air and induced air are mixed downstream of the terminal fan, the terminal inlet static pressure requirement is greater than for a series terminal. This adds operating cost at the air handler. When just one duct path is designated as the critical path for static pressure set point, this can cause the system pressure to increase in excess of 1 in. of water compared to a building with series units. This can greatly increase energy usage. However, ASHRAE *Standard* 90.1 procedures reset the system static pressure to always drive at least one VAV damper to its nearly full-open position, making the increased static pressure required for parallel units not as great.

According to ASHRAE RP-1292, the largest single energy issue in both types of terminal unit, other than operating schedule, was leakage in the parallel unit (Davis et al. 2007). Leakage is typically between 10 and 15% of the total airflow through the parallel unit, and is highest at full cooling. This means that parallel units may need to be oversized to cover the total load to the occupied zone. It also means that the ceiling plenums are cooler with parallel units than those with series units, reducing the amount of free heat that can be reclaimed in heating mode.

Because the motor runs in deadband and heating modes, any heat generated by the motor is delivered to the occupied space. Consequently, the motor energy does not significantly affect the total energy consumed by the parallel unit. Because of this, using more efficient motors will not measurably improve the unit's energy consumption.

7. FAN SELECTION

When selecting a unit for a particular set of conditions, care should be taken so that the air delivery is designed to meet the room's sound criteria and system's static requirements. Specific sound data can be found in manufacturers' catalogs for various airflow deliveries for each unit. This should be the guiding factor in selecting unit sizes. A simple rule of thumb is that, when considering a unit selection for a typical office space, the fan should be selected for performance down from the high end performance by 20 to 25% of the distance to the low end of the fan curve at the specified external static requirement. This allows for low room sound levels while maintaining some flexibility for future changes in the zone. When selecting equipment for large, open areas where sound criteria may not be as critical, select equipment closer to the high end of the fan curve. For a meeting room or an executive office, select equipment slightly below the halfway point on the fan curve. For an auditorium, chief executive offices, conference room, or some similarly sensitive area, select operation nearer the low end of the fan curve.

Avoid selecting equipment right on the maximum or minimum curves. This leaves no flexibility, either in the equipment for future

changes or for variations that may occur due to power variations or duct fittings.

Fan Airflow Control on Fan-Powered Terminals

When designing air systems and using fan-powered VAV terminal units, it is important to match the fan air and primary air capacities to the space requirements. Series units require precise adjustment of fan airflow in relation to the primary air. The parallel unit's fan airflow requires less critical adjustment. Fan-powered terminals nearly always use single-phase motors, most commonly with electronic fan speed control [sometimes called **wave choppers**, **thyristor controllers**, or **silicon-controlled rectifiers (SCRs)**] or with electronically commutated motors.

Fan Shift in Fan-Powered Terminal Units. Before adjusting the fan, the possibility of fan shift must be considered. This occurs when the blower is subjected to variations in pressure or airflow patterns. As the primary airflow changes, the pressure drop and changes in local jets may cause the fan to shift its performance as it rides the fan curve. Consequences from the phenomenon vary from building to building and zone to zone. Noise levels may change greatly as the volume changes, and this may be annoying. Design ventilation rates can also vary, sometimes by more than 20%. This can be aggravated by undersizing the terminal unit.

Electronic Fan Speed Control (PSC Motors). Electronic fan speed controls use a thyristor to adjust the fan's electrical input ac voltage. This is called **phase proportioning** or **wave chopping**. When the current sine wave crosses the zero point, the thyristor acts as a timing device, holding the voltage off the motor for some preset period of time. When the thyristor is turned on, the voltage seeks out the sine wave and then follows the curve to the next current zero crossing, where the process begins again on the opposite side of the sine wave. Basically, this reduces the root mean square (RMS) value of the voltage supplied to the motor. This in turn reduces the torque available to turn the rotor and lowers the motor speed. Amp draw is slightly affected during this process if the motors and blowers are sized properly. Some units may suffer from large changes in amp draw that significantly affect the motor's efficiency and operating characteristics. Reducing the voltage while keeping the amperage draw constant reduces the motor's power consumption.

Nameplate Ratings. The standard that covers fan-powered terminal unit nameplate ratings is ANSI/UL *Standard* 1995. This standard relates to equipment manufacturers and not field issues covered in international and local codes. Nameplate ratings on the unit usually do not match the nameplate ratings on the motor. Amp draw can be above or below the motor nameplate. Even voltage can vary. Differences between the motor label and the unit label may be significant in some cases, but these different ratings do not generally affect the performance or lifetime of the motor or unit. Be sure to refer to the unit nameplate ratings and not the motor nameplate ratings when sizing supply circuit requirements. These ratings are set at the safest possible condition. Because static and set points vary on each unit, performance may not be what is on the unit nameplate.

Electronically Controlled Motor (ECM) Technology. ECMs may provide significant energy savings and superior controllability. They can provide significant power savings on series units; however, they may not provide any savings on parallel units for reasons discussed in Davis et al. (2007).

Sizing Fan-Powered Terminals

Selection of fan-powered terminal units involves four elements: primary air valve, fan size, heating coil, and acoustics. How these elements are selected and their interactive effects determine the overall performance of the units.

Primary Air Valve. Identify the type of controller that is desired and select an inlet size that meets the minimum and maximum airflow desired from the recommended primary air airflow range table

in the Performance Data section of the manufacturer's catalog. Selecting terminals near the top of their range may reduce cost, but increases velocity and noise. Selecting terminals toward the bottom may reduce noise, but may reduce controllability of the minimum airflow. Selecting the maximum airflow setting at between 70 and 85% of full capacity (approximately 2000 fpm inlet velocity) is a good trade-off to avoid possible low-velocity control problems and sound problems at higher velocities.

Fan Size. Parallel fan size is determined by calculating the difference between the unit design heating airflow and minimum primary airflow. If minimum airflow is zero, then fan airflow is the heating airflow. In most cases, the fan can be downsized compared to a series terminal, reducing both first cost and operating cost because the fan only requires the capacity to handle the secondary airflow at reduced downstream static pressure compared to the maximum design airflow. In most applications of a parallel terminal, a minimum primary airflow is required to meet ventilation requirements. This primary airflow contributes to the total resistance experienced by the fan and should be accounted for along with all components downstream of the fan, such as heaters, ductwork, and diffusers. Hot-water coils may be positioned out of the primary airflow (i.e., on the inlet side of the fan, where they would not affect the primary airflow static pressure). In this configuration, heat generated by the water coil shortens the motor life.

Series fan terminal units require the fan to be sized to handle the maximum design airflow. The fan airflow must be at least equal to the primary airflow to ensure the mixing chamber in the terminal does not become pressurized, resulting in primary air spilling out into the ceiling plenum through the induction ports. The external static pressure requirements are the sum of the ductwork and diffusers downstream at design airflow plus an applicable hot-water coil or electric heater, if required. When fan airflow and downstream static pressure have been determined, select the fan size from the fan curves in the Performance Data section of the manufacturer's catalog. Selecting toward the upper end of the range reduces first cost and optimizes fan operating efficiency. Upsizing the fan and operating it at a reduced speed can result in quieter operation. When electric or hot-water coils are required, be sure to include the static pressure required for those items when referring to the fan curves.

Heating Coil. First, determine the heating supply air temperature to the space by calculation using the heat transfer equation:

$$q = 1.085 \times \text{cfm} \times \Delta t$$

where

q = design heat loss in space, Btu
 Δt = supply air temperature (SAT) – room design temperature.

The supply air temperature (SAT) to the space equals the leaving air temperature (LAT) for the terminal unit.

For a series unit, once the terminal LAT is determined, the heating requirements for the coil can be calculated. The leaving air temperature for the coil varies based on the coil design and terminal unit model. It is generally a good idea to limit leaving air temperature to 15°F above room temperature. The LAT is the temperature leaving heating coil for a series unit, but requires calculations using a mixed-air equation for the primary and fan air volumes and temperatures for a parallel unit with the coil located out of the primary airstream. These leaving air temperatures can be effectively used to warm the room, because their airstreams are not so buoyant that they cannot be driven to the floor in overhead applications, and are warm enough to not produce chills from drafts.

Once both coil entering air temperature (EAT) and LAT are calculated, the heat transfer q for the coil must be calculated, using the heat transfer equation. For electric heat, the capacity must be converted from Btu/h to kilowatts for selection. The required kilowatts and number of steps desired should be checked with availability

from the charts in the Performance Data section of the manufacturer's catalog. For hot-water coils, reference the capacity charts in the Performance Data to select the appropriate coil.

$$\text{EAT of coil} = (T_1 Q_1 + T_2 Q_2) / QT$$

where

T_1 = plenum air temperature, °F
 T_2 = primary air temperature, °F
 Q_1 = plenum air quantity, cfm
 Q_2 = primary air quantity, cfm
 QT = total air moved by terminal fan, cfm

These processes are for calculating the total heat requirement based on the room load calculations. At part-load conditions, it may be desirable to modulate the airflow through the terminal unit as well as the heat output to maintain an acceptable discharge air temperature. This can be done with modulating valves on coils or SCRs on electric heaters. Staging the electric heaters can create similar results at a lower equipment cost. Modulating the heat causes the heaters to run longer, but at lower energy consumption. This can make the room more comfortable without increasing energy costs.

Acoustics. Sound levels are affected by air-regulator-generated noise and fan-generated noise. The maximum noise generated by a given air regulator size is determined by the difference between the highest inlet static pressure and external static pressure at the design cooling airflow for a parallel unit. For a series unit, it is the highest inlet static pressure. This represents the most extreme operating condition. To determine fan noise levels, fan airflow (adjusted within its range by the speed controller) and external static pressure conditions are required.

The acoustical performance data are presented in two formats for the parallel and series types, because their sequence of operation differs. With a parallel unit, air regulator and fan operation are evaluated separately because their operations are not simultaneous under most conditions. With a series unit, air regulator and fan are evaluated together, because they operate simultaneously, and fan only for heating with no minimum primary airflow.

From the performance data, determine the sound power levels and predicted room noise criteria for both discharge and radiated path under the appropriate operating conditions. Radiated noise from the unit casing typically dictates the noise level when the terminal unit is installed above the occupied space.

Care should be taken because some published room noise criteria are based on certain path attenuation assumptions that may not be indicative of a specific design. The size of the terminal may be increased to reduce noise, but it is also preferable to evaluate the room noise criteria to ensure the necessary reductions are achieved and finished levels do not exceed the design goal in the occupied space. To do this properly, the engineer must specify all factors in the building specifications that affect sound attenuation. An ideal specification specifies maximum allowed discharge and radiated sound power by octave band rather than just catalog-based NC values.

Example 3. Parallel Terminal with Hot-Water Heat. Select a unit inlet for a maximum/minimum primary airflow at 1000/250 cfm with 1 in. of water inlet static pressure.

The heating airflow required is 600 cfm. Downstream resistance at 1000 cfm is 0.4 in. of water. Zone design heat loss is 20,000 Btu/h, design room temperature is 72°F, plenum air temperature is 75°F, and primary air temperature is 55°F.

Solution:

Air Valve Selection. Based on a good design inlet velocity of 2000 fpm, choose a 10 in. inlet.

Fan Selection. Fan heating airflow = Heating airflow (600 cfm) – Primary airflow (250 cfm) = 350 cfm. The downstream static pressure the fan must overcome is the fan airflow plus primary airflow (600 cfm),

and because this is less than maximum design airflow (1000 cfm), fan downstream static pressure = $(600/1000)^2 \times 0.4 = 0.144$ in. of water. Refer to fan curves to select the proper unit. The correct unit will handle 350 cfm at 0.144 in. of water static pressure with correct setting of the speed controller, and allows for the selection of a one- or two-row hot water coil.

Heating Coil Selection. For heating, the temperature difference (Δt) is the zone supply air temperature (SAT) minus the design set point temperature. Using the heat transfer equation,

$$20,000 \text{ Btu/h} = 1.085 \times 600 \times (\text{SAT} - 72)$$

$$\text{SAT} = 103^\circ\text{F}$$

As the heating coil is on the unit discharge, the unit supply temperature equals the coil LAT. Coil entering air temperature (EAT) is a mixture of plenum and minimum primary air.

Design heating flow \times Coil EAT =
(Primary airflow \times Primary air temperature)
+ [(Design heating airflow – Primary airflow) \times Plenum temperature]

$$600 \times \text{Coil EAT} = 250 \times 55 + (600 - 250) \times 75$$

$$\text{Coil EAT} = 67^\circ\text{F}$$

For the heating coil, the temperature difference is the coil LAT minus the coil EAT.

$$\text{Coil heat pickup } q = 1.085 \times \text{Design airflow (cfm)} \times (\text{Coil LAT} - \text{Coil EAT})$$

$$\text{Coil } q = 1.085 \times 600 \times (103 - 67) = 21,600 \text{ Btu/h}$$

From the hot-water coil data, select a two-row coil at 600 cfm to provide 21,600 Btu/h at about 0.8 gpm (based on a Δt of 110°F between entering air and entering water).

Note 1: The coil selection in this example produces a discharge air temperature that is too high for normal applications. A discharge air temperature limit of 87°F should be used. If additional heat is required, airflow should be increased.

Note 2: The mixed-air condition does not bring the EAT to room temperature. Additional induction or plenum air should be added to increase the mixed-air temperature to near room temperature to avoid reheat.

Note 3: When using a PSC motor, the motor will add 1 to 3°F to the airstream.

Example 4. Series Terminal with Electric Heat. Select a unit to supply a constant 1500 cfm with 0.5 in. of water inlet static pressure. Minimum primary airflow is 375 cfm and downstream resistance caused by ductwork and diffusers is 0.4 in. of water. Zone design heat loss is 45,000 Btu/h, design room temperature is 72°F, plenum air temperature is 75°F, and primary air temperature is 55°F.

Solution:

Air Valve Selection. Based on a good design inlet velocity of 2000 fpm, choose a 12 in. inlet

Fan Selection. Fan airflow equals design airflow with a series unit. Fan external static pressure equals downstream static pressure (ductwork and diffusers). The resistance of electric and hot-water heating coils and their associated additional pressure drop may or may not be taken into account on the fan curves. Be sure it is included in the final static needs. From the fan curves, select a unit that will handle 1500 cfm at 0.4 in. of water and falls in the middle of the fan range as recommended in the section on Fan Size.

Heating Coil Selection. For heating, the temperature difference (Δt) is the zone supply air temperature (SAT) minus the design set point temperature.

$$45,000 \text{ Btu/h} = 1.085 \times 1500 \times (\text{SAT} - 72)$$

$$\text{SAT} = 100^\circ\text{F}$$

Because the heating coil is on the unit discharge, the unit supply temperature equals the coil LAT. Coil entering air temperature (EAT) is a mixture of plenum and minimum primary air.

Design heating flow \times Coil EAT =
(Primary airflow \times Primary air temperature) +
[(Design heating airflow – Primary airflow) \times Plenum temperature]

$$1500 \times \text{Coil EAT} = 375 \times 55 + (1500 - 375) \times 75$$

$$\text{Coil EAT} = 70^\circ\text{F}$$

For the heating coil, the temperature difference is the coil LAT minus the coil EAT.

$$\text{Coil heat loss } q = 1.085 \times \text{Design airflow (cfm)} \times (\text{Coil LAT} - \text{Coil EAT})$$

$$\text{Coil } q = 1.085 \times 1500 \times (100 - 70) = 48,825 \text{ Btu/h}$$

To convert to kWh,

$$48,825/3413 = 14.3 \text{ kWh}$$

From the manufacturer's catalog, select an electric heater with the proper input voltage (208, 240 or 480 volt/three-phase electric heat coil) that could be available with up to three stages with pneumatic or digital control or two stages with electronic control.

Note 1: Although there are air-side pressure drop data in the catalog, it is only necessary to calculate the drop if it is not included in the fan curves.

Note 2: The coil selection in this example produces a discharge air temperature that is too high for normal applications. A discharge air temperature limit of 87°F should be used. If additional heat is required, airflow should be increased.

Note 3: The mixed-air condition did not bring the EAT to room temperature. Additional induction or plenum air should be added to increase the mixed-air temperature to near room temperature to avoid reheat.

Note 4: Using a PSC motor adds 1 to 3°F to the airstream.

Installation and Application Precautions: Avoiding Common Errors and Problems

Sizing Terminals.

- Select terminals based on recommended air volume ranges. The pressure-independent terminal's main feature is its ability to accept factory-recommended minimum and maximum airflow limits that correspond to the designer's space load and ventilation requirements for a given zone. A common misconception is that oversizing a terminal makes the unit's operation quieter. In reality, the oversized terminal damper must operate in a pinched-down condition most of the time, which may actually increase noise levels to the space. Control accuracy may suffer because the terminal is only using a fraction of its total damper travel or stroke. In addition, the low inlet velocities may be insufficient to produce a readable signal for the velocity pressure measuring device and reset controller. This means minimum settings may not hold with a resultant loss of control accuracy and undesirable hunting.
- To maximize performance, size the terminal's maximum airflow limit for 70 to 85% of its rated capacity (approximately 2000 fpm) in accordance with the catalog recommendations. For accurate control, the minimum setting guideline should not be lower than 400 fpm inlet neck velocity for units using inlet velocity sensors. Other minimum guidelines may apply for unit with specialty controls.
- Oversizing the discharge duct may create low static conditions, requiring the fan to operate outside its recommended operating range.
- A problem associated with oversizing terminals with electric heat is insufficient total pressure, which can occasionally trip the airflow safety switch.

Space Restrictions. During design, try to ensure that terminals are located for ease of installation, optimum performance, and maintenance accessibility.

Optimizing Inlet Conditions.

- The type of duct and its approach may have a large and adverse impact on both pressure drop and control accuracy. Although multipoint velocity pressure measuring devices can compensate to a large degree, good design practice should always prevail. Wherever possible, a straight duct inlet connection with a minimum length of three duct diameters and the same diameter as the inlet should be provided.
- Terminal collars are undersized to suit nominal ductwork dimensions. The inlet duct slips over the terminal inlet collar and is fastened and sealed in accordance with job specifications. Never insert a duct inside the inlet collar, or control calibration will be adversely affected.
- Sometimes space restrictions make it impossible to provide an ideal inlet condition. In this case, field adjustment of the airflow settings may be required to compensate for error in the flow measurement. The use of flow-straightening devices (equalizing grids) is recommended after short-radius elbows that are immediately ahead of the terminal and where terminals are unavoidably tapped directly off the main duct. Use of these devices typically increases sound levels.
- The balancing contractor should validate flow rates. See ASHRAE *Standard* 111.

Zoning Requirements. Correctly sizing terminals with regard to the physical conditions of the occupied space is vital to ensure acceptable performance. One large terminal serving a space with divided work areas may result in the single thermostat only providing acceptable temperature control for the area where the thermostat is located. The other area(s) served may be too cold or too hot if they have differing space load requirements.

Optimizing Discharge Conditions. Poor discharge duct connections may have an adverse affect on pressure drop. Try to avoid installing tees, transitions, and elbows close to the unit discharge. Avoid long runs of flex, and keep short flex runs as straight as possible. Make curves as shallow as possible, and ensure that the entrance condition to diffuser outlet is straight. Discharge ducts should be designed for a maximum velocity of 1000 fpm.

Noncompliance with Local Electrical Codes. Some local jurisdictions have more exacting codes than the minimum requirements of national codes and standards such as the International Code Council's (ICC) *International Building Code*[®] (IBC). One example is the primary fusing required of the power circuit in some areas.

Power Source Compatibility. Terminals with an electrical power supply, such as fan-powered terminals and single-duct terminals with electric heat, should be checked for compatibility with source. Voltage, phase and frequency must match. Where motor voltage differs, the single-phase voltage requirement may have to be tapped from a three-phase (four-wire wye) power source.

Avoiding Excessive Air Temperature Rise. Terminals with electric or hot-water reheat coils should be designed to satisfy load conditions, but attention should be paid to the temperature differential (Δt) between the entering room air and ambient temperature. Chapter 19 of the 2013 *ASHRAE Handbook—Fundamentals* recommends a maximum Δt of 15°F to avoid possible stratification when heating from overhead caused by the excessive buoyancy of the warm air. This ensures good room mixing and temperature equalization. Exceeding a Δt of 15°F requires an increase of 25% in the ventilation air per ASHRAE *Standard* 62.1. Absolute maximum discharge air temperature is 120°F. Although this temperature will probably keep the equipment on line, it will not provide comfortable temperatures in the space.

Correctly Supporting Terminals. Although the basic single-duct terminal is light enough that it usually can be supported by the ductwork in which it is installed, these units should be independently

supported. When accessory modules such as heating coils, attenuators, or multiple-outlet plenums are included, the assembly must be supported independently. Larger terminals such as fan-powered terminal units should always be independently supported, secured to building structure, and may require isolation mounting. Be careful not to block access panels with straps, thread rods, or trapeze supports. Be sure to comply with all building and local codes regarding seismic restraints (see Chapter 55).

Minimizing Duct Leakage. To prevent excess air leakage and minimize energy waste, all joints should be sealed with a UL-approved duct sealer. Most leakage can be avoided by practicing good fabrication and installation techniques, particularly upstream of the terminal, which may be required to hold significantly higher pressures than downstream of the terminal.

Acoustic Design and Installation. To help ensure an acceptable room noise level in the occupied space, engineers can minimize the sound contribution of air terminals by taking into account several design considerations and by using the following guidelines.

- Design systems to operate at low (minimum) supply static pressure at the primary air inlet. This reduces the generated sound level, provides more energy-efficient operation, and allows the central fan to be downsized. Excessive static pressure generates noise.
- Use of metal ducts before the inlet can reduce breakout noise from the damper. Between the terminal unit and the air outlet, flexible duct can be more effective than lined duct at reducing terminal unit noise. Flexible duct can also generate sound if bends or sagging is present. Sometimes, flexible couplers can reduce vibration passed from the terminal unit to the duct connections.
- Select terminals to operate toward the middle area of their operating range. Larger inlets reduce velocity and hence noise in low-pressure applications, but may increase noise in higher-pressure applications. For fan-powered terminals, lower fan speeds generally produce lower sound levels. Sound emissions are lower when fan-speed controllers are used to reduce fan rotational speed rather than using mechanical dampers to restrict airflow.
- Whenever possible, locate terminals above noncritical areas that are less sensitive to noise, such as corridors, copy rooms, or storage/file rooms. This isolates critical areas from potential radiated noise.
- Locate terminals in the largest ceiling plenum space available to maximize radiated noise reduction. Install terminals at the highest practical point above ceiling to optimize radiated sound dissipation.
- Avoid locating terminals near return air openings or light fixtures. This decreases the potential for direct paths for radiated sound to enter the space without the benefit of ceiling attenuation.
- Locate terminals to allow use of lined discharge ductwork to help attenuate discharge sound.
- To avoid possible aerodynamic noise, keep airflow velocities below 1000 fpm in branch ducts and below 800 fpm in runouts to air outlet devices.
- In large spaces, consider using a larger number of smaller air outlets to minimize outlet-generated sound.
- Insulated flexible duct on diffuser runouts reduces room noise levels
- Using ceilings with a high sound transmission loss classification helps reduce radiated sound.

See Chapter 8 in the 2013 *ASHRAE Handbook—Fundamentals* and Chapter 48 in this volume for more information on sound and vibration control.

8. CHILLED BEAMS

An **active chilled beam** is an air diffusion device that introduces conditioned air to the space for the purposes of temperature and

latent control. Primary air (i.e., air delivered to meet ventilation, latent, and all or part of the sensible load) is delivered through a series of nozzles, creating induction of room air through a unit-mounted chilled-water coil, which conditions air before reintroducing it to the space. Depending on the nozzle size and configuration, active beams typically induce two to five parts of room air for every part of primary air they deliver to the space. Sensible heat removal by the beam's integral cooling coil complements the cooling effect of the primary air supply.

Passive chilled beams rely on the natural buoyancy of air currents associated with convective heat sources to transport warm air to the upper portion of the space. Upon contact with the beam's integral heat transfer coil, this air is cooled and falls back into the space. Primary air is delivered to the space for the purposes of ventilation and latent control via a separate system. Air circulated through the chilled-beam coil is called secondary air; supply air is comprised of mixed primary and secondary air.

Codes and Standards

Chilled-beam system designs should conform to the following building codes and standards, as well as any applicable local code requirements:

- ISO *Standard 7730* and ASHRAE *Standard 55*
- ASHRAE *Standard 62.1*
- ASHRAE *Standard 90.1*
- IBC
- NFPA *Standard 90A* and *90B*
- ANSI *Standard S12.65*

Application Considerations

Chilled-beam systems must be designed to treat sensible and latent space heat gains, provide adequate space ventilation, and maintain occupant comfort in conformance with ASHRAE *Standard 55* and other applicable codes.

In general, chilled beams offer the opportunity to capitalize on the benefits of decoupled ventilation systems. They also offer the designer the opportunity to manage sensible loads in the space separately from ventilation and latent needs. Chilled beams work well with dedicated outdoor air and demand control ventilation systems.

Benefits. Heat extraction or addition by the coil allows for significant reduction in primary airflow requirements over all-air ducted systems. Energy to transport cooling and/or heating media is reduced because of water's high specific heat and density. As a result, chilled-beam systems require less space for the mechanical services, because of smaller ductwork and air-handling unit sizes. This reduction in mechanical service space requirements means it is possible to reduce the floor-to-floor height of a multistory building.

Effectively, a 1 in. diameter water pipe delivering 57°F water can transport as much energy as a 14 × 14 in. duct delivering air at 55°F. The transport energy required to deliver cooling by water is only 15 to 20% of that which would be required by air. Water provides 3500 times the heat-carrying capability of air.

Free cooling opportunities may be extended as a result of the lower secondary chilled-water temperatures, and provide an improved selection of available system options (e.g., geothermal, dry coolers, closed-circuit fluid coolers). Chilled-beam systems offer opportunities to enhance chiller efficiencies and provide broader evaporator ranges, because of higher chilled-water temperatures, and cascaded evaporator flows between primary and secondary chilled-water loops. Higher inlet water temperatures also make chilled-beam systems as an excellent choice for geothermal applications, where suitable electrical costs allow this as an option.

Chilled-beam systems are typically operated with a constant-(minimal) volume supply airflow to the space. Constant-volume

systems offer enhanced thermal comfort because of their consistent room air movement, and an improved acoustic environment.

Maintenance of chilled beams is virtually nonexistent. Vacuuming the coils is occasionally required, and is typically guided by the needs of the space. Often, it is expected that service intervals could extend to 3 to 5 years. The lack of moving parts in chilled beams inherently produces a highly reliable system, and because most beams do not contain filters, servicing costs are minimal.

Passive chilled beams can provide a very efficient means of perimeter-area temperature control when coupled with underfloor air distribution (UFAD) systems. For more information on UFAD systems, see Chapter 20 of the 2013 *ASHRAE Handbook—Fundamentals*.

Limitations. Space humidity levels must be managed closely because of the limited dehumidification capability of the primary air. This is particularly important where operable windows are used or high infiltration levels are encountered in a humid climate.

Chilled beams may be considered beneficial for the following applications/spaces:

- Environments with moderate to high sensible heat ratios, such as offices, apartments, high rise condos, or classrooms
- Laboratories or other spaces with significant imbalances between sensible loads and ventilation requirements
- Retrofits, because of minimal mechanical space requirements, and in cases of suitable envelope construction

Chilled beams may be inappropriate for the following spaces:

- Environments with high latent gains, such as kitchens, bathrooms, or locker rooms
- Swimming pools, natatoriums, and sauna areas
- Poor building envelopes or buildings with unmanageable latent loads
- Mixed-mode ventilation (operable windows) without proper condensation safeguards

Chilled beams must be independently supported from ceiling grid systems, and subsequently positioned into the grid. Appropriate care must be used when beams are installed in seismic zones, to ensure compliance to all building and safety codes.

Passive beams are restricted to cooling-only applications, and require a separate heating system. Careful consideration is needed in the placement and control of passive chilled beams to ensure thermal comfort.

Cooling

The objective of chilled-beam design is to minimize primary airflow rates, ideally reducing them to the space minimum ventilation requirement. However, where zone cooling requirements cannot be achieved with the minimum primary airflow rate, chilled beams may be used with air-handling units that mix return and outdoor air volumes.

Active and passive chilled beams rely on the primary air supply for dew-point control. As such, the design conditions must be evaluated to confirm that the primary air is appropriately treated to manage the latent space loads. Chilled beams are intended to operate without condensation. Consequently, active chilled-beam supply water temperatures should be maintained at or above the room dew-point temperature to prevent condensation on the coil and its supply water piping. Passive chilled-beam water supply temperatures should be maintained slightly (1 to 2°F) above the room dew-point temperature. In both cases, the chilled-water supply piping must be adequately insulated to prevent condensation on the pipe itself. Where adequate control of space humidity levels cannot be ensured, higher supply water temperatures and/or condensation controls should be considered. This is discussed in the following sections.

Terminal filtration and condensate pans are not required with a properly designed primary air system and chilled-water temperatures maintained above the room dew point. Heating coils provide sensible heat only, and thus filtration and condensate capture devices are not necessary. Chilled-beam systems designed with noncondensing (dry) coils should be treated similarly.

Heating

Heating is limited to active chilled-beam systems; heating with overhead passive chilled beams is not effective.

The hot water serving the active beam's coil must be chosen to limit the discharge air temperature to less than 15°F above the room design set point. Additionally, to ensure proper room air distribution, the discharge velocity should be selected in accordance with guidance presented previously.

Resetting the primary air temperature with a duct-mounted booster coil allows the primary air serving the interior spaces to continue to provide cooling, while the perimeter duct adds heating capability through this reset. Assuming the active chilled beams are the primary heating system, caution is recommended in placing the equipment at ceiling level with respect to the curtain wall's orientation, to ensure air movement across these surfaces promotes a comfortable environment.

Thermal Comfort

Chilled-beams systems are designed to optimize delivery of cooling to the space, but the paramount consideration in sizing and locating beams in the room should focus on occupant thermal comfort. ASHRAE *Standard 55* defines limits on local air temperatures and velocities that maintain acceptable levels of occupant thermal comfort. The standard defines the **occupied zone** as the one in which stationary occupants reside; the height of this zone is generally considered 67 in. for standing occupants or 43 in. for predominantly seated occupants. Velocities in the occupied zone should not exceed 50 fpm, and occupied-zone vertical temperature gradients should be maintained at 5.4°F or less.

Properly applied passive chilled beams have a limited effect on occupant thermal comfort; however, their complementary primary air supply system often does. Stratified or partially mixed air diffusion strategies are commonly used with passive beams because of their minimal influence on the natural buoyancy driven air patterns associated with the chilled-beam operation. The secondary air circulation through the passive beam transports upper-level air back to the occupied zone, possibly altering the level of stratification in the space.

Active chilled beams directly supply a mixture of primary and secondary air to the space and should therefore be treated like the other air distribution devices used in fully mixed air distribution systems. Because the temperature of the chilled water supplying the coil must be at (or above) the space dew-point temperature, it is typically 56 to 60°F; thus, reconditioned air leaving the coil is several degrees warmer than the primary air with which it is subsequently mixed. This results in beam design discharge air temperatures ranging from 58 to 60°F, warmer than those normally used by conventional all-air systems. Because the required supply airflow is inversely proportional to the room to supply air differential, active beams must discharge 15 to 25% more air to the space to satisfy its sensible heat gains.

Space Temperature Control and Zoning

Chilled-beam systems' primary airflow rates are much closer to the space ventilation rates than those of all-air systems, so primary control of the space temperature is normally accomplished by throttling the chilled-water flow. Simple on/off operation of two-position water valves provides adequate control of active chilled beams. Proportional valves are recommended for passive beams, and for active

beams in applications where more precise space temperature control is required.

In applications where primary air is supplied at conventional temperatures (55 to 57°F) to spaces with significant sensible load variations, it may also be necessary to reset the primary airflow rate or temperature during low-load conditions. One approach is to vary the primary airflow rate in reaction to thermal demands and/or occupancy of the space.

Supply of primary air at or close to room temperature overcomes the potential for overcooling. This, however, results in reduced beam cooling capacities and necessitates the use of more or larger beams. It is also likely to require desiccants to provide adequate dehumidification of the primary air. Spaces with high ventilation requirements and significant cooling turndown rates, such as large conference rooms, may be better served by a VAV solution.

Thermal zoning of chilled-beam systems should be performed in a manner generally consistent with other HVAC systems. Each thermal zone consists of a space thermostat, a chilled- (and, where applicable, hot-) water control valve, and multiple chilled beams.

Selection and Location

Chilled beams may be exposed or integrated with an acoustical ceiling system. Active chilled beams may be of either open or closed design. Closed beams induce secondary air from below, whereas open beams induce through their top or sides. When passive or open active beams are applied, an adequate air path must be provided for secondary air to enter the beam.

For sizing and selection purposes, secondary air entering a chilled beam should generally be considered equal to that maintained within the occupied zone unless solid evidence indicates otherwise.

Most active beams suppliers offer various nozzle sizes and configurations. Nozzle configuration affects the beam's pressure requirement and acoustical performance as well as its induction function. Active beams with adjustable discharge or nozzle patterns may also allow for field alteration of the beam's air distribution characteristics. This may also affect the beam's cooling capacity, so changes should be made with caution.

Beam sizing and location must consider cooling capacity, acoustics, thermal comfort, and integration with other equipment and services. Active beams use a horizontal discharge of their supply air mixture through linear openings along their perimeter, and thus display room air diffusion characteristics similar to those of linear slot diffusers. As such, active beams should be selected and located such that velocities within the occupied zone are limited to 50 fpm or less if compliance with ASHRAE *Standard 55* is the design intent. The use of mapping techniques (see the section on Mixed Air Distribution) and/or selection of active beam throw values within the ranges of Table 4 may be used to estimate compliance with these comfort recommendations.

Locating stationary occupants directly below passive beams can result in thermal discomfort. Care must be taken to ensure that the velocity and temperature of the descending airstream entering the occupied zone comply with the thermal comfort requirements of ASHRAE *Standard 55*.

Operational Considerations

Water supply service to active and passive beams should not be activated until space dew-point temperatures are at or below the chilled water's supply temperature.

Where maintenance of adequate space dew-point temperatures cannot be ensured, some type of condensation detection and mitigation strategy should be used. Designers have various methods of accomplishing this, including the following:

- Sensors, attached to the supply water pipe, that sense formation of surface moisture and discontinue chilled-water flow until the moisture has evaporated. This method is relatively inexpensive but also reactive, and results in termination of secondary air cooling while condensation exists.
- Dew-point calculation and reset of the chilled-water supply temperature is a proactive strategy that does not involve full suspension of secondary cooling. This method can be applied on a room-by-room basis, but calculation on a floor-by-floor basis is usually sufficient and less costly.
- For applications in spaces with operable windows or doors, occupants and staff should be educated on the effect this has on their thermal environment.
- In certain applications, condensate trays may be used to collect temporary and infrequent condensation. Where applied, adequate condensate removal means must be ensured; evaporation of the condensate should not be assumed. This may involve using condensate pumps when gravity drainage cannot be accomplished.

CHAPTER 58

INTEGRATED BUILDING DESIGN

<i>Owner Process</i>	58.1
<i>Objectives</i>	58.3
<i>Collaboration</i>	58.4
<i>Project Delivery</i>	58.6
<i>Design Activities and Deliverables</i>	58.7
<i>Tools</i>	58.8

INTEGRATED building design (IBD) promotes holistic collaboration by project team members during all phases of project delivery. It emphasizes optimizing system solutions based on the project’s objectives, in the context of whole-building performance. Optimizing system solutions requires the participation of all team members. For IBD to succeed and be beneficial, the entire project delivery team must be committed to, understand, and remain engaged in the process, from setting the owner’s program requirements through the completion of construction, commissioning, handover and start-up, and operations and facility management.

This chapter provides a working knowledge of IBD, highlights activities that support collaboration, and helps the HVAC design professional develop a structured and integrated approach to project delivery. Table 1 outlines the basic framework and major milestones, listing the questions that must be answered by team members as they complete one phase of work and seek approval to move forward to the next phase.

This table lists the tasks comprised by integrated building design project. It is intended to provide guidance to a project team, and must be adapted to each specific project. It breaks down a typical building project into phases, and in each phase is a list of go/no-go questions to be answered *yes* or *no* by the owner. If all questions are answered *yes*, then the decision is to go forward and begin work in the next phase. If any question is answered *no*, then the decision is no-go: this does not stop the project, but continues the team’s work in the current phase until all answers are *yes*. The owner should require a *yes* answer to every question in a phase before approving work to begin in the next phase, because each phase builds on those before it. If a phase is not done well, then those that follow are at higher risk of producing an inferior project.

All decisions described in Table 1 are made by a cross-functional team. The makeup of this team varies by project and by phase. At a minimum, the team includes those responsible for designing, building, operating, and maintaining the facility’s systems.

Typically, teams make decisions by consensus. That means that all share the responsibility for decisions, and provide their expertise to the decision at hand. Project integration specialists are valuable in this process: their expertise is leading the team, ensuring that all decisions are made by teamwide consensus, and emphasizing compromises that accommodate valid concerns affecting other disciplines. Project integration specialists have a strong technical understanding of how building systems work together, and their skills include cross-functional team leadership, consensus decision management, and capitalizing on the expertise of all members.

The resources in the References and Bibliography as well as other Handbook chapters and ASHRAE guidelines and standards offer in-depth guidance on various IBD application requirements and should be referred to for more information.

The preparation of this chapter is assigned to TC 7.1, Integrated Building Design.

1. OWNER PROCESS

A project begins when an owner wants to satisfy an unmet need. Successful incorporation of IBD objectives is set at this point, before design begins.

Programming

When new facility space is required, the owner must first evaluate options available: build new, modify existing, or relocate. These scenarios should be debated to determine which option provides the best-fit alternative. Questions to consider include the following:

- Are adaptive reuse alternatives suitable in the project and available?
- Does the program have redundancies that contribute to wasteful infrastructure construction?
- Can operating schedules be adjusted to minimize built space?
- Are there consolidation opportunities in and outside the organization that could foster more environmentally responsive built solutions?
- Are there multiple-use opportunities that can support additional program uses, expanded use potential, and operational scalability?
- If accelerated project delivery is required, what are the consequences for not thoroughly developing and evaluating optimized solutions?
- What does the owner feel are the project objectives? Early definition of objectives is instrumental in assembling the correct project team members.
- Based on definition of the project objectives, who will best serve the role as IBD champion for the owner’s interest?

Siting

The proposed building’s location directly influences the course the IBD takes. Site alternatives need to be researched to determine whether site contamination may influence infrastructure solutions, or whether wetland offset measures must be implemented at other sites.

The location and suitability of utility resources must be identified. Sites should allow options and flexibility, because lack of available utilities affects optimization models. Basic features to consider include the following:

- Is potable city water available, or will well water be required? If provided from a municipal source, what line pressures are available?
- Is a municipal sanitary sewer available, or will an on-site septic system be required?
- Is a city stormwater system available? If not, what are the alternatives for handling stormwater runoff?
- How close are electricity, gas, and/or district energy systems?
- Is the site conducive to implementation of renewable site/source energy?

Table 1 Integrated Building Design Checklist

Go/No-Go Question	No	Yes	Go/No-Go Question	No	Yes
Phase 1: Market Justification			Phase 5: Construction Preparation		
Has the market justification assessment been completed by a team of highly skilled people, assigned by the owner?	<input type="checkbox"/>	<input type="checkbox"/>	Is the project price agreed between the owner and contractor(s)?	<input type="checkbox"/>	<input type="checkbox"/>
Has the team identified and clearly defined a need for this built space?	<input type="checkbox"/>	<input type="checkbox"/>	Do the construction documents include answers to all bid questions and scope of work change agreements?	<input type="checkbox"/>	<input type="checkbox"/>
Has the team prepared a plan to complete Phase 2, including key team members, objectives, funding required, and schedule?	<input type="checkbox"/>	<input type="checkbox"/>	Do the construction documents include all cost reduction design changes and related OPR changes?	<input type="checkbox"/>	<input type="checkbox"/>
Has the team demonstrated financial justification and funding available to complete Phase 2?	<input type="checkbox"/>	<input type="checkbox"/>	Does the team agree that commissioning work completed in accordance with construction documents will prove that building performance meets the OPR?	<input type="checkbox"/>	<input type="checkbox"/>
Phase 2: Project Initiation			Are contractors prepared to perform the commissioning tests and inspections required by construction documents?	<input type="checkbox"/>	<input type="checkbox"/>
Is there a commitment to high performance?	<input type="checkbox"/>	<input type="checkbox"/>	Are the means and methods for project communication and decision making clearly defined?	<input type="checkbox"/>	<input type="checkbox"/>
Is integrated building design or integrated project delivery justified?	<input type="checkbox"/>	<input type="checkbox"/>	Has the team prepared a plan to complete Phase 6, including key team members, objectives, funding required, and schedule?	<input type="checkbox"/>	<input type="checkbox"/>
Have the owner's operation and maintenance (O&M) capabilities been documented?	<input type="checkbox"/>	<input type="checkbox"/>	Phase 6: Construction		
Does the owner's O&M staff possess expertise that could contribute to successful outcome of the project?	<input type="checkbox"/>	<input type="checkbox"/>	Are all systems built and equipment installed in accordance with the construction documents and certified as such in accordance with commissioning requirements?	<input type="checkbox"/>	<input type="checkbox"/>
Have these members been identified and included in the owner's team?	<input type="checkbox"/>	<input type="checkbox"/>	Has the owner's facility management/maintenance staff made regular visits during construction to ensure maintainability of installed equipment?	<input type="checkbox"/>	<input type="checkbox"/>
Has the commissioning agent prepared the first draft of the owner's project requirements (OPR)?	<input type="checkbox"/>	<input type="checkbox"/>	Are all systems and equipment operating as intended and certified as such in accordance with commissioning requirements?	<input type="checkbox"/>	<input type="checkbox"/>
Has the project initiation team defined attributes of the concept development and design phases cross-functional team members?	<input type="checkbox"/>	<input type="checkbox"/>	Has the authority having jurisdiction (AHJ) approved the project for occupancy and agreed that all required inspections and tests are complete and satisfactory?	<input type="checkbox"/>	<input type="checkbox"/>
Have members of the concept development and design phases cross-functional team been recruited?	<input type="checkbox"/>	<input type="checkbox"/>	Is the owner O&M training plan complete?	<input type="checkbox"/>	<input type="checkbox"/>
Has a project integration specialist been recruited to join the team?	<input type="checkbox"/>	<input type="checkbox"/>	Has the team prepared a plan to complete Phase 7, including key team members, objectives, funding required, and schedule?	<input type="checkbox"/>	<input type="checkbox"/>
Has the team prepared a plan to complete Phase 3, including key team members, objectives, funding required, and schedule?	<input type="checkbox"/>	<input type="checkbox"/>	Phase 7: Owner Acceptance		
Has the project initiation team demonstrated that there is financial justification and funding available to complete Phase 3?	<input type="checkbox"/>	<input type="checkbox"/>	Are all systems operating in accordance with the OPR?	<input type="checkbox"/>	<input type="checkbox"/>
Phase 3: Concept Development			Does the owner have all documentation required to operate and maintain the building?	<input type="checkbox"/>	<input type="checkbox"/>
Is the OPR complete, documenting clear and measurable targets for building performance, suitable for monitoring building operating performance?	<input type="checkbox"/>	<input type="checkbox"/>	Have all required documents and maintenance procedures been incorporated in the owner's maintenance management system?	<input type="checkbox"/>	<input type="checkbox"/>
Has the team agreed on one set of systems concepts that define the whole building?	<input type="checkbox"/>	<input type="checkbox"/>	Have the owner's O&M people been trained in the proper operation and maintenance of the integrated whole-building systems?	<input type="checkbox"/>	<input type="checkbox"/>
Has the attributes of specialty resources been defined and are they available as needed?	<input type="checkbox"/>	<input type="checkbox"/>	Is the owner prepared to operate and maintain building performance in accordance with the OPR?	<input type="checkbox"/>	<input type="checkbox"/>
Has the team prepared a plan to complete Phase 4, including key team members, objectives, funding required, and schedule?	<input type="checkbox"/>	<input type="checkbox"/>	Has the team prepared a plan to monitor the performance of building systems throughout the warranty period and tune or repair systems as necessary to make the building perform as required by the OPR?	<input type="checkbox"/>	<input type="checkbox"/>
Has the project initiation team demonstrated that there is financial justification and funding available to complete Phase 4?	<input type="checkbox"/>	<input type="checkbox"/>	Phase 8: Use, Operation, and Maintenance		
Phase 4: Design			Does operating performance under normal use and occupancy meet the OPR?	<input type="checkbox"/>	<input type="checkbox"/>
Has the integrated team, including design professionals, construction contractors, and owner's O&M staff, worked together to perform design work?	<input type="checkbox"/>	<input type="checkbox"/>	Are O&M personnel in place and prepared for ongoing operation?	<input type="checkbox"/>	<input type="checkbox"/>
Are schematic design documents complete and delivered to owner?	<input type="checkbox"/>	<input type="checkbox"/>	Do all team members agree that the project is complete?	<input type="checkbox"/>	<input type="checkbox"/>
Are design development documents complete to the extent necessary for pricing and delivered to the owner?	<input type="checkbox"/>	<input type="checkbox"/>			
Has the team prepared a plan to complete Phase 5, including key team members, objectives, funding required, and schedule?	<input type="checkbox"/>	<input type="checkbox"/>			
Has the design team demonstrated that there is financial justification and funding available to complete Phase 5?	<input type="checkbox"/>	<input type="checkbox"/>			

Transportation conditions must also be identified, such as whether local and regional road systems are

- Suitable for moving raw materials in and transporting processed products out
- Sufficient for transporting materials and products consistently

Neighbor relations present another decision matrix for the owner to consider. A facility's location and specific functions may contribute negatively to the surrounding community. Questions that may lead to unique project mitigation objectives include

- What will the effects on traffic be for building occupants and neighboring communities?
- Do operational use schedules complement those of neighboring communities?
- Will abatement of light trespass and ambient noise be required?
- How will stormwater runoff affect adjacent properties?

Budgeting

The next step is for the owner to appropriate funding for design, construction, and operation of the facility. Funding sources should be planned to cover anticipated professional services, capital construction, contingencies, escalation, maintenance, utility/energy, and occupant costs. Encourage collaboration to optimize expenses and leverage noncapital costs to minimize overall total ownership cost.

Occasional budget shortfalls are not uncommon. Early in the process, incorporate a reasonable contingency (~10 to 20%) into the budget to allow for unknowns and minor changes as the project evolves.

Team Selection

Design team members should be highly competent, knowledgeable, and experienced on similar projects. Team selection can vary, depending on the client's in-house capabilities, but typically, members need to assist the owner during programming and siting. Team members' qualifications must support the project's objectives.

2. OBJECTIVES

Project objectives may be defined by the owner before team selection, or developed by the project team during any project phase. The key is to define substantive objectives that can lead to practical, constructable results. This section outlines typical objectives; consult application-specific materials for effects and detailed descriptions.

Various sustainable, green, and high-performance prescriptive point systems are available to promote particular delivery objectives (e.g., sustainable sites, water efficiency, energy and atmosphere, materials and resources, indoor environmental quality). Although these objectives are highly desirable and promote responsible environmental stewardship, meeting the defined project objectives is of primary importance, not accumulating points in a prescriptive rating system.

Energy Use

Energy performance objectives can be as simple as providing minimum prescriptive energy code compliance, or as detailed as providing a net-zero-energy performance facility. The extent and complexity must be tailored to each project. Objectives that may be encountered include the following:

- Provide minimum prescriptive compliance per applicable energy code requirements
- Improve energy performance by an owner-defined percentage beyond applicable energy code benchmark(s)

- Provide a facility site energy density of less than owner-defined consumption per unit area
- Provide a facility source energy density of less than owner-defined consumption per unit area
- Provide owner-defined percentage of facility's source energy from renewable resources
- Limit owner-defined percentage of facility's source energy to nonrenewable or consumable resources

Typically, energy-related objectives address consumption, efficiency, and generation (site and source) issues, and many variations, combinations, and themes are possible. The project's underlying objectives should be fulfilled before accumulating performance-rating-system points becomes the primary focus.

Indoor Environmental Quality (IEQ)

IEQ objectives vary with the programmed use for the building. Each aspect of IEQ must be considered.

Acoustical comfort may require attention for certain facilities or sites. Theaters, for example, have specific noise criteria necessary for proper operation. Meeting these criteria for specific buildings requires knowledgeable collaboration by all parties that control the source noise, transmission paths, and measured point of sound pressure.

Depending on the facility, **thermal comfort** may be critical. The project team must clearly understand the individual facility's thermal conditions and range of acceptable variation. This criterion significantly affects the size, type, and complexity of potential infrastructure solutions.

Depending on the climate and operational needs, **humidity or moisture control** may be appropriate. This objective can be further expanded to address building protection, occupant comfort, or process needs.

Ventilation effectiveness deals with the practical and reliable means of providing ventilation air into the breathing zone of the facility occupants. ASHRAE *Standard* 62.1 identifies zone air distribution effectivenesses E_z ranging from 0.5 to 1.2 for various air distribution configurations. An objective that may be defined is to limit HVAC solution configuration to systems that provide an E_z value of 1.0 or greater.

Light quality can be a concern for some operations. The quality of ambient light in a space can have direct effect on occupants' productivity. Properly applied and controlled, daylighting can improve the visual quality of the occupied space and reduce energy consumption by decreasing the need for artificial indoor lighting systems.

Water Usage

IBD objectives for water usage typically focus on conservation and reclamation efforts. Water has a cost associated with its use, and should be modeled in the total ownership cost of a facility.

Water conservation and reclamation do not apply only to plumbing: HVAC systems can consume significant amounts of water and are prime candidates for environmentally responsible project objectives. Sample objectives that have an HVAC influence include the following:

- Reclaim all cooling condensate discharge for use in gray-water systems. Note that reclaimed gray water can be used in a host of facility service applications, such as cooling tower makeup, landscape irrigation, urinal flushing, etc.
- Capture all facility stormwater drainage for use as gray-water makeup for HVAC, plumbing, and landscaping needs.
- Increase concentration limits and/or decrease cycles on cooling tower blowdown to limit water consumption. This, of course, must be balanced against the suitability of an integrated maintenance program and limited to local water quality characteristics

that do not contribute to scale, corrosion, fouling, and microbial growth.

Vulnerability

Global events and operational needs may dictate addressing building vulnerability. The facility infrastructure may require protection from seismic incidents, explosive blasts, or chemical and biological contamination. Indoor operations that create explosion, chemical, biological, or radiological hazards may also require attention. Additionally, protecting occupants in the facility may be an inclusive or stand-alone priority. In any case, vulnerability objectives create some challenging opportunities for collaboration, and demand that the project team have an effective prioritization system in force on the project. See Chapter 59 for more information.

Environmental Stewardship

Waste reduction is a pressing need in the built world. The capacity of landfills to absorb construction debris is not limitless, and reuse and recycling can help mitigate landfill overuse. When materials cannot be harvested or obtained from the project site, using new construction materials that include recycled content is a proactive consideration.

As concerns with global climate change and greenhouse gases increase, minimizing the carbon footprint of the facility may become a critical objective. This will require a unique collaborative effort to minimize the sum of the embodied energy and carbon emissions of all processes and components required to construct, own, operate, and maintain a facility.

Critical Operations

Some objectives are critical to operations for data centers, emergency response, law enforcement, government, health care, shelters, manufacturing, and pharmaceutical facilities. For example,

- Facilities that require high reliability must focus on ensuring that systems and components meet the specified probability they will operate for the duration of use. As the required reliability increases, infrastructure design must respond in kind with system redundancy and diversity.
- Facilities that require high availability must focus on ensuring that systems and components meet the specified probability they will operate and be accessible when required for use.
- Scalability may dictate that infrastructure have provisions for expansion and growth relative to dynamic business factors and technology development.

General Operations

Accessibility priorities may dictate that some elements have unique requirements to ensure proper performance and serviceable attention during the operational life. Accessibility has an infrastructure cost effect that must be factored into the total ownership cost.

Replaceability objectives may define where facility infrastructure can be located so that replacements can be made when the useful life has expired. Total ownership solutions should plan for the costs to replace equipment and not leave this as a hidden burden for the facility owner to bear later.

Many owners face a dynamic known as **churn** (reconfiguring a space or changing its use). Objectives that plan for churn can help mitigate complete replacement of facility services if changes need to be made.

3. COLLABORATION

Collaborative design requires that all members of the design team possess demonstrated expertise, an ability to work collectively in a nonisolated setting, and a drive of stewardship to support IBD. Team members should share similar corporate philosophies, have

compatible operating procedures, use common optimization tools, and be committed to adhering to consistent interdisciplinary quality assurance/quality control (QA/QC) procedures.

Teamwork

Working with a team requires that participants engage in joint decision making. Individual thinking and processes must give way to support the team and a decision-making mentality that supports the team's direction. Individuals must keep in mind that their actions and reactions affect integrated system solutions. Design in isolation does not support team collaboration.

Team members must foster a professional level of respect for each other. When individuals suggest new strategies to improve the whole, dissident views will occur. Emotions must be removed from these events. Evaluations must be made on objective application and support of meeting project objectives.

The project team leader should be trained to handle conflict management and dissident views in a professional manner. Consensus agreement will not always be apparent, and the project team must avoid fracture of the collaborative effort when differences occur.

Effective, concise, and complete communication must be adopted to keep the team informed of all decisions across all design disciplines. Communications within the project team should be standardized as much as possible. Each form of communication should contain the origination date, any revision dates, project name, project number, and originator's contact information. In addition, a clear and concise subject line should be included to focus recipients on the subject matter at hand. For collaboration to work, all team members must be kept in the communication loop so that each understands where the collaboration process stands.

Team Formation

The importance of an experienced, integrated design leader cannot be overstressed. Systems thinking requires input from individuals who have design experience to match the project at hand. Decisions must be based on understanding how systems and components interact. The integration leader must ensure that those with limited cross-functional experience listen to other viewpoints and adapt their work for the best whole-building solutions.

IBD can succeed when key representatives learn as they go, but the work may take longer and require more iterations as the new participants are trained in the system. IBD provides an excellent opportunity to mentor and train supporting staff in system integration, and the opportunity should be fully exploited.

Participation in IBD requires individuals to have a proactive attitude that supports the ups and downs of iterative system evaluation. Individuals who can see the big picture and appreciate that the whole will be better than the sum of the parts enhance the team's efforts.

Participants should have experience with optimization techniques. This equates to more than being able to run a load calculation. True optimization expertise requires understanding how building systems interact, what elements can be examined for the benefit of the whole, and how to evaluate results in detailed financial models that consider all ownership costs.

Some projects may require adding specialty consultants to the project team to support activities such as smoke control, acoustics, seismic restraint, or food service. Only rarely can one firm meet all necessary needs on complex projects. Managing outside specialty consultants is an added responsibility that must be factored into the collaborative process.

As for the owner, the design team requires an IBD champion to keep focus on the project objectives.

Decision-Making Criteria

Benchmarks or baselines must be established to evaluate how well the evolving system matches the project needs. These

decision-making criteria must be agreed to with the owner before any design work begins. Criteria need to be realistic, allow for maintaining pace with the budget limitations, accommodate strategic flexibility, and address budget correction possibilities when the need arises. The criteria depend on the owner's resource capabilities and financial position, but in all cases should be based on meaningful life-cycle analysis.

Scenarios may arise that challenge the design criteria and defined objectives for the project. Project scopes or financial factors often change during project design, procurement, or construction. This deviation from the original path may require a reprioritization of objectives and a change in the decision-making criteria. The team should be prepared to adapt to such dynamics and be able to refocus the IBD responsively and efficiently.

Strategy Development

IBD strategies should lead the team toward the desired end result: a built facility of integrated systems. Development of these strategies is influenced by the prioritization of project objectives and by the direction of the developing building solution. Using the simple but unquantified objective of reduced energy use as an example, the following broad strategies and substrategies reflect the progressive optimization for a commercial office building in the southeastern United States. Note that the example does not provide an all-inclusive strategy roadmap, or represent a fixed recommendation.

1. Minimize building envelope load
 - Optimize siting and footprint aspect ratio to maximize east/west orientation
 - Incorporate effects of major sky obstructions such as buildings, trees, and geological features
 - Optimize fenestration and door orientations for best whole-building energy consumption
 - Incorporate overhangs to reduce solar radiation component during warm months
 - Optimize glass thermal quality and solar transmittance capacity per orientation
 - Optimize roof thermal and solar reflectance performance
 - Optimize wall and floor thermal performance
2. Minimize building performance load effects
 - Incorporate daylighting to improve visual comfort and to reduce connected ambient light load
 - Modify glass to control solar radiation, but allow visible light transmittance
 - Adjust initial space layout to provide open areas on building perimeter
 - Incorporate passive solar reclaim on south exposure to offset winter heating load
 - Incorporate green roof systems to stabilize year-round plenum temperature
3. Minimize connected internal load
 - Identify a realistic occupant use schedule and integrate with internal load components
 - Optimize applied lighting efficiency and staging controls
 - Maximize efficiency of office equipment
4. Develop HVAC infrastructure based on optimized load profile [for simplicity, other mechanical, electrical, and plumbing (MEP) infrastructure system dependencies are excluded from the primary demonstration]
 - Select best-fit strategy for HVAC systems based on minimized building load, use profile, and ventilation requirements. Note that this exercise requires extensive modeling by the HVAC engineer to find the best-fit solution. (For this example, arbitrarily assume that a water-cooled chilled-water plant, hot-water gas boiler plant, gas-fired desiccant dedicated outdoor

air unit, and four-pipe fan-coil terminal units have been shown to provide the best-fit energy performance solution that maintains budget control.)

5. Optimize HVAC systems
 - *Chiller plant*
 - Analyze terminal unit cooling coil selections to determine water temperature differential needed to provide cooling performance, minimize distribution pipe size, and minimize pumping capacity
 - Optimize condenser water temperature differential to find best fit for chiller, cooling tower, and condenser water pumps
 - Evaluate effect of water-side economizers
 - Evaluate application of condenser water heat recovery as a waste heat source
 - *Boiler plant*
 - Analyze terminal unit heating coil selections to determine water temperature differential needed to provide heating performance, minimize distribution pipe size, and minimize pumping capacity
 - *Ventilation system*
 - Analyze effect of energy recovery on dedicated outside air unit and central plant capacities
 - Evaluate distribution options and effect on power for delivery of ventilation air to the occupied space
6. Optimize HVAC components
 - *Chiller plant*
 - Optimize chiller for best-fit performance compared to projected load profile and condenser water relief opportunities
 - Optimize cooling-tower performance using air or water modulation compared to projected load profile
 - Examine effect of motor efficiency improvements on pumping systems
 - Optimize sizing of noncritical path piping mains and branches
 - *Boiler plant*
 - Optimize boiler performance compared to projected load profile
 - Examine effect of motor efficiency improvements on pumping systems
 - Optimize sizing of noncritical path piping mains and branches
 - *Ventilation system*
 - Examine effect of motor efficiency improvements on fan systems
 - Optimize sizing of noncritical path duct mains and branches

This simple example demonstrates that there are many possible strategies for a project. The magnitude is greatly expanded when multiple objectives are pursued. In the example, note that HVAC system design is not even a factor until development of the least-load-impact building is completed. Only then do applied MEP system solutions come into focus. The example strategy development supports the object: reduce energy use by minimizing load, right-sizing systems to meet the load, and then maximizing component efficiency to match the use profile.

Interdisciplinary Integration

Coordinate with other disciplines to optimize the design arrangement inside the building to shorten construction duration, reduce overall project cost, and enhance convenience for interdisciplinary operation and maintenance.

The entire building project should be considered as an integrated system, with a unified overall scope of work and unified timeline schedule to be performed and achieved by an integrated design and construction team. In this integrated system, all individual systems

and their components should be considered as subsystems of the overall integrated building project. Subsystems in a complete project include the following:

- Overall site plan; entrances and gates; roads and transportation; landscape; electrical substations or electrical main connection; gas or other fuel main intake pressure regulation station; water, sewer, sanitary, and storm drain piping and main connections; telephone, network, security, and fire protection system main connections; outdoor lighting; etc.
- Building foundations, structure system, walls, roofs, ceilings, floors, elevators, electrical, gas, fuel, water, sewer, plumbing, sanitary, mechanical, HVAC, chiller, boiler, noise control, lighting, process systems, energy and process material recovery systems, exhaust air and wastewater treatment systems, hazard control systems, explosionproof and corrosionproof issues, instrumentation and control systems, fire protection systems, etc.
- Mini environmental booths; supply, recirculation, makeup, and exhaust air systems; lighting, process mechanical, chemical, electrical, and control systems; production lines; process conveyers; special gas supply systems; acoustics; operating personnel; material and products access doors, windows, or openings; air showers; room temperature, humidity, static electricity, CO₂, and pressurization control systems; fire protection and after-fire recovery systems; seismic design and emergency response facilities, etc.
- Construction service and construction; installation work; system start-up; test, adjust, and balance; commissioning; and handover to operation
- Building management and system operation and maintenance

Iterative Evaluation and Analysis

As the example strategy for minimizing energy use demonstrates, multiple development steps must be followed in pursuit of IBD objectives. Design of the final product depends on looking at each system-level component contribution and determining whether incorporation of the proposed strategy improves the project as a whole within the guidelines of the decision criteria.

As each strategy is explored, numerous *what-if* questions must be evaluated and accepted or discarded (see Table 1). Acceptance allows the team to move forward, but does not preclude returning for reevaluation later. Nonacceptance may lead to alternative solutions for the target strategy, or to totally discarding the strategy and moving forward. Discarding a strategy does not preclude returning to it later.

Obviously, IBD requires significant effort and creativity to (1) develop applicable strategies to meet project objectives, (2) refine strategy flow as the building evolves, (3) define component variables as each strategy is evaluated, (4) analyze the financial effects of each strategy, and (5) repeat the process over many iterations.

4. PROJECT DELIVERY

Delivery of solutions in the built world is accomplished in many ways and through various delivery techniques. Whether it is design-bid-build, design-build, design-construction manager (design-CM), etc., each delivery method requires interaction between design professionals representing inclusive elements of the project. See the section on Budget Control under Design Activities and Deliverables for discussion of the differences between these delivery methods.

Effort Shift

IBD requires a departure from the conventional **sequential design process (SDP)** methodology. This change includes a shift in effort during the classical design phases (schematic design, design development, and construction documents), as well as extra, enhanced efforts outside the traditional design phases.

The classical design phases promote a certain level of SDP based on their inherent percentage development model. SDP typically unfolds along the following development path:

1. During schematic design, the basic form and function of the facility are defined to meet the program. Facility services are described in concept to support the developed facility construction.
2. During design development, systems proceed in parallel development paths to find best-fit solutions that meet the project budget and provide compliance with prescribed regulatory requirements such as building, life safety, energy, and ventilation codes. Life-cycle cost analysis (LCCA) may be used to optimize individual discipline solutions in response to the schematic design development package.
3. During the construction document phase, all building components are detailed into work results suitable for procurement and construction.

Integrated design alters this traditional delivery model by front-loading collaboration efforts to optimize building system solutions in response to the defined project objectives. Integrated design is most effective when key issues are addressed early in design and planning (Figure 1). An important point to remember is that implementation of IBD does not necessarily mean getting more things done early; it means getting the right things done early. To accomplish this, traditional team roles that lagged during early design activities must participate on equal footing earlier in the process, so that wholistic issues are considered before it becomes too late for responsible inclusion.

Project Delivery Sequence Focus

IBD applies to all phases of project delivery, not just the standard design phases. Successful delivery requires that the entire project team contribute to their roles at the appropriate time. The team should be aware of the unique effort focus required in each phase. The following outline identifies key focus elements that IBD should consider:

- Owner planning
 - Determine best-fit construction need
 - Identify least-impact, best-fit siting option
 - Define project objectives

Fig. 1 Benefits of Early Design Collaboration
(Lewis 2004)

- Structure project budget to support integrated building design (IBD) process
- Select team to support project objectives
- Predesign
 - Refine project objectives
 - Define decision-making criteria
 - Develop strategies to support project objectives
 - Develop initial program solution
- Schematic design
 - Develop facility solution assembly
 - Optimize facility systems
 - Apply facility services solutions to support optimized facility
- Design development
 - Optimize all facility and services systems
- Construction documents
 - Optimize all facility and services components
 - Communicate system solution accomplishments into constructable work results
- Procurement
 - Provide oversight to ensure that procurement document revisions do not negatively affect developed system solutions
 - Adjust project objectives and conduct new strategy evaluations as required to respond to dynamic scope modifications

5. DESIGN ACTIVITIES AND DELIVERABLES

Some of the more common design activities and deliverables are affected by IBD. Some schools of thought suggest decoupling these items from integrated practice, but this perspective unfortunately misses the underlying premise that all activities in the project delivery process are interdependent to some extent. When collaborative design strategies are used, these interdependencies require increased stewardship.

Drawings

The drawings are graphic representations of the work on a project, and include plans, elevations, sections, details, legends, notes, abbreviations, and schedules. They are often diagrammatic and rarely show every detail required to construct a facility. Drawings show quantities, extents, and spatial relationships of the elements of construction to each other and existing conditions and surroundings. They may identify a particular product, material, finish, or process many times. However, the particular product, material, or process should be specified only one time in the specifications. Descriptions and identifiers on the drawings should be simple, concise, and generic. IBD does not change this basic definition.

IBD does have an effect when it comes time to communicate the system solutions onto drawings that will be used for construction. Coordination now becomes an appropriate and critical IBD tool. The project team must take time to ensure that the integrated work results are correctly identified throughout the drawing set.

The project team should avoid issuing drawings in decoupled groups or individual sheets during the procurement phase. Bidding in isolation is just as detrimental as design in isolation when it comes to achieving integrated solutions.

Specifications

The project manual is the textual description of the work and other requirements for a project; it includes procurement and contracting requirements, general requirements, and technical specifications for the work of the project.

Specifications describe the administration, quality, products, materials, workmanship, warranty, testing, and start-up requirements of the work of a project. For uniformity in structure, location of information, consistency, and quality control, it is best if the specifications are organized into divisions and subdivisions (sections) that

correspond to the major divisions of work required to complete the project as defined in *MasterFormat* (CSI 2014).

MasterFormat includes some very important sections to address in IBD delivery, including the following in division 01, General Requirements:

- Submittal procedures
- Sustainable design reporting
- Closeout submittals
- Sustainable design closeout documentation
- Facility performance requirements
- Sustainable design requirements
- Facility environmental requirements
- Indoor air quality requirements
- Facility services performance requirements
- HVAC performance requirements
- Integrated automation requirements
- Commissioning
- General commissioning requirements

Tools are in place in the industry to support communication of integrated system design into work results that can be consistently located. Further study of the *MasterFormat* structure demonstrates that individual facility services, such as HVAC, have defined specification structures to support effective communication of system solutions.

Value Engineering

Value engineering (VE) is similar to life-cycle cost analysis, and may be performed at any phase of design. It is most often performed when potential construction cost overruns have been identified, or alternative systems or substitute equipment is being considered.

In IBD, the intention is that VE is captured by the strategies and iterations necessary to reach the performance objectives of the project. Because any one solution must satisfy all relevant project objectives, the value of each measure can constantly be assessed. The priority on whole-building performance helps ensure that proposed substitutions are indeed improvements and do not sacrifice performance in a different performance category.

Risk Management

Risk management includes the following:

- Systematic, consistent application of written standard office procedures
- Judicious implementation of QA/QC procedures
- Comprehensive record keeping
- Timely and accurate communications
- Written contracts that include certain basic terms and conditions for all services rendered

Because IBD involves significant collaboration, team members need to practice a policy of keeping good, complete, contemporaneous records of the facts discussed and decisions made (and by whom) in meetings, during site visits, in e-mails, and during telephone conversations. Most errors and omissions (E&O) and liability insurance carriers and their legal counsels offer guidance, and customarily provide publications on risk management as part of their service to their insured. Team members should be well versed in how to practice proactive risk management so that fear of liability does not reduce collaborative participation.

Budget Control

Traditionally, there are two types of budgets the design team must manage during the design phase: design cost and construction cost. Note that this is not an absolute, because owners could incorporate some or all of the operating-related budgets into the equation.

Design cost control begins with design team resource allocation, budgeting, and scheduling while preparing the fee proposal. Once a complete scope of work has been defined, a project budget analysis should be prepared and submitted with the fee proposal to the client. In the SDP model, regular monitoring of actual design cost as compared to the original project budget analysis and scope of work should help avoid scope creep and ensure that projects are delivered within the design fee budget. The IBD model requires that design fee budget control include an additional oversight element. Although infinite evaluations may lead to the absolute best built solution, design fee structures have a practical limit on how many evaluations are affordable. It is therefore financially critical for the design professional to develop a clear strategy at the time of fee negotiation so that all parties agree on the extent and quantity of strategy evaluations, how the fee is structured to reflect the applied effort at the time of service, and how additional services are accommodated if additional evaluations are required.

Responsible control of **construction cost** budgets can vary depending on the project delivery model. Design-bid-build models place the design team in an oversight role. Design-build allows the contracting entity to control cost of the delivered solution. Design-CM brings in a third-party construction manager, who is responsible for delivery of the project within the defined construction budget. IBD is achievable under any of these delivery models. However, each requires accurate cost projections to support realistic system evaluation. Likewise, the construction budget needs to represent a level of funding that supports construction of the final system solutions. Cost projection and cost control play hand-in-hand throughout the iterative evaluation process.

Constructability Review

Constructability is a measure of how well construction documents provide the construction team with the information necessary to complete and deliver a project that meets the owner's expectations and documented project requirements. A constructability review is an organized process of reviewing construction documents during the design phases to make recommendations to the owner and design team about how the design may better define expected construction work results. Ideally, in IBD, knowledgeable construction representatives provide objective feedback on the constructability of developing system solutions.

Operational Review

Operational reviews should be conducted during the design development and construction document phases of design. Depending on the owner, this type of review may be increased to correspond with evaluation scenarios. Operational review can also be one of the decision-making criteria used on a project.

Reviewers should be knowledgeable about systems, equipment, controls, operation, and maintenance. Ideally, the review should include representation from the group that will be ultimately responsible for operating the facility. During the review, sequences of operation should be thoroughly reviewed to ensure that integrated solutions are truly integrated. Equipment location should be reviewed to verify that required maintenance clearance and accessibility are provided. Drawings and specifications should be checked to ensure that (1) the appropriate level of system and component commissioning has been prescribed, (2) adequate and usable close-out documentation has been itemized, and (3) sufficient training has been scheduled for operational staff.

Operational constraints must be considered when system solutions are developed. Nonconventional systems and equipment can be somewhat intimidating for building operators. The issues of perceived complexity and risk must be mitigated. Solutions must be kept in perspective with the client's ability to operate and maintain

the facility. Operational review is an excellent process to address these concerns.

Commissioning

Commissioning is a systematic process of applying QA/QC procedures to the design and construction of a building, to verify that key elements of the design are, in fact, constructed as designed, and started, tested, operated, and maintained so that the building meets the designer's intent and owner's expectations.

ASHRAE defines commissioning of HVAC systems as “[a] quality-focused process for enhancing the delivery of a project. The process focuses on verifying and documenting that the facility and all of its systems and assemblies are planned, designed, installed, tested, operated, and maintained to meet the owner's project requirements” (ASHRAE *Guideline 0*).

Several types of HVAC commissioning processes are available: overall, construction, and existing building commissioning (or retro-commissioning). The commissioning process described here applies to new construction and major renovations.

In new construction projects, the overall HVAC project commissioning approach is recommended. It starts at the inception of a building project during predesign and continues through the design, construction, acceptance, training, operation, maintenance, and postacceptance phases, integrated as part of the entire project.

The owner selects and contracts with an HVAC commissioning authority (CA) at very beginning of the predesign phase. The commissioning authority develops the scope of commissioning and reviews design intent during predesign; during the design phase, the CA reviews the design to ensure the HVAC project accommodates the commissioning process. The CA coordinates with the owner, design engineer, and HVAC contractor, and issues commissioning specifications to address owner requirements, define contractors' responsibilities, and review contractors' submittals. This leads to HVAC construction commissioning, and completion of the rest of the commissioning process.

Commissioning is a rigorous and intense process that should be used when integrated-system-based design solutions are provided. See Chapter 43 for more information.

6. TOOLS

IBD requires detailed simulation and evaluation of system solutions across multiple design responsibilities. Performing these simulations by hand can be onerous. Tools are readily available in the industry to assist the project team in maximizing their collaboration efforts.

This section discusses three critical, fundamental types of tools suggested for use in executing IBD. These are not the only options available: many tools are available from government, utility, commercial, manufacturing, and technical society sources. Comprehensive listings of potential resources are available on the National Institute of Building Sciences (NIBS 2014) Whole Building Design Guide web site (<http://www.wbdg.org>).

Building Information Modeling

Building information modeling (BIM) is the process of using intelligent graphic and data modeling software to create optimized and integrated building design solutions. As such, it is an enabling tool for IBD (Figure 2). The ultimate goal of BIM is to assemble a single database of fully integrated and interoperable information that can be used seamlessly and holistically by all members of the design and construction team, and ultimately by owners/operators throughout a facility's life cycle. The desired result is a BIM model where three-dimensional (3D) graphical imaging carries real-time (i.e., immediate and dynamic access) data, and where every line and every object carries real-life intelligent physical and performance

Fig. 2 Overview of BIM Benefits

data. That model includes the aesthetic, physical, and thermal properties of each component, as well as specification and cost data. The design team interfaces with the model to seamlessly generate comprehensive simulation evaluations, including natural daylight modeling, energy modeling, and life-cycle cost analysis of the building.

The modeling technology can start with direct data transfer from the design calculation software into graphic layouts (for systems such as structural steel, fire protection, or other modular elements). Alternatively, it can use the graphic layouts as direct input to load calculations (e.g., energy simulation, pipe sizing, duct sizing). Modeling programs can also link to specifications and to manufacturers' web sites for data input. Either way, building information modeling technology already extends into fully integrated 4D modeling (adding the fourth dimension of time for scheduling software) and 5D modeling (adding the fifth dimension of cost for estimating and budget control).

After design optimization is complete, the original modeling software can compile data from each discipline and generate a set of digital 2D or 3D construction documents for use in procuring construction bids. The model can interface with a contractor's cost estimating, scheduling, and project management software and manufacturers' material, fabrication, and cost databases to generate optimized cost estimates and construction schedules. Development can continue with the provision of automatic bills of material (BOM) and generation of automatic shop drawings for everything from structural steel to sheet metal duct fabrication, fire protection and piping fabrication, electrical cabling and bus duct layouts, etc. As construction progresses, the model can be continually updated to as-built conditions, including integration of manufacturers' installation, operation, and maintenance data. This extends all the way through start-up and commissioning and to facilities management, with hyperlinks to operating and maintenance manuals, service contractors, etc.

A complete building or facility project design process typically involves various complex conditions such as certain or uncertain, complete or incomplete, natural, artificial, scientific, technical, environmental, and/or economical information; codes, standards, rules, and regulations; and preferences of the owner and their operating personnel. Future computerized IBD and construction would not be only a simple simulation of the project design process, but would also help perform project analysis and diagnosis for optimizing design alternatives and project decisions.

There is a significant amount of work being done worldwide on software tool and protocol developments by governmental agencies, nonprofit and research organizations, as well as commercial entities, to facilitate and promote BIM technology. There is also

significant new interoperable application software under development using BIM.

A major key to the success of these efforts is establishing common software protocols.

The International Alliance for Interoperability (IAI) was formed in 1995 to define and develop standards or protocols as a framework for data exchange, creating the industry foundation classes (IFCs), and gaining ISO recognition. IFCs are maintained by buildingSMART® International, the current name for IAI. The buildingSMART web site (<http://www.buildingsmart.com>) provides the IFC specifications, definitions, and model documentation that can be used to develop BIM interoperable software applications. The latest IFC model is called the buildingSMART data model, codified as ISO/PAS Standard 16739.

The National Institute of Building Sciences (NIBS) established the buildingSMART alliance™ to advance open interoperability and full-life-cycle implementation of BIM, and their National BIM Standard (NBIMS) committee establishes standard definitions for building information exchanges to support critical business contexts. NBIMS addresses the need for a life-cycle view of building supply chain processes, the scope of work necessary to define and standardize information exchange between trading partners, suggestions for a methodology to address this work, and examples of work in progress.

Energy Modeling

Energy modeling uses scientific methods and analytical tools to estimate the energy consumption patterns of a given facility, constructed of given materials, located in a given climate zone, and operated according to given schedules. These tools and methods range from simple hand calculations and spreadsheets to the most sophisticated software tools designed to consider numerous building configurations, various zoning options, and multiple systems. Some of the more common software tools include programs free for download such as the U.S. Department of Energy's (DOE) Energy-Plus or DOE-2/eQUEST. Commercial entities and equipment manufacturers also have products available to support building load calculation and detailed energy performance modeling.

Energy modeling should be used to help integrate and optimize a building's energy performance over the facility's expected life cycle. Successful application of this tool comes from evaluating system solutions as early as possible to develop best-fit solutions for the developing design, thus minimizing radical design changes late in the design phases.

Energy modeling may also be used if it becomes necessary to value-engineer a project after the design phase is complete. Simple substitutions of less costly materials, products, equipment, or

systems during the value-engineering stage of a highly integrated building design may have serious and profound negative effects on the building's future energy and environmental performance if not properly analyzed before acceptance.

Energy models should only be developed by team members who have extensive experience in the creation of such models and who truly understand the dynamics of building operations. Energy modeling is used to estimate the energy performance of a building and its systems for comparison to other alternatives performing under similar conditions and constraints at a given time, and is used for informed and intelligent decision making on building orientation, window/wall ratio, envelope insulation levels, daylighting features, and HVAC system selection. Weather patterns change; plug loads and technology use change; users' preference for thermostat set points often differ from those modeled; material properties change and degrade over time; system and equipment maintenance may be kept current or deferred after owner occupancy; and hours of usage and operation change; these are just a few reasons why modeled energy use rarely tracks favorably with actual energy use. Keep the following points in mind when using energy models for system evaluation:

- Model results are not a guarantee of actual or future performance.
- Model results are not a guarantee of actual or future energy costs.

See Chapter 19 in the 2013 *ASHRAE Handbook—Fundamentals* for an in-depth discussion on modeling methods for systems design and design optimization.

Life-Cycle Analysis Tools

All system evaluations share a common need to demonstrate what the financial effects are relative to total ownership cost. This requires a comprehensive comparison of capital, utility, energy, maintenance, replacement, disposal, and occupant costs for the facility's projected life. Life-cycle cost analysis (LCCA) provides a means of examining how each of these factors impact the owner's cost obligations.

A comprehensive methodology for facilitating life-cycle comparisons can be found in the National Institute of Standards and Technology's *Handbook 135, Life-Cycle Costing Manual for the Federal Energy Management Program* (NIST 1996). NIST provides a number of supplemental publications and tools that should be used in conjunction with this source, including the following:

- Annual supplements to *Handbook 135*, providing annually updated energy price indices and discount factor multipliers
- The DOE's Building Life-Cycle Cost (BLCC) Computer Program, which provides an electronic means of applying the methodology of *Handbook 135*

All of NIST's life-cycle publications, tools, and annual updates may be downloaded from the U.S. Department of Energy's Federal Energy Management Program web site (<http://energy.gov/eere/femp/>).

Chapter 37 contains more information on LCCA.

---	--

THIS chapter is intended to be an overview of HVAC security considerations relative to natural events, accidents, terrorism, and national threats, as well as addressing chemical, biological, radiological, and explosive (CBRE) incidents that do not cause major structural damage to a building or its infrastructure. This added focus on CBRE incidents, either accidental (e.g., an industrial spill) or premeditated, is intended to be a general overview and not used as design guidelines.

Because of the nature of security, there is not much documentation available pertaining to designing, constructing, operating, commissioning, or recommissioning and maintaining HVAC equipment and systems from a security and environmental health and safety (EHS) standpoint. Organizations such as the U.S. Department of Defense have guidelines that are considered highly confidential and are only shared with others on an as-needed basis. In other situations, special security organizations follow behind the design and/or construction teams with security measures that are not shared with these design/construction organizations. As a result, the owner's project requirement (OPR) document should include a security and EHS statement, and the HVAC design engineer must include information in the basis of design (BOD) document to raise awareness of the approach and level of security and EHS for the specific project.

In general, HVAC security and EHS apply to all building applications based on a broad range of reasons, needs, and requests. They play a particularly important role for businesses such as pharmaceutical companies, property managers of high-profile commercial buildings where workers and visitors come and go on a regular basis throughout the day and night, and convention centers and sport stadiums entertainment venues where thousands of people are present for a few hours. Recently, security considerations have expanded to include all building programs, whether a K-12 school, movie theater, or simply a tenant fit-out of a small business space.

This chapter is not intended to be used for design or development of life safety systems or procedures, or for protection of personnel during an incident; rather, it offers an approach to HVAC security and EHS to include a segment in the design team BOD document that can address HVAC security, EHS, commissioning, and recommissioning of systems; details the need to provide proactive maintenance of these components and systems; and provides descriptions of some CBRE incidents and their associated effects on buildings, building equipment, and occupants, along with general guidelines for how to deal with their effects on building infrastructure.

Since September 11, 2001, more published information has been available about procedures for preventing, mitigating, and remediate terrorist or other CBRE incidents. ASHRAE's (2003a)

Report of Presidential Ad Hoc Committee for Building Health and Safety under Extraordinary Incidents discusses many aspects of buildings, building infrastructure, and measures that can both reduce the threat and/or damage from such incidents. Several departments of the U.S. federal government, including the Federal Emergency Management Agency (FEMA), Department of Homeland Security (DHS), National Institute for Occupational Safety and Health (NIOSH), Centers for Disease Control (CDC), and Department of Defense (DOD), have produced reports and guidelines for dealing with terrorist threats to buildings (see the Bibliography). Emphasis is generally on actions to reduce the potential harm to building occupants and minimizing the potential for an accident, both reducing the threat of harm, by instituting procedures that reduce the hazard during an incident.

HVAC security and EHS begin in the building program phase of a renovation or new construction project. The design team should address the level of security via a risk evaluation and document the level of security and EHS to be invested in the building program. For most buildings, the risk evaluation will fall into the category of low to medium, but do not overlook the potential for high risk based on the building's application.

In almost any case of a terrorist event affecting a building, its infrastructure, or its occupants, the affected building and its immediate surroundings are likely to be in police or military control for several days (or longer) after the event. During this period, the role of the building(s) owner or physical plant staff is to assist in controlling or remediating the affected areas through their knowledge of the building and its infrastructure systems. Assessment of damage or remaining danger to the building or personnel is difficult, particularly with chemical, biological, and radiological events, in which the contaminating agent often is invisible and is only revealed through adverse health effects. As such, there are no specific guidelines for how or when a building can be brought back online and readied for occupancy; each event is unique. Any preparation or response protocol for CBRE incidents internal or external to the facility should be designed to consider the specifics of the building and its occupants. It is impossible to provide general guidelines for incidents that are so unpredictable and potentially so devastating. This chapter attempts to shed light on design intent, construction administration, commissioning, and recommissioning, and some of the possible effects on buildings, their systems, and their occupants, which may aid in the development of a more specific protocol in line with a particular facility's needs.

1. OWNER'S PROJECT REQUIREMENTS

The initial process of any building program is establishing the owner's project requirement (OPR) document, which is an abbreviated overview of the owner's project goals. Both the OPR and the

The preparation of this chapter is assigned to TG2, Heating, Ventilation, and Air-Conditioning Security.

BOD must be drafted in the conceptual phase of a renovation or new construction project. The OPR covers a wide range of categories to document the owner's intent in investing in this new construction, renovation, or infrastructure project. The OPR identifies the drivers that will shape the design, how it will be constructed, the energy budget, and how it will be operated and maintained over the building's life. It also sets a construction budget and project timeline. Security and EHS requirements may remain confidential, with limited documentation between the owner's security professionals and the designer. A separate design team and construction team also could be brought into the project after design is completed and before the owner begins occupancy, to fulfill the BOD.

When drafting an OPR, the building owner, owner representative, and the design team should consider the following:

- Who are the main occupants?
- What is the intended use of the building?
- What is the total planned population of the building, including visitors and service staff?
- What type of operations will the facility and/or occupants conduct?
- What is the planned response to an incident? Will occupants evacuate, shelter in place, or carry on normal activities uninterrupted?
- How will the building staff become aware of a threat, and what is the likely notification time?
- What level of protection is required against threats?
- Will some occupants have planned responses that differ significantly from the general building plan?
- What level of access will the general public be allowed in the building?
- Does the owner have a dedicated security team and/or consultant?
- What life safety measures are planned for the building?
- Will occupants be required to remain in the building after an incident (e.g., in a high-security prison)?
- Are there any unique environmental health concerns (e.g., explosive atmosphere, laboratory)?

In addition to the preceding, the design engineer should also consider lessons learned from past HVAC security process failures associated with the type of building (e.g., for a hospital project: emergency generators and primary HVAC equipment located below flood water levels that took out the emergency power and special HVAC central air systems serving in-patient space). An Internet search of related issues and concerns is advised.

The OPR should be complete and exhaustive, and should adequately cover the owner's overall goals for the building's HVAC security. Many HVAC security measures are relatively low in cost and effort during new construction or renovation planning, but may require significant cost and effort if implemented after construction is completed. Therefore, it is critical to capture these requirements early in any design process.

All projects should include some minimal level of HVAC security design and planning. These measures are typically included in the life safety requirements, specific designs, or best practices typically applied to building construction. These **baseline measures** include equipment or design features that can be applied to all buildings at a minimal cost and effort to provide basic protection against internal and external threats. Baseline measures support the safe sheltering in place and/or evacuation of occupants during an incident. Many baseline measures can be implemented in an existing facility with little or no additional engineering design or cost, and with minor alteration to the facility operations. **Enhanced measures** include equipment or design features beyond the baseline level, and are intended for facilities with identified risks or critical operations. Costs for design, construction, and sustainment can be significant, depending on the measures selected; however, the protection afforded by these systems typically allows longer-term

sheltering in place or continuous uninterrupted operations for the duration of the incident. Specific design features and equipment to provide these measures of protection are discussed later in this chapter. A building's particular HVAC security design uses its own unique collection of HVAC security measures, depending on risk and requirements.

2. RISK EVALUATION

In parallel with development of the OPR, a risk evaluation should be conducted for the building and its planned design. FEMA and other industry organizations have developed various guidance documents and software to assess the risk and appropriate response from both external and internal events. Significant detail regarding risk management for catastrophic events is included in ASHRAE *Guideline 29-2009*.

Risk is a function of the **probability** of an event occurring and the **consequence** of this event. For HVAC security and EHS planning, the probability of a catastrophic event occurring is typically nearly zero. This probability is shaped by multiple factors, including the facility's occupants, its location, and nearby objects that may pose a threat. The consequence of an event, however, is usually considered extremely high. Factors to be considered include potential loss of life, failure of critical infrastructure, and remediation time and effort.

Figure 1 presents a generalized framework for managing building security risks. The key considerations for a risk analysis include the following:

- **Vulnerabilities:** what elements of the building design, construction, location, or operations present opportunities for catastrophic events?
- **Acceptable vulnerabilities:** what identified vulnerabilities cannot or should not be addressed, and thus must be accepted as operational risks?
- **Impact:** what are the consequences of an adverse event, including remediation, reconstruction, and lost business, and how does this compare to the cost of implementing HVAC security measures?
- **Constraints:** what limitations exist that would shape the HVAC security design of a building?

Successful risk evaluation should include a review of all facets of the planned building design and operations to determine the risk. This evaluation may include the following areas of assessment:

Fig. 1 Risk Management Framework
(Adapted from ASHRAE *Guideline 29-2009*)

Building and occupants

- Identification of potential high-value targets
- Identification of specific vulnerabilities
- Classification of occupants and operations
- Assessment of benefits of containment versus evacuation

Potential threats and vulnerabilities

- Identification of potential aggressors
- Identification of potential delivery systems

Likely support mechanisms

- Identification of likely first-responder units
- Identification of infrastructural support

Postevent remediation

- Consideration for potential consequences if building is unoccupied or unusable for extended periods
- Estimation of relative magnitude of remediation measures

Examples of considerations that may increase the overall risk assessment of the facility include the following:

- Potential effect of building remaining unoccupied for extended periods
- Military and government command centers
- Significant landmarks
- Critical infrastructure elements
- Single-failure point operations or equipment
- Corporate headquarters or critical operations centers
- Transportation hubs
- Communications nodes
- Popular tourist destinations
- Approach and takeoff areas for major airports
- Sites open to the public
- Sites frequently targeted by protests and demonstrations
- Locations near significant potential hazards such as nuclear power plants or chemical manufacturing facilities
- Locations adjacent to major shipping and transportation routes where external events may affect building occupants (e.g., truck fire, ruptured tanker car on train)
- Sites frequently subjected to severe natural or weather events, such as tornados, hurricanes, or earthquakes

Obviously, this list is not exhaustive, and many buildings may have unique circumstances or characteristics that warrant specialized HVAC security measures. Generally, it is difficult or impossible to completely mitigate against all risks; thus, the overall goal of a risk evaluation and implementation of security measures is to move subsequent evaluated risks to lower levels. That is, if a building’s overall risk is assessed as high, measures should be implemented such that subsequent risk assessments for the same building would be medium or low.

3. HVAC SYSTEM SECURITY AND ENVIRONMENTAL HEALTH AND SAFETY DESIGN

Building design and operations during a CBRE event should leverage strongly from the OPR and risk evaluation documents. This section presents generalized recommendations and practices for HVAC system security design, and detailed information on specific threats is provided in subsequent sections. The basis of design (BOD) document should include an HVAC security and EHS segment that highlights the mechanical system design intent as it pertains to the OPR and risk evaluation.

Fig. 2 HVAC Security and Environmental Health and Safety Basis of Design Segment

Figure 2 presents a generalized basis of design HVAC security and EHS section, which can be enhanced on a project-by-project basis.

3.1 MODES OF OPERATION

Three main modes of operation can be considered in HVAC security design: evacuation, sheltering in place, and uninterrupted. Each mode presents unique challenges, costs, and benefits, and each should be reviewed and compared to the risk assessment and OPR to determine which best meets the building owner’s needs.

Evacuation

Evacuation is the immediate, rapid, and controlled egress of occupants from a facility in the event of an emergency. This mode is commonly used in fire protection engineering. Planning and design for evacuation includes measures to prevent catastrophic failure of the facility for a short duration, and egress direction support, including emergency lighting, signage, and doors.

This mode is effective in many cases and generally is the easiest to implement. However, this mode may not be effective against external threats where personnel may evacuate directly into the path of a threat, and can present difficulty for triage and containment. Typically, minimal cost and design efforts are required to implement an evacuation during an event, because most buildings are required to include similar measures and equipment for fire protection. Also, typically limited or no additional training is required for building occupants, most of whom are familiar with normal evacuation procedures.

Shelter-in-Place

This is short-duration occupancy of a facility or section thereof to avoid immediate threats. This mode requires occupants to remain in the building during the event and seal the building against intake or

further dissemination of threats until the immediate danger has passed. Although some facilities provide full-building shelter-in-place coverage, many designate discrete rooms or areas for occupants to remain in. The normal expected duration is on the order of several hours or less.

Sheltering in place is an effective protective measure when implemented properly and quickly after identification of a threat. Many government and military facilities implement some level of sheltering in place. Effective application requires immediate identification of a threat and subsequent shutdown of HVAC systems to prevent the spread of contamination in the building. Additionally, designated shelter-in-place locations may include some food and water supply for occupant consumption during an event, as well as means of communication with emergency responder personnel. Generally during a shelter-in-place event, occupants do not continue normal work because of the anxiety of the event and the potential requirement for occupants to move into a common area (e.g., conference room, break room) without normal work equipment. Because durations are typically expected to be several hours or less, no bedding is required, and the relative population density can be high. Implementation of a shelter-in-place strategy requires early coordination and training of building occupants to avoid confusion during an event.

Uninterrupted Operation

Uninterrupted operation is the continuous occupancy and use of a building, or some portions therein, during an event without contamination of personnel and equipment. This mode allows for occupants to continue doing work without evacuating or sheltering in place. Although some buildings may complete this mode by providing personal protective equipment to occupants, many have installed collective protection systems in the building HVAC systems, including advanced filtration, airflow balancing, controls, and architectural modifications. Collective protection is achieved by filtering all incoming air to a building and providing this air at an overpressure to spaces, thus creating a protective zone where personnel can continue to operate during an event.

This mode can be extremely effective against both internal and external threats, depending upon configuration and design. Typically, buildings can operate in these modes for hours or days, depending upon the threat; however, with this extended duration, bedding, food, and water, along with lower population densities, should be considered. The relative cost (both capital and sustainment) for this mode can be extremely high, so it is generally used only for critical facilities such as command centers and vital infrastructure elements.

3.2 SECURITY AND EHS DESIGN MEASURES

Multiple measures can be implemented to provide HVAC security and protections, some of which are discussed in this section. It is important to consider that these measures are typically combined with other design elements to enhance building protection, and that not all measures may be applicable to all buildings or locations. The BOD is the documentation of design criteria, set points, parameters, and narrative that outlines the HVAC system security. Again, because of the nature of the security OPR, BOD documentation may not be published. BOD considerations may include some or all of the following measures.

Emergency Power

HVAC systems that are designed to respond to a CBRE incident by continuing to operate should be powered from an emergency electrical power distribution system. Some considerations may include redundant external feed from two sources, generator sets, and/or uninterruptible power supplies (UPS). Any of these options may require significant first cost as well as maintenance and sustainment

costs. In designing emergency power for the HVAC system, carefully consider the location of emergency generator(s) and associated switchgear and motor control center so that they are well above flood water levels. Other considerations are to ensure electrical power is provided to the building automation system (BAS) so that the HVAC security system functions with the building automation computer under emergency power.

Redundant Design

Similar to power loss, failure of a critical component can place overall building HVAC security in jeopardy. Building designers should consider including redundant equipment in systems, such as air-handling units, blowers, or motors. Robust systems should include automatic control of these components, thus allowing for switchover from a failed component to the back-up immediately and automatically. If redundant systems cannot be installed, the owner should consider stocking critical or hard-to-find components in the facility so failed components can be replaced quickly in case of a failure.

System Shutdown and/or Isolation

Rapid shutdown and/or isolation of air-handling units, including outside air intakes, can prevent or limit intake of contaminants into the air distribution system and thus decrease the potential spread of these agents. Many facilities use digital controls networks that readily allow the addition of a shutoff actuator button. For manual initiation, these buttons should be located in one or more areas regularly accessible by building occupants or normally staffed locations (e.g., security guard stations, central lobbies, reception desks) and treated in a manner similar to fire alarm activation stations. Automatic initiation methods using external detectors may be used, but the rate of false positives and negatives, capabilities of existing detection technology, and overall reaction time should be considered. On activation, the system should initiate rapid closure of air distribution dampers and rampdown of equipment to prevent movement of air through areas of the building. In these cases, consider using a spring-shut damper, although precautions such as bypass or relief duct systems should be taken in case of potential system damage by these closures.

Protective Equipment

Many facilities have begun to distribute **personal protective equipment (PPE)** to facility occupants. This equipment, including escape hoods and respirators, may be issued to building staff as well as being placed in centrally available locations for occupant and visitor use. Equipment is generally intended for single-time use to allow occupants to safely evacuate the building during an event. Several manufacturers can provide this equipment, with varying levels of protection, shelf life, and recertification requirements. The designer should consider the overall burden to the building when providing PPE to occupants, including capital costs, training, shelf life, and life-cycle costs for the equipment.

100% Outdoor Air Operation

Normal air-handling systems using returns present an issue for internal release scenarios, because these returns can carry contaminants from the release point in the zone and redistribute throughout the HVAC systems, possibly contaminating the entire building. Designing air-handling systems that use 100% outdoor air is a good alternative to prevent this type of distribution, and limits the spread of contaminants in a space. Although 100% outdoor air systems can present a significant cost and energy burden, this may be offset by the added capability for occupant protection. Typically, this approach is suitable for small buildings or sections of a building. Alternatively, the designer may consider using local terminal units with integrated fans to provide local recirculation and meet space

heating or cooling demands, thus reducing the outdoor air required to each unit.

HVAC Zoning

Using multiple HVAC zones in a building allows localized control of the air movement equipment, and can limit the transport mechanisms for contaminant spread. Each zone, especially when enclosed with walls or partitions, can contain airborne contaminants without widespread movement to adjacent spaces. HVAC zoning can provide occupants with enhanced control over the systems in their spaces and can also help limit the spread of airborne diseases such as influenza.

Increased Standoff Distances

Close proximity to publicly accessible areas increases the risk of an external event having catastrophic consequences for a facility. The presence of a buffer with controlled or limited access can significantly lessen the effect of an airborne contaminant release or blast. This standoff area must have limited access to the general public and should limit vehicular traffic to emergency access, deliveries, and facility maintenance. Increased standoff distances also provide additional area for emergency first responders during or after an event. Although these buffer areas present an additional cost associated with capital investment, they also provide occupants with aesthetic benefits, including additional green space.

Occupant Notification Systems

The moments immediately before, during, and after an event can be confusing for building staff and occupants, especially if some occupants panic and do not fully understand what actions should be taken. Most buildings include some type of notification system that can be used to communicate to occupants in critical situations. Systems include loudspeakers, alarm horns and strobes, automated telephone alerts, or computer notification systems; at minimum, many buildings can implement mass e-mail notification or designation of certain personnel to serve as runners with little or no cost. Building managers may consider providing emergency action information cards for all occupants to keep in their work spaces, to refer to during an emergency.

Air Intake Protection

For new buildings and HVAC systems, fresh-air intakes should be elevated to help prevent malicious acts (e.g., inserting a hazardous material directly into the intake) and minimize the concentration of hazardous materials during a ground-level release. Intakes should be placed at the highest practical level on the building, at least 10 ft above grade. Most ground-level releases near the building will remain close to ground level, and the concentration of hazardous material in the air decreases with increasing height. Existing fresh-air intakes close to ground level can be modified to prevent physical tampering by placing fencing or barriers or building a plenum around the intake to limit potential intake of contaminants. Physical access to system intakes should be limited, and security cameras focused on intake areas may be considered. To prevent direct tampering of intakes, a sloped screen should be installed at the top of the intake to prevent direct insertion of any hazardous substance or container.

Increased Prefiltration Efficiency

A relatively simple and cost-effective protective measure that can be undertaken in most every facility is upgrading existing pre-filters to a higher-efficiency model. An increase in prefiltration efficiency can prevent the intake of a significant fraction of external airborne material, including biological and radiological particles; a related benefit includes the reduction of airborne allergens entering a building, thus resulting in a potential decrease in worker health

issues and absenteeism. Typically, increased efficiency pre-filters present a relatively minimal cost increase as compared to standard pre-filters, and require no system modifications or additional maintenance.

Additional Filtration

As with increased prefiltration, adding additional filtration can reduce or eliminate airborne threats entering a building. Multiple options and levels of efficiency are available, ranging from cost-efficient low-efficiency models to military-grade filtration. Full-time filtration provides occupants with protection without the requirement for advance notification; however, part-time or standby systems can be effective if advance warning or detection is available. The current standard used in multiple government, military, and private-sector buildings includes high-efficiency air filtration (HEPA) filters for biological and radiological threats, and activated and impregnated carbon filters for chemical threats. These filtration measures present significant capital and sustainment costs, which may make these systems unaffordable for lower-cost, noncritical buildings.

Location of Mechanical Equipment

When designers develop plans for building mechanical systems, one of the main considerations is system accessibility for regular maintenance and replacement. However, in some cases, the placement of mechanical systems may present security risks. Mechanical and electrical rooms should be placed in secure areas of the building that are not accessible to the general building population, and should be located away from any potential hazards such as flood areas, hazardous materials storage, loading docks, central lobbies, and areas that may be vulnerable to vehicle impact. Where possible, mechanical spaces should be accessible by maintenance personnel from within the facility to allow repair during an event.

Physical Security Measures

Many physical security measures can be applied to HVAC systems and overall building protection that may prevent the release of a hazardous material or contaminant. Security screening at entry points can help detect containers that may contain hazardous materials. This screening may include x-ray scanning, metal detectors, or manual searching of personal belongings such as briefcases and handbags. Rooftop access should be restricted to authorized personnel, because mechanical equipment, exhaust stacks, and ducting may allow introduction of contaminants. Rooftop entries and exits should be monitored and controlled by the building security system.

Air Supply Quantities and Pressure Gradients

Many contaminant releases depend on air movement to move contaminants throughout the building. This transport can be influenced by small differential pressures between spaces, often less than 0.10 in. of water. These gradients may be effectively used to limit the spread of airborne contaminants between offices, corridors, and common areas. HVAC designers may consider providing a small excess of air to selected areas to effectively overpressurize these spaces with respect to adjacent spaces. This is of particular importance in systems where the HVAC system includes filtration equipment, allowing the protected space to be maintained at an overpressure with clean filtered air.

Sensors

Detection and early warning of a threat are extremely important to building protection. With rapid notification, building staff can implement measures to protect against the threat, including initiating sheltering in place or evacuation. However, implementing a robust detection system can pose many challenges. Technology is being developed in both the government/military and commercial

sectors, but these new devices still have limitations. Currently, although many products exist for point and standoff detection, some of these methods still place a significant burden on the building staff, such as laboratory-scale analysis for confirmation and specially trained personnel. In all cases, designers should consider the sustainment cost and relative frequency of false positives/negatives when specifying detection equipment.

Mailroom and Lobby Measures

The mailroom and central lobbies of buildings are highly vulnerable areas: they act as building interfaces with the general public. In most buildings, these are areas where uncleared personnel or packages come in proximate contact with the facility and where threats can cause the greatest harm. These areas should be given special consideration and additional protective measures to ensure all threats are minimized.

In entry areas, many buildings have mandatory security access procedures for regular building occupants as well as visitors. Security measures such as magnetometers, x-ray scanners, and personnel screening may be used to limit potential hazards from entering the building. Designers should consider using segregated HVAC systems in lobby areas with dedicated air-handling units (AHUs) for the lobby area, and maintaining the lobby spaces at a negative differential pressure with respect to interior spaces. Lobby windows and doors should include blast-resistant glazing and construction, and walls between the lobby and general building interior may include enhanced blast resistance ratings. Security or reception personnel should have controls in their work areas to allow rapid lockdown of all building entries and exits.

The anthrax mailings of 2001 highlighted the vulnerability of buildings to attack by mailborne threats. The U.S. Postal Service and package delivery companies have since implemented enhanced security, but building owners may consider additional measures. Mailrooms and package-receiving areas should include the measures described for lobbies, especially segregated HVAC systems that maintain these areas at a negative pressure compared to the rest of the building. Some facilities have enhanced mail- and package-screening procedures, including separate mail-handling facilities, x-ray or metal detection scans, individual parcel opening and screening, and laboratory analysis of packages. At minimum, mailroom staff should review incoming mail and immediately notify law enforcement of any suspicious letters and packages, such as those with exposed wires, irregular shapes or weights, mis-addressed labels, or unexpected senders or locations.

3.3 COMMISSIONING AND RECOMMISSIONING

To ensure equipment and system performance per the BOD, HVAC security and EHS should be commissioned following ASHRAE *Guideline* 29's recommendations. Recommissioning after a set number of years, or designing the BAS to provide continuous commissioning, is also recommended.

3.4 MAINTENANCE MANAGEMENT

Because of the nature of HVAC security, operation is a critical requirement as it pertains to reliability and repeatability. Similar to how emergency generators are operated once a week, once a month, and fully loaded annually, HVAC security systems need to be operated on a scheduled basis to ensure the equipment will respond in an emergency situation. Operation of the building automation system is an integral part of this routine exercising of the HVAC systems.

Proactive maintenance management also contributes to system performance and reliability. Modern facilities most likely have computerized maintenance management software (CMMS) system to manage the maintenance process and documentation of this process. It is important to emphasize the value of documentation

management; the design engineer should account for this in the design phase, specifying in the operation and maintenance requirements that the CMMS system will be populated and the work orders formatted and ready to be used before project closeout. These requirements should complement the CMMS database criteria so that project closeout documents are electronic and compatible with the CMMS system. Predictive maintenance should also be incorporated into the engineered systems in sync with the continuous commissioning design, operation, and reporting.

4. CHEMICAL INCIDENTS

A chemical incident is defined as the accidental or intentional release of a gaseous or vaporous compound into breathable air. Releases of toxic liquids, solids, or powders are not addressed in this chapter. A release may occur inside or outside a building, and may be of short duration (e.g., from a broken container, an accidental valve opening, or a terrorist incident) or sustained (e.g., from a leaking storage tank or broken supply line). Descriptions of classes of and individual air contaminants, including chemicals, are found in Chapter 11 of the 2013 *ASHRAE Handbook—Fundamentals*, and removal techniques are covered in Chapter 30 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* and Chapter 46 of this volume. Discussions in this chapter are limited to chemicals that are considered acutely toxic or corrosive, and present immediate danger to building occupants or systems.

Industrial buildings, where harmful chemicals may be used routinely, are likely at higher risk for internal chemical incidents than a typical commercial building, but, because of training, established procedures, and experienced personnel, they are also likely to be more prepared to handle an incident. Most commercial buildings, except for some government and high-profile buildings, do not have procedures in place for handling a chemical incident. A terrorist chemical event in a typical commercial building adds new difficulties, because details of the release are not known until long after the incident, and affected buildings and occupants are generally caught off guard, with little or no procedure in place for handling the event.

Chemical substances that can cause physical distress when introduced into breathable air are numerous; this chapter addresses only gaseous or vaporous compounds, and of those, addresses only two groups (1) those specifically known as chemical agents (in terms of warfare/terrorist activities) that might be intentionally introduced into a building's environment, and (2) a few common industrial gaseous substances that might accidentally be introduced into a building HVAC system through external or internal release, thus requiring HVAC or facility remediation of some kind. The purpose of this section is to address buildings that have no expectation of an accidental chemical release, based on the activities performed within the facility, as opposed to those of surrounding, related facilities (e.g., industrial facilities that have their own response plans). For control of airborne gases and vapors that are used as part of the building's normal operation, such as in laboratories or industrial processes, see Chapter 30 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* and any of the application-specific chapters in this volume.

4.1 TYPES OF CHEMICAL AGENTS

Intentional contamination of facilities and their HVAC systems (and thus very ready dispersion to occupants) with gaseous or vaporous chemical substances has become a real concern. Chemical agents are classified by the U.S. Army (2005) either as toxic or incapacitating. Toxic chemical agents include nerve, blister, lung-damaging, and blood agents. Any of these agents may be introduced in sufficient quantity so as to injure building occupants and, in the

process, compromise the building's HVAC system. Irritating agents (e.g., tear gas), which cause temporary trauma through reflexive action but are not generally lethal, are not considered by the U.S. military to be chemical agents.

Incapacitating Agents

Incapacitating agents are defined by the U.S. DOD as chemical agents that produce temporary physiological or mental effects, or both, that make individuals unable to make a concerted effort to perform their assigned duties. In occupational medicine, *incapacitation* generally means *disability*, and denotes the inability to perform a task because of a quantifiable physical or mental impairment. Thus, by definition, any of the chemical warfare agents may incapacitate a victim; however, by the military definition, incapacitation refers to impairments that are temporary and nonlethal, and does not include low-dose "lethal" agents. Incapacitating agents may cause symptoms that persist for hours to days, but are temporary and recoverable even without treatment. Incapacitating agents can be classified as either central nervous system (CNS) depressants or stimulants.

CNS depressants are compounds that depress or block activity of the CNS by inhibiting the transfer of information across synapses. Common CNS depressants include

- 3-quinuclidinyl benzilate (BZ)
- Cannabinols
- Phenothiazines
- Fentanyl
- Hypnotics

CNS stimulants cause excessive nervous activity by facilitating transmission of impulses across certain synapses that may otherwise be insufficient pathways. The brain becomes flooded with information, making concentration and decision making difficult. The most common CNS stimulant is d-lysergic acid diethyl amide (LSD).

Symptoms of poisoning by these agents include confusion, disorientation, restlessness, dizziness, staggering, or vomiting. Some may cause dryness of mouth, elevated temperature, pupil dilation, slurred/nonsensical speech, inappropriate behavior, and hallucinations. If several personnel exhibit any such behavior, it is prudent to move outside the building, because these agents are usually delivered by smoke-producing munitions or aerosols and are introduced through the respiratory system.

Irritants

Irritants can be classified as either tear-producing or vomiting-producing agents. The sole purpose of irritants, which include tear gas, riot control agents, and lachrimators, is to produce immediate discomfort and eye closure, thus rendering the victim incapable of fighting or resisting. Irritants cause eye discomfort, and some may cause vomiting; all are usually introduced to an environment as a gas. Police forces use irritants for crowd control. Irritants were used before World War I, and, during the war, they were the first chemical agents used, well before better-known agents such as chlorine, phosgene, and mustard gas.

Tear gas (CS) and chloroacetophenone (CN; sold in diluted form as a protective spray) are by far the most important pulmonary irritants. Capsaicin (methyl vanillyl nonenamide) is the active ingredient in pepper spray, also called OC (oleoresin capsicum). Pepper spray has, to some extent, replaced CN as a personal protective agent, with less dangerous effects. As its common name implies, the active ingredient is the burning agent in pepper plant fruits.

Although CS and CN are the most important agents in this class, several others require mention. Chloropicrin (PS) and bromobenzene cyanide (CA) were developed before World War I. Both largely have been replaced, because they were too lethal for their intended

effects but not lethal enough to compete with the more effective blistering and nerve agents. PS still is used occasionally as a soil sterilant or grain disinfectant.

Toxic Chemical Agents

Nerve Agents. Nerve agents are organophosphate ester derivatives of phosphoric acid, and are among the deadliest of rapid-onset chemical agents. Nerve agents can be divided into G and V agents. **G agents** are fluorine- or cyanide-containing organophosphates. These agents are colorless and have an odor that ranges from weakly "fruity" to odorless. In an unmodified state, G agents are highly volatile, resulting in low persistency. However, they can be combined with various thickening substances, increasing persistency and penetration of intact skin. The primary hazard of G agents is vapor contact because of their high volatilities.

V agents are sulfur-containing organophosphates. These agents are low-volatile oily liquids, resulting in increased persistency. The increased persistency makes V agents primarily a contact hazard.

Common nerve agents include

- VX
- Tabun (GA)
- Sarin (GB)
- Soman (GD)
- Cyclosarin (GF)

Both G and V agents are potent inhibitors of the enzyme acetylcholinesterase (AChE) and present the same symptoms after exposure. Inhibiting AChE allows acetylcholine to accumulate, which mimics a massive release of acetylcholine in the nervous system. Nerve agents may be absorbed through any body surface (skin, eyes, respiratory) or ingested. Symptoms of nerve agent poisoning include

- Sweating and/or muscular twitching
- Pupil contraction, eye pain, or blurred vision
- Headache, pain
- Weakness
- Nausea, vomiting (particularly in ingestion)
- Mucous secretions in respiratory pathways, nose, or throat
- Wheezing, coughing
- Severe exposure: convulsions; vomiting; red, pinpoint eyes; unconsciousness; or respiratory failure

Mild exposure to nerve agents may cause anxiety, restlessness, and giddiness. Further exposure results in the listed symptoms and/or memory impairment, slowed reactions, or difficulty in concentration. Moderate exposure, if diagnosed and monitored, shows abnormalities in electroencephalograms (EEGs) as well as the symptoms listed. Reactions to nerve agents are immediate (i.e., within minutes of exposure). Recovery from nerve agent exposure is slow, usually days, and susceptibility to the agent is increased for months afterward.

Nerve agents are liquid at room temperature, but their volatilities can vary. Highly volatile agents (G agents) can be easily introduced as vapors into HVAC systems, whereas low-volatility agents (V and thickened G agents) can be introduced as droplets or vapors by mechanical means. Highly volatile agents are less persistent and require less intense cleanup than naturally persistent, highly volatile agents, which require intense cleanup if introduced into a building. For the most part, these agents are moderately soluble in water and highly soluble in lipids. They are rapidly inactivated by strong alkalis and chlorinating compounds, which are used in the decontamination/neutralization of these agents.

If nerve agents are suspected, evacuate the facility immediately. Because many nerve agents are (or can be made) persistent and dose is accumulative, evacuation is necessary. A facility must be decontaminated if exposed to nerve agents.

Blister Agents. Blister agents (vesicants) can be classified as mustards, arsenicals, and urticants. These agents are generally used as warfare agents meant to degrade fighting efficiency rather than to kill. They are usually thickened to make them persistent and contaminate surfaces, but may be introduced as a gas or vapor. Vesicants result in burns and blisters to the skin, eyes, and/or respiratory tract.

Mustard agents contain either sulfur or nitrogen and are persistent in cold and temperate conditions. They can be combined with other substances to thicken the agent, increasing their persistency. Warmer temperatures decrease persistency, but concentrations in air can be high because of the greater evaporation rate. Common mustard agents include

- Sulfur mustard (H and HD)
- Nitrogen mustards (HN)

Arsenical agents contain a central arsenic atom. These agents hydrolyze rapidly with water and lose most of their vesicant properties. Arsenicals are more volatile than mustards and are less toxic than other blister agents. Common arsenical agents include

- Lewisite (L)
- Mustard-lewisite (HL)
- Phenyldichloroarsine (PD)

Urticants are halogenated oximes and have a disagreeable, penetrating odor. The most recognized urticant is phosgene oxime (CX), which is one of the most irritating substances known.

The most likely routes of exposure are inhalation, dermal contact, and ocular contact. Depending on the particular vesicant, clinical effects may occur immediately (as with phosgene oxime or lewisite) or may be delayed for 2 to 24 h (as with mustards). Blister agents must be cleaned from the skin and membranes immediately to lessen their effects. Persons exposed to blister agents must be handled so as not to contaminate those helping them. Evacuation is necessary, and contaminated people should be kept outdoors to prevent accumulation of the vesicant in a confined space. Effects of exposure include

- Mild to severe conjunctivitis, possibly progressing to ulceration
- Lesions on skin; burns
- Itching
- Pain (immediate with exposure to lewisite)
- Respiratory damage (in small doses may take time to appear as bronchitis, etc.)

Vesicants are, for the most part, soluble in nonaqueous solvents, not in water. They are more dangerous as liquids, because the degree to which they cause health problems is related to their concentration on body surfaces. In general, they have high vapor pressures and thus are easily vaporized in a confined space. Decontamination of exposed surfaces is needed.

Lung-Damaging Agents. Lung-damaging (choking) agents are those that primarily attack lung tissue, causing pulmonary edema. Examples include

- Phosgene (CG)
- Diphosgene (DP)
- Chlorine
- Chloropicrin (PS)

As choking agents, most of these agents (except for diphosgene) exist as gases at room temperature and pressure, and are thus easily spread through ventilation systems. Exposure symptoms include

- Choking sensations, coughing
- Tightness in chest
- Nausea, vomiting
- Headache

Because these agents are gaseous, they will disperse. They all have specific odors; for example, CG smells like fresh-mown hay. Thorough ventilation of contaminated areas is necessary. Choking agent gases typically are heavier than air, and thus tend to accumulate in low-lying areas.

Blood Agents. Blood agents, also known as cyanogens, interfere with the absorption and use of oxygen at the cellular level, and thus are usually introduced through the respiratory system. Examples include hydrogen cyanide (AC) and cyanogen chloride (CK). These agents are highly volatile and gaseous at temperatures over 70°F and are nonpersistent even at low temperatures. They therefore dissipate quickly in air, especially hydrogen cyanide, which is light; cyanogen chloride is heavier than air and tends to collect in low places. These two blood agents have different symptoms. Symptoms of exposure to AC include

- Faint odor of almonds
- Internal hemorrhaging
- Pink skin color
- Highly toxic, high concentrations can cause immediate death

CK symptoms include

- Intense irritation to the lungs and eyes
- Coughing
- Tightness in chest
- Dizziness
- Unconsciousness
- Respiratory failure

Because these agents are not persistent, thorough ventilation should dissipate the gases.

Other HVAC-Compromising Gases and Vapors

Accidental contamination of facility HVAC systems by gaseous or vaporous chemical substances has been a real concern for years, mainly because of the extensive production, use, and transport of large quantities of hazardous materials for manufacturing purposes. Intentional contamination of a facility could be accomplished with chemicals other than the specific chemical agents discussed previously. Contamination inside a building should result in immediate evacuation. However, external contamination might entail evacuation to a more distant location or shelter in place (i.e., not evacuating). Contamination from an incident in the immediate vicinity of (but external to) a facility might require shutdown of the facility's HVAC system for a short period of time. For instance, a large corrosive spill nearby might necessitate staying in a building for protection while transportation is arranged (if not available immediately). This might occur at a school where children would be more susceptible to injury upon exiting the building, having no way to evacuate a safe distance. Because the situations and possibilities are so varied, this discussion is limited to more typical scenarios.

Toxic Gases. The most common toxic gas that might threaten a facility and its personnel is carbon monoxide (CO), which is colorless, odorless, and tasteless. Carbon monoxide is produced by incomplete combustion of fossil fuels (gas, oil, coal, wood) used in boilers, engines, oil burners, gas fires, water heaters, solid-fuel appliances, and open fires. Dangerous amounts of CO can accumulate when, as a result of poor installation, poor maintenance, or failure, an appliance's fuel is not burned properly, or when rooms are poorly ventilated and the carbon monoxide is unable to escape. Because CO has no smell, taste, or color, it is important to have good ventilation, maintain all appliances regularly, and have reliable detector alarms installed to give both a visual and audible warning in case of a dangerous build-up of CO. Scenarios involving toxic gases usually entail evacuation to a safe distance. HVAC systems normally require cleaning using clean purge air through the ventilation distribution system.

Table 1 Corrosive Gases and Vapors

Corrosive Gases	Corrosive Acidic Vapors	Corrosive Basic Vapors
Hydrogen cyanide	Hydrochloric acid	Sodium hydroxide
Ammonia	Sulfuric acid	Ammonium hydroxide
Sulfur dioxide	Nitric acid	Caustic soda
Chlorine	Hydrofluoric acid	Potassium hydroxide
Hydrogen bromide	Acetic acid	Other hydroxides
Boron trichloride	Other acids	
Monomethylamine		
Phosphorus pentafluoride		

Corrosive Substances. Corrosive gases and vapors encompass a large class of materials. A few are purely gaseous in nature at room conditions, but some vapors result from the vapor pressure created by a liquid (or solid) presence. Some examples of corrosive gases and vapors are given in Table 1.

Corrosive gases and vapors are hazardous to all parts of the body, although some organs (e.g., eyes, respiratory tract) are particularly sensitive. The magnitude of the effect is related to the solubility of the material in body fluids. Highly soluble gases (e.g., ammonia, hydrogen chloride) cause severe nose and throat irritation, whereas lower-solubility substances (e.g., nitrogen dioxide, phosgene, sulfur dioxide) can penetrate deep into the lungs. Exposed skin may also be at risk for irritation or burns at higher concentrations or longer-term exposures. For some substances, warnings such as odor or eye, nose, or respiratory tract irritation may be inadequate. Accidents involving corrosive substances inside or outside a building require cleanup and decontamination of the facility’s HVAC system and other equipment, because of the substances’ persistence. In some cases, physical damage to a building’s infrastructure may result from exposure to corrosives (e.g., etching of metal surfaces, which can lead to holes in ducting and compromised wiring). Building codes outline methods of design and installation for mechanical and electrical systems in corrosive environments (NFPA 2005), but in buildings that are not classified as such, and thus are not constructed accordingly, systems may be damaged when exposed to corrosive chemicals. In such a case, the building and its systems should be thoroughly inspected and tested before reoccupation.

5. BIOLOGICAL INCIDENTS

Biological incidents involve the intentional or accidental release of unwanted bioaerosols and/or biocontaminants in or around a building, such that the building’s integrity or usefulness is compromised. Bioaerosols are airborne particulates derived from living organisms and include living microorganisms, viruses, spores, and toxins derived from remnants or fragments of living tissue. Bioaerosols are in the air, both indoors and outdoors, and their presence mostly goes unnoticed except for seasonal allergies or an occasional cold. There is an evolved balance between the types and levels of bioaerosols in the ambient air and the animals who breathe that air. That balance can be disturbed locally by the purposeful or accidental release of a bioaerosol in or around a building. Unfortunately, bioaerosols are difficult to detect and identify in real time, because identification generally involves DNA analysis or other skilled analytical techniques. As a consequence, bioaerosols may be fully distributed in a building hours or days before anything is detected, much less identified, and the first sign of an incident may be symptoms of personnel.

There are hundreds of known bioaerosols that are pathogenic to humans to varying degrees. These include the spore-forming bacteria *Bacillus anthracis* (commonly known as anthrax), *Variola* spp. (the virus that causes smallpox), the bacteria *Yersinia pestis* (cause

Table 2 Limited List of Human Pathogenic Microorganisms

Bioaerosol	Incubation Period, Days	ID ₅₀ , Organisms	LD ₅₀ , Organisms
<i>Bacillus anthracis</i> (anthrax)	2 to 3	10,000	28,000
<i>Ebolavirus</i> spp. (Ebola)	14 to 21	10	Low
<i>Francisella tularensis</i> (tularemia)	1 to 14	10	Low
<i>Hantavirus</i> (Hanta)	14 to 30	N/A	N/A
<i>Variola</i> spp. (smallpox)	12	N/A	N/A
<i>Yersinia pestis</i> (bubonic plague)	2 to 6	N/A	N/A

of bubonic plague), and many others. Human susceptibility varies by microorganism, and is gaged by several dose measures:

- **ID₅₀, mean infectious dose**, is the number of microorganisms or bioaerosol particles that causes 50% of an exposed population to be infected.
- **LD₅₀, mean lethal dose**, is the number of microorganisms or bioaerosol particles that causes death in 50% of an exposed population.

One of the greatest threats in a biological incident or attack is toxins, which are poisonous chemicals produced by living organisms and that may have effects resembling those of chemical agents. Toxicity and lethality of toxins vary, but highly toxic, stable toxins pose a risk for weaponization. Two classifications of potentially threatening toxins are neuro- and cytotoxins. **Neurotoxins** interfere with nerve impulse transmission and have significant effects on the nervous system. However, they can work in different manners, inhibiting or stimulating various enzymes and blocking various receptors. Effects are similar to those of chemical nerve agents, and include convulsions or paralysis, blurred vision, seizures, and muscle fatigue. **Cytotoxins** disrupt or destroy cells and cellular processes such as protein synthesis and other biochemical process. Symptoms may be similar to those of chemical blister, choking, and vomiting agents, as well as nausea, diarrhea, rashes, inflammation, and necrosis. Toxins can be produced by a variety of organisms such as bacteria, fungi, mold, algae, plants, and animals.

A summary of potential bioaerosol weapon agents is given in Table 2 along with ID₅₀ and LD₅₀ values. A more comprehensive list can be found in Kowalski (2003). More detailed descriptions of bioaerosols, their health effects, and methods of measurement can be found in most epidemiology texts. *Bioaerosols: Assessment and Control*, from the American Conference of Governmental Industrial Hygienists (ACGIH 1999), is a recommended starting point for quantitative determination of bioaerosol levels. General information on bioaerosols, their health effects, and their removal from building airstreams is found in Chapters 10 and 11 of the 2013 *ASHRAE Handbook—Fundamentals*, as well as Chapter 29 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*.

The primary threat to buildings from airborne biological incidents is adverse health effects to building occupants. Once an event happens, there is an immediate danger to building occupants from the initial dose, but there is also the risk of prolonged exposure from contaminated surfaces and reaerosolization of the agent. Depending on the agent, the prolonged exposure risk may dissipate quickly if the pathogenic organism has a short life outside a host, or it may remain indefinitely until the contaminating agent is fully removed. Anthrax, which is a spore-forming bacterium, falls into this latter category because it can lie dormant in many environments for long periods of time, only to come out of dormancy when exposed to a proper host. Excluding incidents of extreme mold growth [which is not covered in this chapter; see, e.g., ASHRAE (2003b) for information], biological incidents present no real threat

to the integrity of building equipment; however, building equipment may play an important role in both distribution and possible removal of air contaminants. Remediation after an incident is likely to involve comprehensive cleaning of building equipment (particularly air-handling equipment), and may require removal and replacement of contaminated systems. Techniques for remediating contaminated equipment include surface cleaning with bleach or alcohol solutions, treatment with ultraviolet (UV) light, and volume gaseous treatments with ozone, hydrogen peroxide, or gas plasma. New technologies and procedures are under development, particularly since the anthrax events of 2001 in the United States. See the Bibliography and Online Resources for sources of information on the latest developments in remediation technology.

It is important to determine as much as possible about a release, whether purposeful or accidental, as rapidly as possible. It may be more difficult to completely assess the nature of a purposeful release, because it may contain more than one pathogenic agent, with different incubation periods, and the release may have taken place in several locations. Accidental releases are more likely to be a single pathogen at a single location, and the release is more likely to have been known to occur.

Biological pathogens have been weaponized to enable delivery in a variety of forms. Effective delivery of bioagents to a large population is difficult because of the need to get relatively large doses to large numbers of people. Dilution of contaminants in ambient air is rapid, and very large numbers of organisms are required to produce lethal concentrations. The confines of a building and controlled air exchanges rates can help maintain concentrations of agents for longer periods of time than would occur in outdoor air. However, filtration and real-time killing mechanisms in building air-handling systems can remove or render ineffective airborne bioaerosols. Engineering requirements for design of filtration or other techniques for treating indoor air are addressed more fully in other publications [e.g., NIOSH (2003)]. Information is rapidly evolving; for the latest, consult the most recent versions of publications on building protection.

6. RADIOLOGICAL INCIDENTS

The occurrence of a significant accidental or intentional radiological release to the environment is of low probability because there are limited locations where considerable amounts of radiological material reside. These sources include spent fuel or low-level radioactive waste (radwaste) storage facilities, nuclear generating stations, and weapons fabrication and storage facilities. These facilities are usually analyzed beforehand, as part of the construction licensing process, for postulated accidental releases of radiological material and the consequences to both on- and off-site personnel.

An intentional release of radiological material is most likely to be in the form of the deployment of a nuclear weapon or a **radiological dispersal device (RDD)**, sometimes called a **dirty bomb**. It is normally assumed that a terrorist group is highly unlikely to possess and use conventional, sophisticated nuclear weapons because of the difficulties of obtaining or independently developing the necessary materials and technology. Development and deployment of an RDD, however, is considered viable because of its simplicity of design. RDDs combine conventional explosives and radioactive material, and are designed to scatter dangerous amounts of radioactive material over a general area. Terrorist use of RDDs also seems more likely because radiological materials used in medicine, agriculture, industry, and research are comparatively more obtainable than weapons-grade uranium or plutonium. A significant amount of the damage from an RDD would be from the initial blast. See the section on Explosive Incidents for design of HVAC system protection against blast effects.

6.1 RADIOACTIVE MATERIALS' EFFECTS AND SOURCES

Decay of radioactive materials produces energetic emissions (ionizing radiation) that can effect changes in human tissue cells. These energetic emissions are divided into **alpha** particles, **beta** particles, and **gamma/x-rays**. Alpha and beta radiation can only travel very short distances (several feet, maximum) and do not have enough energy to penetrate the outer layers of human skin; they are, however, a hazard if directly inhaled or ingested. Gamma and x-rays can travel long distances in air and can pass through the body, potentially exposing internal organs to significant damage, depending on the amount absorbed. The radiation effect on humans is usually measured in röntgen equivalent man (rem), the product of the absorbed dose and the biological efficiency of the radiation.

In developing an RDD, a significant quantity of radioactive material must first be collected. Some common radioactive materials currently used in industry include

- Cobalt-60 (Co-60), cesium-137 (Cs-137), and iridium-192 (Ir-192) are used in cancer therapy, industrial radiography and gages, food irradiation, oil well production, and medical implants. These are all considered gamma emitters.
- Strontium-90 (Sr-90) is used in the production of radioisotope thermoelectric generators (RTGs), which produce electricity for remote devices such as spacecraft. This is considered a beta emitter.
- Plutonium-238 (Pu-238) and americium-241 (Am-241) are used in oil well production, RTGs, and industrial gauges. These are considered alpha emitters.

6.2 RADIOLOGICAL DISPERSION

Dispersion may be by conventional explosives, using aircraft to disperse the material in the form of an aerosol or particulate, or simply placing a container of radioactive material within a confined area or facility. In most cases, a dirty bomb or other RDD would have localized effects (based on the strength of material used) ranging from less than a city block to several square miles. The area affected by the dispersion of the material is a function of various factors, including

- Meteorological conditions, including atmospheric stability and wind speed
- Local topography, location of buildings, and other landscape characteristics
- Amount and type of radioactive material dispersed
- Dispersal mechanism (e.g., particulate, aerosol)
- Physical and chemical form of the radioactive material (e.g., dispersal as fine particles versus heavier droplets or particulate)

Radioactive material released as either an aerosol or fine particulate in a plume spreads roughly at the speed and direction of the prevailing wind velocity. The conditions of atmospheric stability (sometimes referred to in terms of the Pasquill stability classification) also determine the fallout's overall spread and concentration. Atmospheric dispersion computer models are sometimes used to predict the spread, location, and concentration of a postulated radioactive plume. These analytical tools can be useful in providing early warning to residences and facilities projected to be in the affected fallout path.

6.3 RADIATION MONITORING

Radioactivity cannot be seen, smelled, or tasted by humans. However, in the United States, there are many radiation-monitoring programs available at the federal, state, and local level that can measure radiation levels and/or track the released radiation plume. There may be a local facility (e.g., a nuclear power plant) that can

track radiological fallout in the affected area. State-level officials have access to various monitoring programs for their areas. These programs use current weather patterns and wind velocities to track radiological plumes and provide public warning. Depending on the severity of the release, the radioactive plume may travel several hundred miles or, more typically, be localized.

6.4 FACILITY RESPONSE

Physical safety of personnel should be of primary concern in responding to a radiological event. Time, distance, and shielding are the three most important aspects to minimizing the effects of human exposure to ionizing radiation. Shielding with stone, concrete, or other dense materials is usually not considered in the initial design of most commercial buildings. However, most facilities use these materials for structural strength (foundations and basements) or for fire protection in protective corridors and stairways. Consider developing procedures to instruct building occupants to immediately move to identified safe locations in the facility in the event of a known or suspected release. Limiting the time of exposure to a radiation field also helps reduce the total amount of exposure and subsequent health effects. Distance from the radiation source is the greatest factor in reducing the amount of direct (deep-dose) exposure, especially if the hazard is present for a considerable time period. The distance required to minimize this dose is usually small (several feet).

Perhaps the greatest potential hazard from the release of low-level radiological debris from an RDD is inhalation or ingestion. Health effects from ingested contamination particles that enter the body from breathing, cuts/abrasions, eating, or drinking can be more severe than external exposure, depending on the amount of material consumed. Individuals should be instructed to move to more isolated rooms, or areas in the facility that may be isolated or filtered from significant inleakage of contaminated air. Distribution of personal protection equipment (PPE) should also be considered, depending on the risk assessment of a potential threat. If the release is determined to be internal, an organized evacuation should occur (consider developing evacuation procedures). Because evacuees may have become externally contaminated, an egress plan should be considered that includes a radiation detection monitoring procedure implemented either by internal personnel or by local emergency authorities. This procedure may include instruction to dispose of outer clothing and the use of showers to remove radioactive particles from body surfaces.

7. EXPLOSIVE INCIDENTS

Detonation of high explosives near a building generates pressures that act on all exposed surfaces. The magnitude of pressure depends on the size and shape of the charge, distance from the charge, and any intervening barriers. In addition to increased pressures, blasts may generate projectiles from either loose materials or fragments from damaged components. This section considers only loads that do not generate significant structural damage; it is assumed that, if the structure is severely damaged, continued operation of the HVAC systems is not crucial. Also, it is important to remember that life safety is the primary goal of all protective systems. This section deals strictly with HVAC equipment and systems, but any solutions must not compromise the safety of building occupants.

7.1 LOADING DESCRIPTION

Detonation of high explosives generates a pressure wave (blast wave) that propagates out from the explosion with decreasing velocity. The free-field blast wave, far from any surfaces, is characterized by a rapid, almost instantaneous increase in pressure, followed by a gradual decay in pressure and a negative-pressure phase. A typical

Fig. 3 Free-Field and Reflected Pressure Wave Pulses

free-field blast overpressure P_{so} , reaching the target at time t_A , is shown in Figure 3. When the blast wave impinges on a rigid surface, the pressure is reflected (P_r) and magnified over the free-field values. Peak pressure varies inversely with the cube of the distance from the explosion. Intervening barriers may reduce the blast load, but quantifying the effect is difficult, and great care must be taken when determining the resulting loads.

Internal explosions can generate extremely large loads on HVAC equipment. In addition to short-duration reflected pressures generated by the explosion, a quasi-static pressure may develop, greatly increasing the impulse to which the equipment is exposed. The magnitude and duration of quasi-static loading is a function of room volume and vented area.

In addition to direct air blast, HVAC equipment in buildings subjected to explosions can experience large accelerations and relative displacements caused by the resulting structure motion. The structure responds to loads imposed both through the foundation (ground shock) and from the air blast (air shock). In general, accurately predicting the time history of motion in the building is extremely difficult. However, because structural design of equipment is based on peak loads, there is usually no need to determine the full time history. Methods are available for predicting the peak motion caused by a given event, including the frequency dependence of the response.

Blast loads can also enter the interior space of buildings through utility openings, even if the building shell is undamaged. The blast can damage the passageway itself, and can also build up pressure in the building and subsequently damage other equipment. Pressure build-up depends upon the opening area and volume of interior space, as well as the pressure differential.

Explosions can produce primary and secondary fragments that may damage equipment and piping. Primary fragments are generated from the explosive casing, whereas secondary fragments result from damage to the structure and nonstructural components (e.g., concrete spalling, glass breakage). Predictions of fragment size and velocity can be used to estimate damage to equipment, ducts, and piping.

7.2 DESIGN CONSIDERATIONS

The best protection from any explosive effects is to locate equipment in a nonvulnerable area. Assuming the exterior building shell is adequately designed, any interior room may be considered protected. Barrier walls can protect equipment that must be externally located, or equipment can be positioned far enough away from any possible blast location that pressures are reduced below damaging levels. In general, correctly locating equipment is the least expensive option

for handling blast loads. Hardening equipment, anchorage, and connection should be considered only after relocation has been eliminated as a possibility.

In addition to the direct air blast, equipment in a building subject to a blast experiences a support shock loading. Guidelines for the maximum shock that can be withstood by various equipment types are given in Chapter 55. Although general information can be obtained from these tables, it is important to realize that the data are several decades old and may not apply to modern HVAC equipment. If the shock is greater than the equipment's capacity, it may be possible to provide a shock isolation system to lower the demand. The isolation system works by decoupling horizontal motion of the support structure from that of the equipment. Note that this is different from typical equipment isolation applications, which are generally concerned with vertical vibrations of the equipment itself.

Although it has been stated that proper seismic design also protects against blast loads, this is not generally true. The effect of blast loading on equipment has some similarities to that of seismic loads, but there are some key differences. Both loads generate horizontal and vertical forces that act on equipment. However, in both magnitude and distribution, seismic forces are proportional to equipment mass, whereas blast loads are proportional to the equipment surface area. The effect is essentially the same for some types of equipment, such as pumps, where the mass and surface area distributions are approximately identical. However, equipment covered by a sheet metal shell is loaded very differently. Seismic loads are applied directly to the heavy components in the shell, whereas blast loads are applied to the shell itself, with little or no load acting directly on the interior components. Thus, even equipment that has been seismically rated or certified needs additional investigation for blast resistance.

In contrast, anchorage design is identical for blast and seismic loads. Properly designed seismic anchorage for most equipment in moderate to high seismic zones is adequate for reasonable levels of blast loading. In either case, loads applied to equipment are used to determine shear and uplift loads on the anchorage that are checked against the allowable load for the specific attachment hardware. Although in reality the dynamic reactions from the resulting equipment motion are the actual anchorage force, for nonisolated equipment it is usually conservative to assume a static distribution of the maximum applied loads. This is not always the case for isolated equipment, because resonance of the load, equipment, and isolation system may produce dynamic forces well above those predicted from a static analysis.

When designing HVAC systems for blast load, it is important to remember that there are two types of failure. The first is a temporary loss of service, such as might be caused by tripping a breaker. The second, more serious case involves actual damage to the equipment or system. It is important to determine which scenario is important for the system, and design accordingly. Preventing temporary outages is, in general, much more expensive than preventing a catastrophic failure.

Exposed piping and ductwork are also subject to both pressure and fragment loading. Pressure loading can be carried through proper selection and spacing of supports. The flexure and shear capacities of the pipe or duct, and the capacity of the support, determine the spacing. Fragment effects are more difficult to analyze, because the exact size and velocity of any fragments are impossible to predict. The only way to fully protect against fragments is to locate the pipe or duct where fragment impact is not possible.

Openings in the building for HVAC or other purposes must also be designed for blast effects. HVAC systems can be damaged by pressure propagated through the opening or blockage of the opening. Grilles or louvers can be analytically designed to resist the blast load, preventing blockage and allowing continued operation. Additionally, the pressure increase in ducts, and subsequently in interior

rooms, can be calculated. Properly designed silencers may reduce pressure in ducts. Design of openings for blast resistance must also be closely coordinated with protection from chemical and biological agents.

---	---

ULTRAVIOLET germicidal irradiation (UVGI) uses short-wave ultraviolet (UVC) energy to inactivate viral, bacterial, and fungal organisms so they are unable to replicate and potentially cause disease. UVC energy disrupts the deoxyribonucleic acid (DNA) of a wide range of microorganisms, rendering them harmless (Brickner et al. 2003; CIE 2003). Early work established that the most effective UV wavelength range for inactivation of microorganisms was between 220 and 280 nm, with peak effectiveness near 265 nm. The standard source of UVC in commercial systems is low-pressure mercury vapor lamps, which emit mainly near-optimal 253.7 nm UVC. Use of germicidal ultraviolet (UV) lamps and lamp systems to disinfect room air and air streams dates to about 1900 (Reed 2010). Riley (1988) and Shechmeister (1991) wrote extensive reviews of UVC disinfection. Application of UVC is becoming increasingly frequent as concerns about indoor air quality increase. UVC is now used as an engineering control to interrupt the transmission of pathogenic organisms, such as *Mycobacterium tuberculosis* (TB), influenza viruses, mold, and potential bioterrorism agents (Brickner et al. 2003; CDC 2002, 2005; GSA 2010; McDevitt et al. 2008; Rudnick et al. 2009).

UVC lamp devices and systems are placed in air-handling systems and in room settings for the purpose of air and surface disinfection (Figure 1). Control of bioaerosols using UVC can improve indoor air quality (IAQ) and thus enhance occupant health, comfort, and productivity (ASHRAE 2009; Menzies et al. 2003). Detailed descriptions of UVGI components and systems are given in Chapter 17 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*. Upper-air (also commonly called upper-room) devices are installed in occupied spaces to control bioaerosols (suspended viruses, bacteria, and fungi contained in droplet nuclei and other carrier particles) in the space. In-duct systems are installed in air-handling units to control bioaerosols in recirculated air that may be collected from many spaces, and to control microbial growth on cooling coils and other surfaces. Keeping the coils free of biofilm buildup can help reduce pressure drop across the coils and improve heat exchanger efficiency (and therefore the energy required to move and condition the air), and eliminates one potential air contamination source that could degrade indoor air quality. UVC is typically combined with conventional air quality control methods, including dilution ventilation and particulate filtration, to optimize their cost and energy use (Ko et al. 2001).

This chapter discusses these common approaches to the application of UVC products. It also surveys the most recent UVC design guidelines, standards, and practices and discusses energy use and economic considerations that arise when applying UVC systems. Other UV-based HVAC applications, such as photocatalytic oxidation (PCO), are not discussed in this chapter.

The preparation of this chapter is assigned to TC 2.9, Ultraviolet Air and Surface Treatment.

1. FUNDAMENTALS

Ultraviolet energy is electromagnetic radiation with a wavelength shorter than that of visible light and longer than x-rays (Figure 2). The International Commission on Illumination (CIE 2003) defines the UV portion of the electromagnetic spectrum as radiation having wavelengths between 100 and 400 nm. The UV spectrum is further divided into UVA (wavelengths of 400 to 315 nm), UVB (315 to 280 nm), UVC (280 to 200 nm), and vacuum UV (VUV; 200 to 100) (IESNA 2000). The optimal wavelength for inactivating microorganisms is 265 nm (Figure 3), and the germicidal effect decreases rapidly if the wavelength is not optimal.

UV Dose and Microbial Response

This section is based on Martin et al. (2008).

UVGI inactivates microorganisms by damaging the structure of nucleic acids and proteins at the molecular level, making them incapable of reproducing. The most important of these is DNA, which is responsible for cell replication (Harm 1980). The nucleotide bases (pyrimidine derivatives thymine and cytosine, and purine derivatives guanine and adenine) absorb most of the UV energy responsible for cell inactivation (Diffey 1991; Setlow 1966). Absorbed UV photons can damage DNA in a variety of ways, but the most significant damage event is the creation of pyrimidine dimers, where two adjacent thymine or cytosine bases bond with each other, instead of across the double helix as usual (Diffey 1991). In general, the DNA molecule with pyrimidine dimers is unable to function properly, resulting in the organism's inability to replicate or even its death (Diffey 1991; Miller et al. 1999; Setlow 1997; Setlow and Setlow 1962). An organism that cannot reproduce is no longer capable of causing disease.

UVGI effectiveness depends primarily on the UV dose (D_{UV} , $\mu\text{J}/\text{cm}^2$) delivered to the microorganisms:

$$D_{UV} = It \tag{1}$$

where I is the average irradiance in $\mu\text{W}/\text{cm}^2$, and t is the exposure time in seconds (note that $1 \text{ J} = 1 \text{ W/s}$). Although Equation (1) appears quite simple, its application can be complex (e.g., when calculating the dose received by a microorganism following a tortuous path through a device with spatial variability in irradiance). The dose is generally interpreted as that occurring on a single pass through the device or system. Although the effect of repeated UV exposure on microorganisms entrained in recirculated air may be cumulative, this effect has not been quantified and it is conservative to neglect it.

The survival fraction S of a microbial population exposed to UVC energy is an exponential function of dose:

$$S = e^{-kD_{UV}} \tag{2}$$

where k is a species-dependent inactivation rate constant, in $\text{cm}^2/\mu\text{J}$. The resulting single-pass inactivation rate η is the complement of S :

$$\eta = 1 - S \tag{3}$$

Fig. 1 Potential Applications of UVC to Control Microorganisms in Air and on Surfaces
(ASHRAE 2009)

and is a commonly used indicator of overall UVC effectiveness, representing the percentage of the microbial population inactivated after one pass through the irradiance field(s).

Inactivation rate constants (k -values) are species-dependent and relate the susceptibility of a given microorganism population to UV radiation (Hollaender 1943; Jensen 1964; Sharp 1939, 1940). Measured k -values for many species of viruses, bacteria, and fungi have been published in the scientific literature and previously summarized (Brickner et al. 2003; Kowalski 2009; Philips 2006). As shown in Figure 4, bacteria are generally more susceptible to UVC energy than fungi, but this is not always the case (see Chapter 17 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*). It is more difficult to generalize when it comes to viruses. Reported k -values for different species of microorganisms vary over several orders of magnitude. Consequently, choosing which k -value to use

for UVC system design is often difficult and confusing. The variation in reported k -values makes generalizing the use of Equation (2) particularly complicated for heterogeneous microbial populations. Even accurately determining S for one specific microorganism can be difficult, because the reported k -values for the same species sometimes differ significantly.

Variations in published k -values may relate to differences in conditions under which the UV irradiance of the microbial population was conducted (in air, in water, or on surfaces), the methods used to measure the irradiance level, and errors related to the microbiological culture-based measurements of microbial survival (Martin et al. 2008). Because no standard methods are currently available for the determination of inactivation rate constants, care is necessary when applying values reported in the literature to applications under different environmental conditions.

Fig. 2 Electromagnetic Spectrum (IESNA 2000)

Fig. 3 Standardized Germicidal Response Functions

Fig. 4 General Ranking of Susceptibility to UVC Inactivation of Microorganisms by Group

UV Inactivation of Biological Contaminants

The focus of this chapter is application of UVC energy to inactivate microorganisms, specifically bacteria, fungi, and viruses on surfaces and in air streams. The application of UVC for upper-air treatment generally applies to pathogenic bacteria and viruses. Under some circumstances, these pathogens have the potential to be transmitted throughout the HVAC system.

As shown in Table 1, infectious diseases can be transmitted by a variety of means. UVC is effective against microorganisms in the air that flows through the UVC irradiation field and on irradiated surfaces.

As shown in Table 2 and Figure 4, viruses and vegetative bacteria are the generally most susceptible to UV inactivation, followed by Mycobacteria, bacterial spores, and finally fungal spores. Within each group, an individual species may be significantly more resistant or susceptible, so this ranking should be used only as a general guideline. Note that the spore-forming bacteria and fungi also have vegetative forms, which are markedly more susceptible to

inactivation than are the spore forms. Viruses are a separate case. As a group, their susceptibility to inactivation is even broader than for the bacteria or fungi.

2. TERMINOLOGY

Just as it is customary to express the size of aerosols in micrometers and electrical equipment’s power consumption in watts, regardless of the prevailing unit system, it is also customary to express total UVC output, UVC irradiance and fluence, and UVC dose using SI units.

Multiply I-P	By	To Obtain SI
Btu/ft ² (International Table)	1135.65	μJ/cm ²
Btu/h·ft ²	315.46	μW/cm ²
To Obtain I-P	By	Divide SI

Burn-in time. Period of time that UV lamps are powered on before being put into service, typically 100 h.

Table 1 Modes of Disease Transmission

Exposure	Examples
Direct contact with an infected individual	Touching, kissing, sexual contact, contact with oral secretions, or contact with open body lesions Usually occurs between members of the same household/close friends/family
Indirect contact with a contaminated surface (fomite)	Doorknobs, handrails, furniture, washroom surfaces, dishes, keyboards, pens, phones, office supplies, children's toys
Droplet contact	Infected droplets contact surfaces of eye, nose, or mouth Droplets containing microorganisms generated when an infected person coughs, sneezes, or talks Droplets are too large to be airborne for long periods of time, and quickly settle out of air
Airborne droplet nuclei (residue from evaporated droplets) or other particles containing microorganisms $\sim \leq 5 \mu\text{m}$	Size allows them to remain airborne for long periods of time Organisms generally hardy (capable of surviving for long periods of time outside the body, resistant to drying) Organisms enter the upper and lower respiratory tracts
Fecal-oral	Usually associated with organisms that infect the digestive system Microorganisms enter via ingestion of contaminated food/water and shed in feces Lack of proper hygienic and sanitation practices
Vectorborne	Transmission through animals Bite, feces of a vector, contact with outside surface of a vector (e.g., a fly)

Table 2 Representative Members of Organism Groups

Organism Group	Member of Group
Vegetative Bacteria	<i>Staphylococcus aureus</i>
	<i>Streptococcus pyogenes</i>
	<i>Escherichia coli</i>
	<i>Pseudomonas aeruginosa</i>
	<i>Serratia marcescens</i>
Mycobacteria	<i>Mycobacterium tuberculosis</i>
	<i>Mycobacterium bovis</i>
	<i>Mycobacterium leprae</i>
Bacterial Spore	<i>Bacillus anthracis</i>
	<i>Bacillus cereus</i>
	<i>Bacillus subtilis</i>
Fungal Spores	<i>Aspergillus versicolor</i>
	<i>Penicillium chrysogenum</i>
	<i>Stachybotrys chartarum</i>
Viruses	Influenza viruses
	Measles
	SARS
	Smallpox

Cutaneous damage. Any damage to the skin, particularly that caused by exposure to UVC energy.

Disinfection. Compared to sterilization, a less lethal process of inactivating microorganisms.

Droplet nuclei. Residual viable microorganisms in air, following evaporation of surrounding moisture. These microscopic particles are produced when an infected person coughs, sneezes, shouts, or sings. The particles can remain suspended for prolonged periods and can be carried on normal air currents in a room and beyond to adjacent spaces or areas receiving exhaust air.

Erythema (actinic). Reddening of the skin, with or without inflammation, caused by the actinic effect of solar radiation or artificial optical radiation. See CIE (1987) for details. (Nonactinic erythema can be caused by various chemical or physical agents.)

Exposure. Being subjected to infectious agents, irradiation, particulates, or chemicals that could have harmful effects.

Fluence. Radiant flux passing from all directions through a unit area, often expressed as J/m^2 , J/cm^2 , or $(\mu\text{W}\cdot\text{s})/\text{cm}^2$.

Irradiance. Power of electromagnetic radiation incident on a surface per unit surface area, typically reported in microwatts per square centimeter ($\mu\text{W}/\text{cm}^2$). See CIE (1987) for details.

Mycobacterium tuberculosis. The namesake member of the *M. tuberculosis* complex of microorganisms, and the most common cause of tuberculosis (TB) in humans. In some instances, the species name refers to the entire *M. tuberculosis* complex, which includes *M. bovis*, *M. africanum*, *M. microti*, *M. canettii*, *M. caprae*, *M. pinnipeditii*, and others.

Ocular damage. Any damage to the eye, particularly that caused by exposure to UV energy.

Permissible exposure time (PET). Calculated time period that humans, with unprotected eyes and skin, can be exposed to a given level of UV irradiance without exceeding the NIOSH recommended exposure limit (REL) or ACGIH Threshold Limit Value® (TLV®) for UV radiation.

Personal protective equipment (PPE). Protective clothing, helmets, goggles, respirators, or other gear designed to protect the wearer from injury from a given hazard, typically used for occupational safety and health purposes.

Photokeratitis. Defined by CIE (1993) as corneal inflammation after overexposure to ultraviolet radiation.

Photokeratoconjunctivitis. Inflammation of cornea and conjunctiva after exposure to UV radiation. Exposure to wavelengths shorter than 320 nm is most effective in causing this condition. The peak of the action spectrum is approximately 270 nm. See CIE (1993) for details. Note that different action spectra have been published for photokeratitis and photoconjunctivitis (CIE 1993); however, the latest studies support the use of a single action spectrum for both ocular effects.

Radiometer. An instrument used to measure radiometric quantities, particularly UV irradiance or fluence.

Threshold Limit Value® (TLV®). An exposure level under which most people can work consistently for 8 h a day, day after day, without adverse effects. Used by the ACGIH to designate degree of exposure to contaminants. TLVs can be expressed as approximate milligrams of particulate per cubic meter of air (mg/m^3). TLVs are listed either for 8 h as a time-weighted average (TWA) or for 15 min as a short-term exposure limit (STEL).

Ultraviolet radiation. Optical radiation with a wavelength shorter than that of visible radiation. [See CIE (1987) for details.] The range between 100 and 400 nm is commonly subdivided into

UVA: 315 to 400 nm
UVB: 280 to 315 nm
UVC: 200 to 280 nm
Vacuum UV 100 to 200 nm

Ultraviolet germicidal irradiation (UVGI). Ultraviolet radiation that inactivates microorganisms. UVC energy is generated by germicidal lamps that kill or inactivate microorganisms by emitting radiation predominantly at a wavelength of 253.7 nm.

UV dose. Product of UV irradiance and specific exposure time on a given microorganism or surface, typically reported in millijoules per square centimeter (mJ/cm^2).

Wavelength. Distance between repeating units of a wave pattern, commonly designated by the Greek letter lambda (λ).

3. UVGI AIR TREATMENT SYSTEMS

Design Guidance

Early guidelines published by General Electric (1950), Philips (1985), and Westinghouse (1982) are still used by many system designers today. First et al. (1999), Kowalski (2003, 2006, 2009), NIOSH (2009), and Riley et al. (1976) made meaningful advances in the analysis and modeling of UVGI systems that improved guidance for system design, yet no consensus guidelines exist that comprehensively address all aspects of UVGI system design required to ensure desired performance.

UVC system design today relies on performance data from lamp, ballast, and fixture manufacturers and the experience of system designers. Many equipment manufacturers have methods for estimating the UV dose delivered, which may include using tabulated data charts, mathematical modeling, and complex formulas. Like most HVAC components, UVC systems are often oversized to ensure performance. This oversizing, though conservative, can potentially increase equipment and utility costs, and may result in less energy-efficient systems.

Although application support for UVC technologies is growing and many successful systems have been installed, “the most important needs in the area of UVGI are industry standards to rate devices and installations, as well as guidance for installation and maintenance” (EPA 2007). ASHRAE Technical Committee 2.9, Ultraviolet Air and Surface Treatment, was created in 2003 (initially as a Task Group, converted to a standing Technical Committee in 2007) in part to address these deficiencies by initiating research programs, preparing Handbook chapters, and serving as the cognizant committee for developing the needed standards. So far, two new ASHRAE standards have been developed that provide end users with ratings of equipment performance and aid UVC system designers in selecting appropriate components:

- *Standard 185.1, Method of Testing UVC Lights for Use in Air Handling Units or Air Ducts to Inactivate Airborne Microorganisms*, establishes a test method for evaluating the efficacy of UVC lights for their ability to inactivate airborne microorganisms installed inside general ventilation systems.
- *Standard 185.2, Method of Testing Ultraviolet Lamps for Use in HVAC&R Units or Air Ducts on Irradiated Surfaces*, establishes a similar test method to measure the intensity of ultraviolet lamps on irradiated surfaces under typical HVAC&R operating conditions.

Work is ongoing to initiate round-robin testing between laboratories that can potentially conduct testing on UVC devices according to these new standards. Such testing will generate critical data on the repeatability of the testing methods and identify issues that must be addressed in updates to the standards.

For any application, the ability of UVC to inactivate microorganisms is a function of dose. **Dose** is the length of time of exposure multiplied by the irradiance measured in $\mu\text{W}/\text{cm}^2$ (see Chapter 17 in the 2012 *ASHRAE Handbook—HVAC Systems and Equipment* for more details). A key difference between surface decontamination and airborne inactivation of organisms is exposure time. In a duct system, exposure time is on the order of seconds or fractions of seconds because of the rapid movement of air through the duct. Therefore, the irradiance must be sufficiently high to provide the dose necessary to inactivate the pathogen in seconds or a fraction of a second, depending upon the configuration and characteristics of the UVC system.

As mentioned previously, organisms differ in their susceptibility to UVC inactivation. Depending on the application, a public health or medical professional, microbiologist, or other individual with knowledge of the threat or organisms of concern should be consulted during the design process.

Upper-Air UVC Devices (Fixtures)

The primary objective of upper-air UVC placement and use is to interrupt the transmission of airborne infectious pathogens within the indoor environment. The source of these infectious organisms may be infected humans, animals, or bioaerosols introduced for terrorism purposes. Humans are the predominant sources of airborne agents that infect people (ACGIH 1999). The measles and influenza viruses and the tuberculosis bacterium are three important infectious organisms known to be transmitted indoors by means of air shared, by any means, between infected and susceptible persons. Studies of person-to-person outbreaks indicate at least two transmission patterns: within-room exposure such as in a congregate space, and transmission beyond a room through corridors and by entrainment in ventilation ductwork, where air is then recirculated throughout the building. ASHRAE provides guidance on protecting buildings from extraordinary incidents in which a bioterror agent is aerosolized into a building (ASHRAE 2003).

UVC is used, in combination with other environmental controls, to protect building occupants in all areas of concern (Brickner et al. 2003; Kowalski and Bahnfleth 2003). Since the 1930s (Riley and O’Grady 1961; Wells 1955) and continuing to the present day (First et al. 2007a, 2007b; Miller et al. 2002; Xu et al. 2003), numerous experimental studies have demonstrated the efficacy of upper-air UVC. Additionally, evidence of effectiveness has been shown for inactivation of tuberculosis (Escombe et al. 2009); in reducing measles transmission in a school, and the interruption of influenza transmission within a hospital (McLean 1961).

Various upper-air UVC devices are designed to generate a controlled UVC field above the heads of occupants and to minimize UVC in the lower, occupied area of the room. Settings appropriate to upper-air UVC placement include congregate spaces, where unknown and potentially infected persons may share the same space with uninfected persons (e.g., a medical waiting room or homeless shelter). Common corridors potentially used by unknown infected persons in a medical facility would also benefit from upper-air UVGI fixtures. Upper-air UVC also covers situations where untreated recirculated air might enter an occupied space (see Figures 5 and 6 for illustrations of upper-air pathogen control using UVC). Upper-air UVC is very effective in areas with no, or minimal ventilation, 2 air changes per hour (ach) equivalency, up to normal recommended levels of 6 ach can be achieved. Ventilation patterns (natural and mechanical) should promote good air mixing in the space equipped with UVC so that infectious microorganisms encounter the UVC zone and are inactivated, thus reducing the risk of exposure of occupants to airborne infectious agents. Recent studies that have used natural ventilation and UVC have shown that upper-air UVC is an effective, low-cost intervention for use in TB infection control (Escombe et al. 2009).

Upper-air UVC devices are designed and installed to irradiate only air in the upper part of the room (Figures 7 and 8). Parameters for UVC effectiveness include room configuration, UV fixture

Fig. 5 Typical Elevation View of Upper-Air UVC Applied in Hospital Patient Room

Fig. 6 Typical Elevation View Showing UVC Placed above Heads of Room Occupants for Safety

Fig. 7 Upper-Air UVC Treating Congregate Setting
(TUSS Project, St. Vincent's Hospital, New York City)

placement, and the adequacy of air currents in bringing contaminated air into the upper UV zone. UVC devices should be placed appropriately spaced to accommodate the area, shape, and height of the space in which air is to be disinfected. Figures 9 to 11 show examples of upper-air fixture placement. An upper-air computer-based tool can calculate the average fluence in the upper room (Rudnick et al. 2012; Vincent et al. 2013; Zhang et al. 2012). Additionally, computational fluid dynamics (CFD) is being used to understand the interaction between airflow and upper-air UVC (Gilkeson and Noakes 2013; Xu et al. 2013; Zhu et al. 2013).

Upper-air UVC devices typically use low-pressure UVC lamps in tubular and compact shapes, and accommodate a variety of electrical wattages and voltages. Beyond lamp size, shape, and ballasts, fixtures are available in open or restricted energy distribution, depending on the physical space to be treated. UVC fixtures are selected based on the floor-to-ceiling height. Ceiling heights above 10 ft may allow for more open fixtures, which may be more efficient because they may allow for a larger irradiation zone. For occupied spaces with lower ceilings (less than 10 ft), various louvered upper-air UVC devices (wall-mount, pendant, and corner-mount) are available for use in combinations, and are mounted at least 7 ft from the floor to the bottom of the fixture. The fixture should be mounted so that its UV energy is distributed parallel to the plane of the ceiling. Device construction and placement prevent excessive ultraviolet energy from striking occupants below. For example, in high-risk

(Centers for Disease Control and Prevention)

Fig. 9 Suggested Layout of UVC Fixtures for Patient Isolation Room
(First et al. 1999)

areas such as corridors of infectious disease wards, a maximum UV irradiation of $0.4 \mu\text{W}/\text{cm}^2$ at eye level is an acceptable engineering guide (Coker et al. 2001). No long-term health effects of UVC exposure at these levels in the lower occupied part of rooms are known. Figure 5 shows a typical elevation and corresponding UV levels, and Figure 6 illustrates typical UVC energy distribution in a room.

Application guidance with placement criteria for UV equipment is provided by Boyce (2003), CDC (2005), CIE (2003), Coker et al. (2001), First et al. (1999), IESNA (2000), and NIOSH (2009). An example of the guidance provided by Coker et al. is shown in Table 3. Additionally, manufacturer-specific advice on product operation and placement should be followed. A new computer-aided lighting software program is being modified to help automate the placement of fixtures, and to calculate the uniformity and average UV provided (Brickner et al. 2009). Upper-air UVC fixtures that are typically used in developed countries are often cost-prohibitive for use in less developed parts of the world. International guidance is needed to

(First et al. 1999)

understand best practice for UVC application in the developing world where extensive drug-resistant TB is an increasing global threat (Nardell et al. 2013).

Some upper-air installations rely on air convection and mixing to move air from the lower to the upper portion of the room, where it can be irradiated and airborne microorganisms inactivated (Kethley and Branc 1972). The overall effectiveness of upper-air UVC systems improves significantly when the air in the space can be well mixed. Although convection air currents created by occupants and equipment can provide adequate air circulation in some settings, mechanical ventilation systems that maximize air mixing are preferable. If mechanical ventilation is not possible, fans can be placed in the room to enhance mixing. Many fixtures incorporate a safety switch that breaks the circuit when fixtures are opened for servicing, and should contain baffles or louvers appropriately positioned to direct UV irradiation to the upper air space. Baffles and louvers must never be bent or deformed.

A UVC installation that produces a maintained, uniform distribution of UV irradiance averaging between 30 and 50 μW/cm² is effective in inactivating most airborne droplet nuclei containing mycobacteria, and is presumably effective against viruses, as well (First et al. 2007a, 2007b; Miller et al. 2002; Xu et al. 2003). Beyond UVC irradiance, effectiveness of upper-air UVC is related to air mixing, relative humidity, and the inherent characteristics of the pathogenic organisms being addressed (Ka et al. 2004; Ko et al. 2000; Rudnick 2007). Effectiveness can improve greatly with well-mixed air (First et al. 2007a, 2007b; Miller et al. 2002; Riley and Permutt 1971; Riley et al. 1971), so ventilation systems that maximize air mixing receive the greatest benefit from upper-air UVC. Relative humidity should be less than 60%; levels over 80% rh may reduce effectiveness (Kujundzic et al. 2007; Xu et al. 2003).

Depending on the disinfection goals, upper-air devices should be operated similarly to in-duct UVC systems. Systems designed to reduce or eliminate the spread of airborne infectious diseases in buildings with continuous occupancy and/or with immunocompromised populations should be operated 24 h per day, 7 days per week. Upper-air systems designed for improved indoor air quality installed in

SPACE USAGE	ROOM DIMENSIONS			UVGI FIXTURE COVERAGE			
	L ft	W ft	H ft	MH ft	A ft ²	V ft ³	(N) WM
CONFERENCE/OPEN OFFICE ROOM	8.9	5.5	2.6	2.2	49	117.4	(3) 8.5 W

Design Concept: Congregate setting, high occupancy, shared air with adjacent auditorium (multipurpose room). Dropped ceiling for an open office plan. Look for long path lengths, evenly space fixtures along one wall.

L = length, W = width, H = floor-to-ceiling height, A = area covered, V = room volume, MH = mounting height above finished floor, N = number of UVGI fixtures, W = nominal wattage, WM = wall mounted, CM = ceiling mounted

more traditional commercial buildings may be operated intermittently, or powered on during hours of normal building occupancy and powered off when the facility is empty. This may provide acceptable indoor air quality during periods of building occupancy while saving energy and requiring less frequent lamp replacements. However, intermittent operation must be factored into the initial system design because cycling UV lamps on and off may negatively affect lamp and ballast performance and life.

In-Duct UVC Systems: Airstream Disinfection

The principal design objective for an in-duct UVC air disinfection system is to distribute UV energy uniformly in all directions throughout the length of the duct or air-handling unit (AHU) to deliver the appropriate UV dose to air moving through the irradiated zone with minimum system power. Enhancing the overall reflectivity of the inside of the air handler can improve UVC system performance by reflecting UVC energy back into the irradiated zone, thus increasing the effective UV dose. Using materials such as aluminum or other highly reflective materials can increase reflectivity. Properly designed in-duct UV air disinfection systems are also able to maintain the cleanliness of cooling coil surfaces and condensate pans, when the UV lamps are installed in close proximity to this equipment. On the other hand, systems designed specifically for coil and condensate pan applications may not be adequate for proper air disinfection.

Design dose is a function of the design-basis microbe (i.e., the targeted microorganism with the smallest k-value) and the desired level of disinfection. Generally, single-pass inactivation efficiencies are specified, analogous to the specification of a particulate filter

MERV rating. In some cases, the design disinfection level may be a true performance specification based on the exposure in an occupied space. Determining this value requires analysis of the entire system that is used to determine the single-pass performance. Which approach is selected depends on the type of application. Laboratory/hospital installations are more likely to have specific, identified targets than, for example, school or office installations. The required average irradiance for a typical in-duct system is on the order of 1000 to 10,000 $\mu\text{W}/\text{cm}^2$, but it could be higher or lower depending on the application requirements.

In-duct air disinfection systems should be designed to have the desired single-pass inactivation level under worst-case conditions of air temperature and velocity in the irradiated zone. The worst-case performance reflects the combined effect of the number/power of UVC fixtures; air residence time, which is inversely proportional to air velocity; and lamp/ballast characteristics, including wind chill effect and depreciation (as discussed in Chapter 17 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*). Lee et al. (2009) showed that it may be advantageous to use simulation to determine the design condition, given the complex interactions between air temperature, velocity, and lamp performance. Lamps may be located anywhere in an air conveyance system; however, some locations provide more efficiency and potentially greater benefit. In most cases, the lowest maximum velocity in a system occurs inside an air-handling unit. For this reason, and also because it provides the ability to treat air from many spaces and simultaneously irradiate cooling coils and condensate pans, this is a very common choice, although systems may also be located in air distribution ducts.

Because they are typically installed in air handling units, most in-duct systems are designed for an air velocity of around 500 ft/min. At this velocity, an irradiance zone 8 ft in length achieves a 1 s exposure. As a rule of thumb, a minimum 0.25 s exposure should be provided; otherwise, system cost and power consumption will be excessive. UVC devices are most often located downstream of the heating/cooling coils. However, in some cases, mounting fixtures upstream of the coil may result in lower in-duct temperatures, resulting in a more optimum lamp performance temperature and more cost-effective disinfection. The trade-off is reducing the effectiveness of disinfection of the cooling coil and forgoing irradiation of the drain pan that lamps mounted downstream of the coil provide.

In-duct air disinfection systems designed to reduce the spread of airborne infectious diseases (e.g., tuberculosis, influenza) in buildings with continuous occupancy and/or with immunocompromised populations (e.g., hospitals, prisons, homeless shelters) should be operated on a continuous basis. However, properly designed systems installed in more traditional commercial buildings (e.g., offices, retail) can be operated intermittently, or powered on during hours of normal building occupancy and powered off when the facility is empty. This may save energy costs and require less frequent lamp replacement while providing acceptable indoor air quality during periods of occupancy. However, the effect of intermittent operation on lamp and ballast life must be factored into the design analysis: cycling reduces the operating hours to failure of hot cathode lamps. In-duct UVC should always be used in combination with proper filtration. Filters may help to protect UV lamps from dust and debris accumulation which may reduce UV output over time, and filters enhance the overall air cleaning capabilities of the system.

Studies of Airstream Disinfection Effectiveness

Laboratory studies [e.g., RTI (2005); VanOsdell and Foadre (2002)] conclusively demonstrate the ability of commercially available equipment to achieve a high level of disinfection of moving airstreams. These studies have generally involved tests with surrogates rather than actual infectious disease agents, but it can be assumed that an infectious agent with a k -value similar to an experimental surrogate will be similarly inactivated. Previous field studies showed

clinical effectiveness (i.e., reduced incidence of infection) (Nagy et al. 1954; Rentschler and Nagy 1940), but similar recent studies are lacking. Although pilot studies have begun (Bierman and Brons 2007; Rudnick et al. 2009), further recorded field studies are needed to benchmark installed system performance. Many UV airstream disinfection systems have been installed in hospital environments to help reduce pathogens by complementing conventional dilution/filtration systems.

4. HVAC SYSTEM SURFACE TREATMENT

Coil and Drain Pan Irradiation

Conditions in HVAC systems can promote the growth of bacteria and mold-containing biofilms on damp or wet surfaces such as cooling coils, drain pans (Levetin et al. 2001), plenum walls, humidifiers, fans, energy recovery wheels, and filters. Locations in and downstream of the cooling coil section are particularly susceptible because of condensation and carryover of moisture from coil fins. Cooling coil fouling by biofilms may increase coil pressure drop, and reduce airflow and heat exchange efficiency (Montgomery and Baker 2006). Filters capture bacteria, mold, and dust, which may lead to microbial growth in damp filter media. As the growth proliferates, a filter's resistance to airflow can increase. This can result in more frequent filter changeouts and increased exposure to microbes for maintenance workers and building occupants. As airflow and coil performance degrades, so does the air quality in occupied spaces (Kowalski 2006).

Conventional methods for maintaining air-handling system components include chemical and mechanical cleaning, which can be costly, difficult to perform, and dangerous to maintenance staff and building occupants. Vapors from cleaning agents can contribute to poor air quality, chemical runoff contributes to groundwater contamination, and mechanical cleaning can reduce component life. Furthermore, system performance can begin to degrade again shortly after cleaning as microbial growth reappears or reactivates.

UVC can be applied to HVAC systems to complement conventional system maintenance procedures. A large dose can be delivered to a stationary surface with a low UVC irradiance because of the essentially infinite exposure time, making it relatively easy to cost-effectively prevent the growth of bacteria and mold on system components. In contrast to air disinfection irradiance levels, which may exceed 1000 $\mu\text{W}/\text{cm}^2$, coil surface irradiance levels on the order of 1 $\mu\text{W}/\text{cm}^2$ can be effective (Kowalski 2009), although 50 to 100 $\mu\text{W}/\text{cm}^2$ is more typical. Using reflectors to focus lamp output on surfaces may reduce the power required for surface treatment, but at the expense of reducing air treatment effectiveness. Potential advantages of UVC surface treatment include keeping surfaces clean continuously rather than periodically restoring fouled surfaces, no use of chemicals, lower maintenance cost, and potentially better HVAC system performance.

Lamps can be installed to target problematic components such as cooling coils, condensate pans, or filters (Figure 12), or applied to give broad distribution of UVC energy over an entire enclosure (e.g., mixing box/plenum) that might have microbial activity. Like in-duct air-treatment equipment, systems for surface treatment in air-handling units should be designed to withstand moisture and condensate and selected to operate over a full range of system operating conditions.

Alternative and Complementary Systems

ASHRAE (2014) identifies the following demonstrated ways of reducing airborne infectious disease transmission:

- UVC
- Dilution, personalized, and source capture ventilation
- In-room airflow control

Fig. 12 Section View of Typical HVAC Surface Treatment Installations

- Room pressure differentials
- Filtration

From one perspective, these may be viewed as distinct, mutually exclusive alternatives for bioaerosol control. In principle, ventilation alone, filtration alone, or UVC alone can yield the same level of control of a given contaminant source. However, in most cases, multiple modes of air quality control are used in the same system, often as a result of code requirements. For example, air quality codes for commercial buildings based on ASHRAE *Standard* 62.1 minimally require both dilution ventilation and particulate filtration at prescribed levels.

When used in combination with other mandatory air treatment modes, UVC provides an incremental benefit. For example, if a particulate filter removes 85% of a given agent in an incoming airstream and a UVC system with a single-pass efficiency of 85% for the same contaminant is installed in series with it, the combined filter/UVC system would have a combined single-pass capture and inactivation efficiency of approximately 98% (i.e., the incremental benefit of adding an 85% efficient device is only 13%). Situations involving ventilation, filtration, and UVC can be evaluated quantitatively by analyzing the entire system.

An example of this type of analysis was given by Nazaroff and Wechsler (2009) for several common arrangements of air cleaners in combination with ventilation. The performance of an air cleaner added to a system with ventilation is defined in terms of an effectiveness ϵ , which is the difference in contaminant concentration in a space of interest caused by adding an air cleaner and the concentration that would exist without the air cleaner:

$$\epsilon = \frac{C_{\text{baseline}} - C_{\text{control}}}{C_{\text{baseline}}} \quad (4)$$

where C_{baseline} is the concentration without the air cleaner and C_{control} is the concentration after addition of the air cleaner. This performance measure would show, for example, that adding UVC to a system with a low ventilation rate would have a higher effectiveness (i.e., greater impact) than adding the same device to the same system with a higher ventilation rate. The extension of this concept to multiple-space systems and multiple air cleaners and air cleaner types is straightforward. System designers can use such methods to obtain more accurate cost/benefit estimates and also to optimize the characteristics and placement of air cleaners.

Even in the absence of the constraints imposed by building codes, the system designer should consider the potential benefits of combining air treatment methods. For example, the cost of particulate

filters and their negative impact on fan energy use increase in inverse relation to the sizes of particles to be controlled (i.e., filters for smaller particles tend to be more expensive and have higher pressure drop than filters for larger particles). On the other hand, many larger microorganisms that may be resistant to UVC, such as some fungal spores, can be captured effectively by filters of moderately high efficiency and cost (Kowalski 2009). In addition, using UVC to suppress microbial growth on filters that capture but do not kill is a potential complementary use of these two technologies. Ultimately, the decision to use or not use one of the available, effective microbial control methods should be based on a complete analysis that considers overall performance goals for air quality, impact on energy use, and economic factors. Such an analysis is illustrated for a typical air disinfection system by Lee et al. (2009), as discussed in the following section.

5. ENERGY AND ECONOMIC CONSIDERATIONS

The major costs of owning and operating a UVC system include initial equipment and installation costs, maintenance costs (primarily lamp replacement), and energy cost (direct cost of lamp operation plus impact on heating and cooling energy consumption). For a given system, these costs are relatively straightforward to estimate. The benefits of a UVC system are not so easily quantified. Energy use is of concern in its own right, but it is also the major operating cost component of most systems and considerations of energy conservation measures inevitably lead to the issue of cost effectiveness. Therefore, it is appropriate to discuss energy use in conjunction with its economic impact.

Air treatment systems and room surface disinfection systems have the objective of improving the safety, health, and productivity of building occupants through reduced incidence of infectious disease and sick building complaints. Although many studies exist to support claims of UVC's effectiveness in these applications, it is difficult to express the resulting benefits in economic terms. A conservative approach to economic evaluation is to compare the costs of alternative approaches such as dilution ventilation and particulate filtration that have the same effectiveness.

When alternative systems are compared with UVC, all associated costs must be carefully estimated. Increased ventilation adds to heating- and cooling-coil loads and may also affect fan energy use. Particle filtration systems have their own associated installation and maintenance costs, and may significantly increase air-side pressure drop and, therefore, fan energy consumption.

Cooling-coil treatment systems have the two-fold objectives of maintaining coil performance and minimizing energy use by reducing air-side flow resistance and increasing the overall heat transfer coefficient relative to a conventionally maintained, mechanically and chemically cleaned coil. As in the case of air disinfection systems, the costs to install and operate such systems are easily estimated, but although there are many reports of significant improvement in performance, there is little peer-reviewed literature documenting its effectiveness.

Upper-Air UVC Devices

The effectiveness of upper-air UVC performance has often been described in terms of equivalent air changes per hour (ach): that is, by the rate of outside airflow measured in room volumes per hour that would achieve the same reduction of microbial air contamination in a well-mixed space. Riley et al.'s (1976) study of UVGI efficacy found that one 17 W UVC lamp covering 200 ft² produced 10 equivalent ach versus a natural die-off of 2 ach when a surrogate for tuberculosis was released in the room. The UVC lamp took less than 20 min to inactivate the bioaerosol versus over 30 minutes for a natural die-off. In a bioaerosol room study, McDevitt et al. (2008) showed seasonal variations of between 20 to 1000 equivalent ach for

a surrogate for smallpox. Ko et al. (2001) modeled the cost of using three air-cleansing strategies to control transmission of tuberculosis in a medical waiting room. They calculated a present value per avoided tuberculin skin test conversion (evidence of infection) of \$1708 for increased ventilation, \$420 for HEPA filtration, and \$133 for upper-air UVC: that is, UVC was less expensive by a factor of 3 to 13. Another metric is cost to provide a typical level of treatment per unit of floor area. The estimated health care benefit, typical of such analyses, was much larger than the cost: roughly \$40/ft² per year.

In-Duct Air Disinfection

Bahnfleth et al. (2009) and Lee et al. (2009) used simulation to investigate the energy use and operating cost of in-duct UVC air treatment applied upstream or downstream of the cooling coil in a cooling-only variable-air-volume system located in New York and compared it with equivalent added particulate filter. A representative MERV 12 filter was estimated to provide the same performance as UVC designed for 85% single-pass inactivation under design conditions. They computed not only the costs associated with the alternatives considered, but also estimated the health benefit using a method based on the Wells-Riley equation as applied by Fisk et al. (2005). They found that locating the UVC system upstream of the cooling coil in the normally warmer mixed-air section of the air-handling unit reduced its required size by roughly 50% relative to a downstream location using typical in-duct lamp characteristics. Annual energy cost at an average electric rate of \$0.10/kW·h (\$0.03/1000 Btu) was approximately \$0.02/ft² for the downstream location and \$0.01/ft² for the upstream location, whereas the additional MERV 12 filter cost \$0.10/ft². Annualized life-cycle cost, including installation and maintenance, was \$0.74/ft² for the downstream location, \$0.38/ft² for the upstream location, and \$1.79/ft² for MERV 12 filtration. The drawback to the more economically advantageous upstream UVC location is that it is considered a less favorable location for cooling coil irradiation, which many air treatment systems are designed to do as a benefit of increased airflow and heat exchange efficiency and reduced coil cleaning.

Upper-Air Versus In-Duct

Economic factors clearly favor an upper-air fixturing when the building being treated with UVC has no air distribution system. When a recirculating central air distribution system is present, a choice becomes possible between upper-air devices, which must be distributed throughout occupied spaces, and in-duct systems, which can be centralized. As noted in the preceding discussion of in-duct systems, an annual operating cost of \$0.01 to 0.02/ft² is possible at an electric rate of \$0.10/kW·h (\$0.03/1000 Btu). The same study (Lee et al. 2009) estimated an installed cost for equipment of \$0.13 to 0.25/ft². By comparison, a typical upper-air system might cost more than \$2/ft² to install and more than \$0.10/ft² to operate, based on typical sizing procedures and current equipment costs. This comparison seems to strongly favor in-duct systems where they are applicable, but is based on an assumption of equal performance that may not be valid. In a health care setting, controlling transmission of airborne pathogens at their source would suggest an upper-room approach. However, where possible, a whole-building approach to UV should be considered where feasible.

Cooling Coil Surface Treatment

Cooling coil surface treatment is done as an alternative to periodic mechanical and chemical cleaning of coils. By suppressing the formation of biofilms and mold growth on coils, coil irradiation should reduce air-side pressure drop, increase heat transfer coefficient, and reduce both fan and refrigeration system energy consumption. Several studies have documented the ability of coil irradiation to reduce microbial growth (Levetin et al. 2001; Shaughnessy et al. 1998). No

peer-reviewed studies have yet been published to document the effect of coil irradiation on energy consumption, but there are many strong anecdotal reports of its effectiveness. As noted previously, the U.S. General Services Administration has sufficient confidence in this application to include it in its mechanical requirements (GSA 2010).

6. ROOM SURFACE TREATMENT

Environmental contamination in health care settings and transmission of health-care-associated pathogens to patients occurs most frequently via contaminated hands of health care workers and transmission of pathogens to patients (Boyce 2010). A primary concern in health care settings has been reducing nosocomial infections and finding new approaches for these environments to help eliminate infections from hospital settings. Hospital-acquired infections generate a high financial burden for the health care industry and the consumer. In the United States, an estimated 1.7 million hospital-acquired infections occur annually, leading to about 100,000 deaths (U.S. DHHS 2009). UVC for surface disinfection, particularly in health care settings, has been applied to reduce the number of microorganisms on surfaces, and consequently UVC should contribute to a reduction in these healthcare-acquired infections (HAIs). Scientific studies have shown reductions in viable infectious agents on surfaces after UV exposure. However, further evidence of reductions in HAIs is needed, as well as a method to test various portable UVC devices being used for “whole-room” decontamination.

Various portable UVC devices are available for hospitals, which can be easily moved into patient rooms, surgical suites, ICUs, and other critical areas that need surface and air disinfection during a terminal cleaning process or when a patient is diagnosed with a disease transferred by pathogens. Some of the pathogens of interest and their reduction in health care settings are multidrug resistant, such as methicillin-resistant *Staphylococcus aureus* (MRSA), *Clostridium difficile*, *Acinetobacter baumannii*, and vancomycin-resistant *Enterococci* (VRE). These pathogens can be inactivated by proper application of UVC energy. A study by Rastogi et al. (2007) investigated the efficacy of UVC disinfection of *Acinetobacter baumannii* on contaminated surfaces relevant to medical treatment facilities. The UVC exposure to surfaces resulted in ≥ 4 -log (CFU) reduction in viable cells of *A. baumannii*.

UVC fixtures can also be installed in surgical suites to disinfect surfaces and air between or during procedures. A 19-year study on UVC during orthopedic surgery showed that 47 infections occurred following 5980 joint replacements. The infection rates for total hip replacements decreased from 1.03% to 0.72% ($p = 0.5407$), and for total knee replacements from 2.20% to 0.5% ($p < 0.0001$). The study concluded that UVC appears to be an effective way to lower the risk of infection in the operating room during total joint replacement (Ritter et al. 2007). Safety precautions must be followed when applying UVC during surgery to protect workers from accidental exposure (see the following discussion of intensity of source) or upper air fixtures may be used as discussed previously. Tools used in healthcare applications can be irradiated with UVC for simple surface disinfection. However, UV irradiation should never replace sterilization of surgical instruments.

UVC surface disinfection could also be applied in schools, morgues, nursing homes, and homeless shelters: surfaces can be irradiated with fixed or portable in-room UVC fixtures that serve as part of the room’s disinfection methodology.

Application of UVC to any surface is based on the UV dose delivered to the surface. The dose ($\mu\text{J}/\text{cm}^2$) of UVC needed to disinfect a surface depends on the selected target and desired disinfection level. Different microorganisms require various levels of UVC energy for inactivation (see Figure 4). Vegetative forms of bacteria

tend to be more susceptible to UVC energy than spore-forming microorganisms. UVC irradiates all line-of-sight objects and into shadowed areas (e.g., tables, chairs, surgical equipment, objects) through reflection. Different materials absorb and reflect UVC energy at different rates, depending on the overall reflectivity of the materials, irradiation time, and intensity, so the desired level of disinfection can be achieved, even on surfaces which are not directly irradiated. UVC surface disinfection should only be applied as an adjunct to normal surface cleaning procedures of the facility. No living organisms, including animals and plants, should be in the room when UVC is used. It should be noted that most organic compound-based materials degrade when exposed to UVC energy.

The same principles as for in-duct applications apply here. There are two primary methods of UVC delivery: direct (line of sight) and indirect (reflection). Most surface applications use a direct source, where the source (typically a mercury vapor lamp) is contained in an assembly designed to direct the UVC energy at a particular surface or in a particular direction with no impedance to the energy beam. In an indirect application, the energy is reflected onto a surface using a reflective material. The reflected UVC energy can be measured to determine accurately when a given amount of the UVC dose has been delivered to the desired target.

The basics of determining the radiant energy levels to a surface are as follows:

Length of exposure. When disinfecting surfaces, it must be first determined if the target is moving or stationary. This helps to determine if there are any limiting factors associated with the length of exposure time. In most surface disinfection applications, time is relative to intensity, meaning that increasing the intensity of the source can decrease the exposure time necessary. It is important to remember that microorganisms require a higher or lower intensity for inactivation, depending on their structure (Brickner et al. 2003).

Intensity of source. UVC lamp and equipment manufacturers normally provide the intensity of a given source (lamp or fixture) at a given distance. A distance correction factor may be needed when calculating a desired dose or intensity for a surface. UVC energy follows the same inverse square law for intensity as visible energy and other electromagnetic sources: the amount of energy at the surface is measured in proportion to the square of the distance from the energy's source (UVC lamp), assuming no loss through scattering or absorption. Temperature and airflow corrections may also be necessary, depending on the location of the application. The intensity of a source is given in power per unit area (i.e., $\mu\text{W}/\text{cm}^2$).

Distance from source to surface. In a point irradiation application, the distance is relatively easy to calculate. Calculating time requirements and intensity levels for a three-dimensional object or space is more complex. The varying distances from the source are the first challenge, because the object itself creates a shadowing effect, and any shadows from the local environment must be taken into consideration. However, portable devices are available that effectively measure the reflected dose from shadow areas and offer quantifiable results.

Studies on in-room UVC disinfection devices have shown that UVC can be successfully applied to reduce microbiological loads of surfaces located in shadow areas in addition to line of sight (Rutala 2009). The reductions were up to 4-log for organisms such as MRSA, VRE, *Acinetobacter*, and *C. difficile*. Furthermore, it was concluded that UV room decontamination with the test device reduced colony counts of pathogens by greater than 99.9% within 20 min. Note that, depending on the portable or stationary UVC device, performance could greatly differ with respect to irradiation time, because overall dose delivered to surfaces is the critical measure of portable device performance.

7. SAFETY

Hazards of Ultraviolet Radiation to Humans

UVC is a low-penetrating form of UV compared to UVA or UVB. Measurements of human tissue show that 4 to 7% of UVC (along with a wide range of wavelengths, 250 to 400 nm) is reflected (Diffey 1983) and absorbed in the first 2 μm of the stratum corneum (outer dead layer of human skin), thus minimizing the amount of UVC transmitted through the epidermis (Bruls 1984).

Although UV is far more energetic than the visible portion of the electromagnetic spectrum, it is invisible to humans. Therefore, exposure to ultraviolet energy may result in transient corneal inflammation, which can go unnoticed.

Ocular damage generally begins with **photokeratitis** (inflammation of the cornea), but can also result in **photokeratoconjunctivitis** [inflammation of the conjunctiva (ocular lining)]. Symptoms, which may not be evident until several hours after exposure, may include an abrupt sensation of sand in the eyes, tearing, and eye pain, possibly severe. These symptoms usually appear within 6 to 12 h after UV exposure, and resolve fully within 24 to 48 h. Acute overexposure to UVC radiation may cause some incapacity due to eye discomfort, but this generally abates after several days, leaving no permanent damage.

Cutaneous damage consists of erythema, a reddening of the skin akin to sunburn but without tanning. The maximum effect of erythema occurs at a wavelength of 296.7 nm in the UVB band. UVC radiation at a wavelength of 253.7 nm is less effective in causing erythema. Because ultraviolet radiation is carcinogenic, questions have been raised concerning open-air UVC systems. The International Commission on Illumination (CIE) completed a review of UVC photocarcinogenesis risks from germicidal lamps using basic biophysical principles: because of the attenuation provided by the stratum corneum and epithelial tissues of the skin, upper-air disinfection can be safely used without significant risk for long-term delayed effects such as skin cancer (CIE 2010).

Sources of UV Exposure

UVC energy does not normally penetrate through solid substances, and is attenuated by most materials. Quartz glass, soda barium glass, and TFPE plastic have high transmissions for UVC radiation.

UVC energy can reflect from most metals and several types of painted and nonpainted surfaces; however, a surface's ability to reflect visible light cannot be used to indicate its UV reflectance. The fact that a blue glow can be observed on a metal surface from an operating low-pressure UV fixture lamp could indicate the presence of UV, and a measurement should be performed to ensure there is no exposure risk. The lack of reflected blue light clearly indicates the absence of UV energy. Note that ultraviolet energy is invisible to the normal human eye; however, it follows the same optical path as the visible blue light spectrum generated by the UVC lamp.

Well-designed and commissioned UVC installations, education of maintenance personnel, signage, and use of safety switches can help to avoid overexposure. During commissioning and before operation of the UVC installation, hand-held radiometers with sensors tuned to read the specific 254 nm wavelength should be used to measure stray UVC energy and should be used in upper-air systems.

Exposure Limits

In 1972, the Centers for Disease Control and Prevention (CDC) and National Institute for Occupational Safety and Health (NIOSH) published a **recommended exposure limit (REL)** for occupational exposure to UV radiation. The REL is intended to protect workers from the acute effects of UV exposure, although photosensitive persons and those exposed concomitantly to photoactive chemicals might not be protected by the recommended standard.

Exposures exceeding CDC/NIOSH REL levels require that workers use personal protective equipment (PPE), which consists of eyewear and clothing known to be nontransparent to UVC penetration and which covers exposed eyes and skin.

UV inspection, maintenance, and repair workers typically do not remain in one location during the course of their workday, and therefore are not exposed to UV irradiance levels for 8 h. Threshold Limit Value[®] (TLV[®]) consideration should be based on real-time occupancy of spaces treated by UVC (ACGIH 2007; Sliney 2013). This recommendation is supported by UV monitoring data from First et al. (2005), which showed that peak meter readings poorly predict actual exposure of room occupants.

Evidence of Safety

During the height of the tuberculosis resurgence in the United States in the 1990s, the Tuberculosis Ultraviolet Shelter Study (TUSS), a double-blind, placebo-controlled field trial of upper-air UVC, was conducted at 14 homeless shelters in six U.S. cities from 1997 to 2004 (Brickner et al. 2000). Following available recommended placement, installation, and maintenance guidelines, each building in the study was evaluated for treatment with upper-air UVC fixtures. At the conclusion of the study, the safety of room occupants was evaluated using data from a total of 3,611 staff and homeless study subjects regarding eye and skin irritation. Analysis showed no statistically significant difference in the number of reports of symptoms between the active and placebo periods. There was one definite instance of UV-related photokeratoconjunctivitis (from eye overexposure). This occurred from a placement of an elevated bunk bed in a dormitory where a single bed had been used when the UV fixtures were first installed. By moving the UV fixture, this incident was resolved (Brickner and Vincent 2013). This study demonstrated that, with careful application, side effects of UV overexposure can be avoided. Because of the enclosed nature of in-duct UVC systems, with careful adherence to safety guidelines, these systems should not result in UV exposure.

Because in-duct UVC systems are installed inside air-handling units or ventilation ductwork, typical building occupants are not expected to be exposed to UV energy. On the other hand, building facilities workers and maintenance personnel are at risk of high UV exposures with in-duct systems. To minimize the risk to these workers, UVC systems should be designed with specific safety features and all workers that could potentially work around the UV fixtures should receive UV-specific training.

Safety Design Guidance

Upper-air systems should have on/off switches and an electrical disconnect device on the louvers. If UV radiation measurements at the time of initial installation exceed the recommended exposure limit, all highly UV-reflecting materials should be removed, replaced, or covered. UV-absorbing paints containing titanium oxide can be used on ceilings and walls to minimize reflectance in the occupied space.

Warning labels must be posted on all upper-air UV fixtures to alert personnel to potential eye and skin hazards. Damaged or illegible labels must be replaced as a high priority. Warning labels must contain the following information:

- Wall sign for upper-air UVC
Caution: Ultraviolet energy. Switch off lamps before entering upper room.
- General warning posted near UVC lamps.
Caution: Ultraviolet energy. Protect eyes and skin.

Upper-air UVC fixtures can vary widely in their luminaire efficiency factors, which rates the performance of emitted UVC from a fixture. Zhang et al. (2012) developed a protocol and performed goniometric measurements (i.e., measuring both radiance and irradiance at concurrent angles) for upper-air UVGI fixtures, which

is now being used to test total UVC fixture output (Leuschner and Salie 2013). These goniometric measurements are reported in standard IES format compatible with computer-aided design (CAD) lighting software adapted for use with upper room UVC devices (Rudnick et al. 2012; Vincent et al. 2013).

In-duct systems should be fully enclosed and sealed to prevent leakage of UV radiation to unprotected persons or materials outside of the HVAC equipment. All access panels or doors to the lamp chamber and panels or doors to adjacent chambers where UV radiation may penetrate or be reflected should have warning labels posted in appropriate languages. Labels should be placed on the outside of each panel or door, in a prominent location visible to people accessing the system. At a minimum, the labels should state

- General warning posted near UVGI/UVC lamps
Caution: Ultraviolet energy. Protect eyes and skin.
- Multilingual warning posted on the door of air handlers where UVC is present in ductwork.
Caution: Ultraviolet energy in duct. Do not switch off safety button or activate lamps with door open.

Lamp chambers should have door safety interlock switches and electrical disconnect devices. Disconnection devices must be able to be locked or tagged out, and should be located outside the lamp chamber, next to the chamber's primary access panel or door. Switches should be wired in series so that opening any switched access deenergizes the system. It is recommended that on/off switches for UV lamps not be located in the same location as general room lighting; instead, they should be in a location that only authorized persons can access, and should be locked or password protected to ensure that they are not accidentally turned on or off.

The lamp chamber should have one or more viewports of UVC-absorbing materials. Viewports should be sized and located to allow an operating UV system to be viewed from outside of the HVAC equipment.

8. INSTALLATION, START-UP, AND COMMISSIONING

The operating instructions and advice of UVC system designers and lamp manufacturers should always be followed to ensure the proper operation of any UVGI/UVC system. It is important to operate any such system within the temperature and relative humidity ranges considered during the system design process. The following section presents some general guidelines for initially verifying and maintaining adequate system performance.

Upper-Air UVC Devices

Those responsible for the commissioning process should inspect fixture placement and eye level irradiance measurements using a 254 nm selective radiometer. UVC levels can be measured with a UV radiometer directly facing the device at eye height at various locations in a room, and must be taken in the same location each time. UVC measurements should be taken at eye level (between 5.5 and 6.0 ft) at compass points from each figure. Check reflective surfaces (e.g., TVs, monitors). CAD software can be used to preview safety of UVGI/UVC upper room installations (Vincent et al. 2013). Incorporate readings into final commissioned drawings. If the readings indicate an eye-level exposure that exceeds the 8 h TLV for UVC of 6 $\mu\text{J}/\text{cm}^2$, the UV systems must be deactivated until adjustments can be made or the manufacturer can be contacted. Measurements should be made at initial installation, whenever new UV lamps are installed (newer lamp designs may provide increased irradiance), and whenever modifications are made to the UVC device or room (e.g., adjusting fixture height, relocating or repositioning louvers, adding UV-absorbing or -reflecting materials, changing room dimension or modular partition height).

In-Duct UVC Systems

Installation, start-up, and commissioning of in-duct UVGI systems are straightforward. Those responsible for installation should ensure that the system is installed as designed and that all lamps, ballasts, and/or fixtures are the same as included in the final design. Take care to ensure that all safety interlocks and view ports are installed in appropriate positions and functional. Once the UV lamps are powered on, ensure that all lamps are burning. Unfortunately, there are no good methods for in situ testing of in-duct system performance, so relying on final design parameters is essential to ultimate system performance.

9. MAINTENANCE

All UVC systems require periodic inspection, maintenance, and lamp replacement to ensure proper system performance. Whenever maintenance is performed on UVC systems, the appropriate safety guidelines outlined elsewhere in this chapter should be carefully followed.

Material Degradation

UVC energy can be detrimental to most organic materials. If the UVC is not applied properly and sensitive materials are not shielded or substituted, degradation can occur. However, the degradation may not be enough to cause failure of the material if UVC only penetrates micrometers into the material before the degradation plateaus off, leaving a still fully functional material, as found by ASHRAE research project RP-1509 sponsored by TC 2.9 (Kaufman 2010). Air filters are known to be sensitive to degradation by UVC, especially those made from synthetic materials. Glass fibers by themselves are unaffected by UV exposure, but binding materials in glass fiber filters may be degraded. As a general rule, synthetic air filters should not be exposed to UV.

Some indoor plants do not tolerate prolonged UVC exposure and should not be hung in the upper room where upper air UVC devices are installed.

Visual Inspection

Maintenance personnel should routinely perform periodic visual inspection of the UVC lamp assembly. Typically, a viewing port or an access door window is sufficient for in-duct applications. Closer visual inspection may be required for upper-air systems because a single burned-out lamp in a multilamp fixture may not be apparent from the lower room. Personal protective measures are required for this close-up inspection.

Any burned-out or failing lamps should be replaced immediately. If lamps become dirty in dusty environments, they should be cleaned with a lint-free cloth and isopropyl alcohol. Care should be taken to ensure no film remains on the surface of the lamps after cleaning. This film could reduce UV output from the lamp. Complete lamp fixtures should be replaced whenever they are visibly damaged or in accordance with manufacture warranty guidelines.

Radiometer

Another means of monitoring UVC lamps is through the use of a stationary or portable radiometer. These are generally used to monitor the “relative” output of the UVC system by measuring the UV intensity produced by the lamps. Caution is needed when using a radiometer in critical applications, because these devices are intended only to give a relative indication of the lamp output unless measured identically each time with a calibrated instrument. Radiometer sensors can degrade over time with constant exposure to UV. If accurate measurements of UV intensity are required, a calibrated laboratory radiometer should be used and readings must always be taken in the exact position each time as the readings are extremely sensitive to inverse square law losses and gains.

Lamp Replacement

UVC lamps should be replaced at the end of their useful life, based on equipment manufacturer recommendations or radiometer measurements. Where applicable, it may be prudent simply to change lamps annually (8760 h when lamps are run continuously) to ensure that adequate UV energy is supplied by a given system. Lamps can operate after their useful life, but at reduced performance, and require regular measurement to ensure that a maintained level of UVC is being generated. A blue visible light emitted from the lamp does *not* indicate that UVC is present. The typical rated life of UVC lamps is 9000 h of operation. Switching lamps on and off too often may lead to early lamp failure, depending on the ballast type used. Consult the lamp manufacturer for specific information on expected lamp life and effects of switching.

Lamp and Ballast Disposal

UVC lamps should be treated in the same manner as other mercury-containing devices, such as fluorescent lamps. Some lamps may need to be treated as hazardous waste and not discarded with regular waste, although low mercury lamps may be an exception; however, check state and local codes for proper determination. The U.S. EPA’s universal waste regulations allow users to treat mercury lamps as regular waste for the purpose of transport to a recycling facility (EPA 2014). This simplified process was developed to promote recycling. The National Electrical Manufacturers Association maintains an online list of companies claiming to recycle or handle used mercury lamps (NEMA 2009). The most stringent of local, state, or federal regulations for disposal should be followed.

UVC systems currently depend on the use of an electronic ballast to provide the UV lamp with power; however, many older systems used magnetic ballasts instead. Magnetic ballasts manufactured before 1979 contain polychlorinated biphenols (PCB) in the dielectric of their capacitors (EPA 2007). Recycling is the best way to dispose of all magnetic ballasts. The process allows the reuse of copper and aluminum wire, steel laminations, and steel cases, and disposes of capacitors and potting compound as hazardous waste in high-temperature incinerators.

Failed electronic ballasts should be treated as electronic waste. Many lamp and ballast recyclers are expanding their businesses and becoming certified to accept electronic waste. Some recyclers now accept both lamps and electronic ballasts.

Personnel Safety Training

Workers should be provided with as much training as necessary, including health and safety training, and some degree of training in handling lamps and materials. Workers should be made aware of hazards in the work area and trained in precautions to protect themselves. Training topics include the following:

- UVC exposure hazards
- Electrical safety
- Lock-out/tag-out (for in-duct units)
- Health hazards of mercury
- Rotating machinery (for in-duct units)
- Slippery condensate pans (for in-duct units)
- Sharp unfinished edges (for in-duct units)
- Confined-space entry (if applicable) (for in-duct units)
- Emergency procedures

Workers expected to clean up broken lamps should be trained in proper protection, cleanup, and disposal.

No personnel should be subject to direct UV exposure, but if exposure is unavoidable, personnel should wear protective clothing (no exposed skin), protective eyewear, and gloves. Most types of eyewear, including prescription glasses, may be sufficient to

protect eyes from UV, but not all offer complete coverage. Standard-issue safety goggles or clear full-face masks may be the best alternative.

If individual lamp operating conditions must be observed, this should preferably be done using the view port or window(s).

During maintenance, renovation, or repair work in rooms with upper-air UV systems, all UVC devices must be deactivated before personnel enter the upper part of the room.

For in-duct systems, access to lamps should be allowed only when lamps are deenergized. The lamps should be turned off before air-handling unit (AHU) or fan shutdown to allow components to cool and/or to purge any ozone in the lamp chamber (if ozone-producing lamps are used). If AHUs or fans are deenergized first, the lamp chamber should be opened and allowed to ventilate for several minutes. Workers should always wear protective eyewear and puncture-resistant gloves for protection in case a lamp breaks.

Access to the lamp chamber should follow a site-specific lock-out/tag-out procedure. Do not rely on panel and door safety switches as the sole method to ensure lamp deenergizing. Doors may be inadvertently closed or switches may be inadvertently contacted, resulting in unexpected lamp activation.

If workers enter the condensate area of equipment, the condensate pan should be drained and any residual water removed.

In general, avoid performing readings with the fan running and workers inside an AHU (e.g., only to test for output reduction caused by air cooling). Tests of this nature should be instrumented and monitored from outside the equipment.

Lamp Breakage

If workers break a lamp, they should warn all other workers to exit the HVAC equipment area. Panels or doors should be left open and any additional lamp chamber access points should also be opened. Do not turn air-handling unit fans back on. After 15 min, workers may reenter the HVAC equipment to begin lamp clean-up.

If a lamp breaks in a worker's hand, the worker should not exit the HVAC equipment with the broken lamp. The worker should carefully set the broken lamp down, and then exit the space. When possible, try not to set the broken lamp in any standing condensate water. Follow standard ventilation and reentry procedures.

Cleanup requires special care because of mercury drop proliferation, and should be performed by trained workers. As a minimum, workers should wear cut-resistant gloves, as well as safety glasses to protect eyes from glass fragments. Large bulb pieces should be carefully picked up and placed in an impervious bag. HEPA-vacuum the remaining particles, or use other means to avoid dust generation.

CHAPTER 61

SMART BUILDING SYSTEMS

<i>Automated Fault Detection and Diagnostics</i>	61.1
<i>Sensing and Actuating Systems</i>	61.5
<i>Smart Grid Basics</i>	61.7

SMART building systems are building components that exhibit characteristics analogous to human intelligence. These characteristics include drawing conclusions from data or analyses of data rather than simply generating more data or plots of data, interpreting information or data to reach new conclusions, and making decisions and/or taking action autonomously without being explicitly instructed or programmed to take the specific action. These capabilities are usually associated with software, but they can also be possessed by hardware with embedded software code, or firmware. The line between systems that are “smart” and “not smart” is blurry, and, for purposes of this chapter, does not need to be absolutely defined. The purpose of this chapter is to introduce readers to emerging technologies that possess some of these smart characteristics.

Smart technologies offer opportunities to reduce energy use and cost while improving the performance of HVAC systems to provide better indoor environmental quality (IEQ). This chapter covers smart systems and technologies in the fields of automated fault detection and diagnostics, sensors and actuators, and the emerging modernized electric power grid and its relationship to buildings and facilities.

1. AUTOMATED FAULT DETECTION AND DIAGNOSTICS

Many buildings today use sophisticated building automation systems (BASs) to manage a wide and varied range of building systems. Although the capabilities of BASs have increased over time, many buildings still are not properly commissioned, operated, or maintained, which leads to inefficient operation, excess expenditures on energy, poor indoor conditions at times, and reduced lifetimes for equipment. These operation problems cause an estimated 15 to 30% of unnecessary energy use in commercial buildings (Katipamula and Brambley 2005a, 2005b). Much of this excess consumption could be prevented with widespread adoption of **automated fault detection and diagnostics (AFDD)**. In the long run, automation even offers the potential for automatically correcting problems by reconfiguring controls or changing control algorithms dynamically (Brambley and Katipamula 2005; Fernandez et al. 2009, 2010; Katipamula and Brambley 2007; Katipamula et al. 2003a).

AFDD is an automatic process by which faulty operation, degraded performance, and failed components are detected and understood. The primary objective is early detection of faults and diagnosis of their causes, enabling correction of the faults before additional damage to the system, loss of service, or excessive energy use and cost result. This is accomplished by continuously monitoring the operations of a system, using AFDD processes to detect and diagnose abnormal conditions and the faults associated with them, then evaluating the significance of the detected faults and deciding how to respond. For example, the temperature of the supply air provided by an air-handling unit (AHU) might be observed to be chronically higher than its set point during hot weather. This conclusion might be drawn by a trained analyst visually inspecting a time series plot of the supply air temperature. Alternatively, a computer algorithm could

process these data continuously, reach this same conclusion, and report the condition to operators or interact directly with a computer-based maintenance management system (CMMS) to automatically schedule maintenance or repair services.

Automated diagnostics generally goes a step further than simply detecting for out-of-bounds conditions. In this air-handler example, an AFDD system that constantly monitors the temperature and humidity of the outdoor, return, mixed, and supply air, as well as the status of the supply fan, hot-water valve, and chilled-water valve of the air handler, might conclude that the outdoor-air damper is stuck fully open. As a result, during hot weather, too much hot and humid outdoor air is brought into the unit, increasing the mechanical cooling required and often exceeding the capacity of the mechanical cooling system. As a result, the supply air temperature is chronically high. This is an example of how an AFDD system can detect and diagnose this fault.

Over the past two decades, fault detection and diagnostics (FDD) has been an active area of research among the buildings and HVAC&R research communities. Isermann (1984), Katipamula and Brambley (2005a, 2005b), and Rossi and Braun (1997) described an operations and maintenance (O&M) process using AFDD that can be viewed as having four distinct functional processes, as shown in Figure 1. With only a few exceptions, most AFDD systems for building applications existing today lack the evaluation process (Katipamula and Brambley 2005a, 2005b). Automated correction after detection and diagnostics also has been an active area of research in the past decade (Brambley and Katipamula 2005; Fernandez et al. 2009, 2010; Katipamula and Brambley 2007; Katipamula et al. 2003a, 2003b).

As shown in Figure 1, the first functional step of an AFDD process is to monitor the building systems and detect abnormal (faulty)

Fig. 1 Generic Process for Using AFDD in Ongoing Operation and Maintenance of Building Systems
 Adapted from Katipamula and Brambley (2005a)

The preparation of this chapter is assigned to TC 7.5, Smart Building Systems.

conditions. This step is generally referred to as the **fault detection** phase. If an abnormal condition is detected, then the **fault diagnosis** process identifies the cause. If the fault cannot be diagnosed using passive diagnostic techniques, proactive diagnostics techniques may be required to isolate the fault (Katipamula et al. 2003a). Following diagnosis, **fault evaluation** assesses the impact (energy, cost, and availability) on system performance. Finally, a decision is made on how to react to the fault. In most cases, detection of faults is easier than diagnosing the cause or evaluating the effects of the fault. Detailed descriptions of the four processes are provided in Katipamula and Brambley (2005a, 2005b) and Katipamula et al. (2003a).

Applications of AFDD in Buildings

AFDD has been successfully applied to critical systems such as aerospace applications, nuclear power plants, automobiles, and process controls, in which early identification of malfunctions could prevent loss of life, environmental damage, system failure, and/or damage to equipment. In these applications, AFDD **sensitivity**, the lowest fault severity level required to trigger the correct detection and diagnosis of a fault, is a vital feature; **false-alarm rate** is the rate at which faults are incorrectly indicated when no fault has actually occurred. A high false-alarm rate could result in significant economic loss associated with investigation of nonexistent faults or unnecessary stoppage of equipment operation.

The ability to detect faults in HVAC&R systems has existed for some time, and has been used primarily to protect expensive equipment from catastrophic failure, ensure safety, and provide alarms when a measured variable goes outside its acceptable operating range. In recent years, the motivation for development and use of AFDD has expanded to include expectations of improved energy efficiency and indoor air quality (IAQ), as well as reduced unscheduled equipment downtime (Braun 1999). Developers expect that AFDD will someday be applied ubiquitously, leading to prolonged equipment life for everything from large equipment (e.g., chillers) to small components (e.g., individual actuators).

The need for AFDD capabilities has been established by surveys, site measurements, and commissioning assessments that have documented a wide variety of operational faults in common HVAC&R equipment and systems.

AFDD shows promise in three areas of building engineering: (1) commissioning, (2) operation, and (3) maintenance.

Commissioning of existing buildings involves in part ensuring that systems are installed correctly and that they operate properly. Faults found during commissioning include installation errors (e.g., fans installed backward), incorrectly sized equipment, and improperly implemented controls (e.g., schedules, set points, algorithms). Most commissioning actions that discover these faults, which include visual inspections and functional testing, are performed manually. Data are collected during some tests using automated data loggers, and analysis might be done with computers, but the process of interpreting the data and evaluating results is performed manually. AFDD methods could automate much of the functional testing and interpretation of test results, ensuring completeness of testing, consistency in methods, records of all data and processing, increased cost effectiveness, and the ability to continuously or periodically repeat the tests throughout the life of the facility (Katipamula et al. 2003a; PEI and Battelle 2003). AFDD methods applied during initial building start-up differ from those applied later in a building lifetime. At start-up, no historical data are available, whereas later in the life cycle, data from earlier operation can be used. Selection of methods must consider these differences; however, automated functional testing is likely to involve short-term data collection, whether performed during initial building commissioning or during routine operation later in the building's lifetime, and therefore, the same methods can be used regardless of when the functional tests are performed. Such a short

time period is generally required for functional testing to eliminate the possibility that the system being tested changes (e.g., performance degrades) during the test itself. Besides use in functional testing, AFDD methods could be used to verify the proper installation of equipment without requiring visual inspection. Labor intensity could be minimized by only performing visual inspections to confirm installation problems after they have been detected automatically.

During **building operation**, AFDD tools can detect and diagnose performance degradation and faults, many of which go undetected for weeks or months in most commercial buildings. Many building performance problems are automatically compensated by controllers so occupants experience no discomfort, but energy consumption and operating costs often increase. For example, when the capacity of a packaged rooftop air conditioner decreases because of refrigerant loss, the unit runs longer to meet the load, increasing energy use and costs, and occupants experience no discomfort (until design conditions are approached). AFDD tools can detect these, as well as more obvious, faults.

AFDD tools not only detect faults and alert building operation staff to them, but also identify causes of faults so that **maintenance** efforts can be targeted, ultimately lowering maintenance costs and improving operation. By detecting performance degradation rather than just complete failure of physical components, AFDD tools can also help prevent catastrophic failures by alerting building operation and maintenance staff to impending failures before failure occurs. This condition-based maintenance allows convenient scheduling of maintenance, reduced downtime from unexpected faults and failures, and more efficient use of maintenance staff time.

AFDD Methods

AFDD tools use many different methods for detecting faults and subsequently isolating or diagnosing their causes. Figure 2 shows a categorization of these methods (Katipamula and Brambley 2005a), in which fault detection and diagnostic methods are organized into three primary categories based on (1) quantitative models, (2) qualitative models, and (3) process history.

Quantitative model methods use quantitative models of the underlying equipment, relationships between types of equipment, and processes occurring in the equipment and its components. Sets of quantitative mathematical relationships capture the underlying physics of the processes. The quantitative results from applying the models to actual driving conditions represent baseline performance without faults. Differences between measured performance and the baseline performance from the models under identical driving conditions, known as **residuals**, are used to detect the occurrence of faults. Quantitative models can be based on detailed fundamental physical principles and engineering relationships or on simplified models representing the physical processes. Analyses of residuals can also be used to distinguish among possible causes of a fault to provide a fault diagnosis. Quantitative model-based methods are applicable to information-rich systems, where satisfactory models can be built in an affordable way and sufficient sensors are available to provide the data that are required. Methods described by Castro (2002), Dexter and Ngo (2001), Haves and Norford (1997), Li and Braun (2007a, 2007b, 2007c, 2007d, 2009a), Norford et al. (2002), Reddy (2007a), Seem and House (2009), Shaw et al. (2002), and Siegel and Wray (2002) fall into this category.

Qualitative model methods include qualitative physics-based methods and rule-based methods. Qualitative-physics-based methods express the underlying physical relationships (equations) as qualitative expressions (De Kleer and Brown 1984) but have seen limited use in AFDD for HVAC&R. Rule-based methods have been applied widely as the basis for AFDD for HVAC&R, using rules based on the rules of thumb used by expert practitioners in a field (**expert systems**); rules derived from knowledge of the fundamental

Fig. 2 Classification Scheme for AFDD
Adapted from Katipamula and Brambley (2005a)

physical processes occurring in HVAC&R components, equipment, and systems (i.e., the equations governing the physical processes); and alarms based simply on conditions exceeding prescribed upper and/or lower bounds for acceptable values of variables during operation (e.g., an alarm triggered by duct static pressure exceeding its upper limit). The techniques presented by Dexter and Ngo (2001), Gerasenko (2002), House et al. (2001, 2003), and Lo et al. (2007) are some examples.

Process-history-based methods depend on the availability of a large amount of historical data. These methods include **black-box** (input-output) models derived from the data and **gray-box** models that use first principles or engineering knowledge to specify the mathematical form of terms in the model but for which parameters (e.g., coefficients in the model) are determined from process data. Black-box methods include statistically derived models (e.g., regression), artificial neural networks (ANNs), and pattern-recognition techniques. Approaches based on process history primarily apply to large systems such as whole buildings, where it is difficult to construct an analytical model that captures all important physical behaviors adequately in a cost-effective way, but existing instrumentation yields sufficient data for analysis. Methods used by Bailey (1998), Choi et al. (2004), Li and Braun (2003), Reddy et al. (2003), Riemer et al. (2002), Rossi (2004), and Rossi and Braun (1997) can be classified in this category.

For further details of each of the basic modeling techniques and AFDD methods, any constraints that would limit the application of each technique, and to assess strengths and weaknesses of each technique for application to fault detection and diagnostics, see Katipamula and Brambley (2005a, 2005b).

Benefits of Detecting and Diagnosing Equipment Faults

The benefits of AFDD have been validated in part by studies that documented common HVAC equipment operating faults and their effects (Breuker and Braun 1998a; Breuker et al. 2000; Comstock et al. 2002; House et al. 2001, 2003; Jacobs 2003; Katipamula et al. 1999; Proctor 2004; Rossi 2004; Seem et al. 1999). Faults examined included economizers not operating properly, incorrect refrigerant charges, condenser and filter fouling, faulty sensors, electrical problems, chillers with a variety of faults, air-handling units with too little or too much outdoor-air ventilation, stuck outdoor-air dampers, and other problems.

Studies of the benefits of HVAC fault detection and correction have found positive savings. Rossi’s (2004) fault survey of unitary

equipment used measurements by service technicians to compute four performance indices from which unit efficiency was estimated and savings potential calculated. Half of the equipment was estimated to have a savings potential of at least \$170/year, and 33% had a potential of at least \$225/year. Li and Braun (2007e) investigated the following factors that affect the economics of air conditioning: (1) energy efficiency ratio (EER) or coefficient of performance (COP), which quantifies the energy performance of the refrigeration cycle (lower scores equal greater operating costs); (2) cooling capacity Q_{cap} , the degradation of which can affect comfort in the conditioned space, increase compressor run times, and reduce equipment lifetimes; and (3) sensible heat ratio (SHR), which can decrease with many faults, leading to higher total equipment load and greater energy consumption for the same sensible building load. All three factors can be combined in an overall **economic performance degradation index (EPDI)**, which is defined as the net increase in the total operating costs (Li and Braun 2007e) and is given by

$$EPDI = \frac{1}{1 - r_{\Delta SHR}} \left(\frac{1}{1 - r_{\Delta COP}} \times \frac{\bar{C}_{utility}}{\bar{C}_{utility} + \bar{C}_{equip}} + \frac{1}{1 - r_{\Delta cap}} \times \frac{r_{equip} \bar{C}_{equip}}{\bar{C}_{utility} + \bar{C}_{equip}} \right) - 1 \quad (1)$$

where

$$r_{\Delta SHR} = \frac{(SHR_{normal} - SHR)}{SHR_{normal}} = 1 - r_{SHR} = \text{degradation ratio of SHR}$$

$$r_{\Delta COP} = \frac{(COP_{normal} - COP)}{COP_{normal}} = 1 - r_{COP} = \text{degradation ratio of COP}$$

$$r_{\Delta cap} = \frac{(Q_{cap,normal} - Q_{cap})}{Q_{cap,normal}} = 1 - r_{cap} = \text{degradation ratio of capacity}$$

$$r_{SHR} = SHR / SHR_{normal} = \text{SHR ratio}$$

$$r_{COP} = COP / COP_{normal} = \text{COP ratio}$$

$$r_{cap} = Q_{cap} / Q_{cap,normal} = \text{capacity ratio}$$

SHR = actual sensible heat ratio

COP = average actual coefficient of performance

Q_{cap} = average actual equipment cooling capacity

\bar{C}_{equip} = average equipment price, \$/kWh

$\bar{C}_{utility}$ = $\bar{C}_{elec} \bar{W}_{normal}$ = average normal cost of operation, \$/h

\bar{C}_{elec} = average electricity price, \$/kWh

\bar{W}_{normal} = power consumption of unit (including both compressors and fans)

The subscript “normal” on a variable indicates that the variable corresponds to the fault-free operating condition.

The total cost penalty ΔOC of not correcting faults, which equals the cost savings from servicing the faults, can be determined from the EPDI from the relation

$$\Delta OC = EPDI \times OC_{normal} = EPDI / (1 + EPDI) \times OC \quad (2)$$

where OC is the total cost of operation before servicing to correct faults, and OC_{normal} is the total cost of operation expected after correction of the faults (i.e., the cost of fault-free operation).

Using this overall economic performance degradation index, Li and Braun (2007c) estimated the operating cost savings associated with the application of AFDD for rooftop air conditioners in California. Monitoring of 20 field sites, which included small retail, play areas for fast-food restaurants, and modular classrooms in coastal and inland California, for three years found operating cost savings from \$17.6 to \$180/ton·yr, the precise savings depending on the specific location and application.

AFDD has the potential to reduce service costs as well as operating costs. Li and Braun (2007b) also developed an economic evaluation procedure to estimate service cost savings, which includes savings from reduced preventive maintenance inspections, fault prevention, lower-cost FDD, better scheduling of multiple service activities, and shifting service to the low season. Based on the 20 monitored field sites, \$105/ton·yr (around 70% of the original service costs) can be saved if the AFDD technology in Li and Braun (2007a) could be fully applied. To fully apply the AFDD technology, hardware and software costs were estimated at \$250 to \$600 for individual units, and \$700 to \$1500 for a site with four units. Payback periods were less than one year, with savings in operating costs of \$20 to \$180/ton·yr and an estimated 70% reduction in service costs.

Criteria for Evaluating AFDD Methods

AFDD sensitivity and false-alarm rate are important criteria for evaluating AFDD methods not only for critical systems but also for HVAC&R systems. However, the trade-offs between the savings that could be achieved with early detection of a fault and the cost associated with a false alarm are not easily quantified. The sensitivity of AFDD for HVAC&R applications has been evaluated in terms of loss of efficiency and loss of capacity of the monitored system (Breuker and Braun 1998a, 1998b; Comstock et al. 2001; Reddy 2007b). Many early building automation systems provided an unmanageably large number of alarms, often leading to the alarms either being ignored or turned off. This experience suggests that overly sensitive AFDD methods that provide many false alarms could lead to frustration by users and be disabled by O&M staff. AFDD tools should, therefore, minimize the occurrence of false alarms.

Sensitivity and false-alarm rate are useful for quantifying performance of an AFDD tool; however, AFDD tools and the methods underlying them have numerous other characteristics that affect their performance and the cost of implementation. Dexter and Pakanen (2001) identified the following characteristics that should be considered when selecting an AFDD method or tool: (1) sensors and control signals used, (2) design data used, (3) training data required, and (4) user-selected parameters. Generally, it is desirable to limit each of these.

Types of AFDD Tools

The prevalence of faults in HVAC&R systems, as evidenced by the findings of studies cited previously, and the expectation of performance gains achievable by detecting and diagnosing faults (e.g., improved energy efficiency, occupant comfort, indoor air quality, reduced unscheduled equipment downtime), have spurred the development of a wide range of AFDD algorithms. AFDD tools

are created by implementing these algorithms in software. The level of complexity of an AFDD tool rises with the number of components and systems analyzed; however, addressing a broader range of components and systems also generally improves the richness of the types of faults that can be discovered. Some of the types of AFDD tools that have been developed for HVAC&R applications are described here.

Portable Service Tools. Portable service tools are generally applied while a technician is servicing equipment and, therefore, collect data over only short periods of time (e.g., minutes or hours rather than days, weeks, or months), which usually correspond to a steady-state system operating conditions. These products are used by service technicians, commissioning agents, and others to evaluate system performance to guide selection and implementation of corrective measures to address faults. The sensors themselves may be temporarily or permanently installed. If permanently installed, a portable service tool is connected to them during equipment or system servicing. Common measurements include dry-bulb air temperature, air relative humidity, refrigerant temperatures measured on the surfaces of tubes, and refrigerant pressures. These portable tools can perform data acquisition and analysis, providing results on site during servicing. With this class of diagnostic tool, data are collected usually at steady-state operating conditions for a relatively small period of time (e.g., minutes).

An example portable AFDD service tool is one for rooftop packaged air-conditioners. For systems that use direct-expansion vapor compression, diagnostic tools use several performance indicators (e.g., superheat, subcooling, airflow rate) that have corresponding performance expectations based on system characteristics and operating conditions. Patterns of changes in these parameters compared to expected values during proper operation are used to identify occurrence of specific faults. Data and diagnostic messages are then provided to the user to guide the servicing or repair of the system. The diagnostic tool can then be used to validate that the repair has been performed properly and corrected the fault.

Controller-Embedded AFDD. Control-embedded AFDD software code resides in local device- (or application-) specific controllers, where it can be integrated tightly with control logic and have access to data at the sampling interval of the controller. Access to these higher-frequency data may enable the detection of faults, such as unstable control loops, that might be difficult to detect using data collected at longer data-trending intervals. Embedded AFDD tools can reduce network traffic by executing the AFDD code in local controllers and propagating only key parameters or results to higher levels of a BAS architecture for additional analysis, data visualization, and reporting. Embedding AFDD software in controllers can also facilitate integration of the outputs with the alarming capabilities of the building automation system. Computational and memory limits may place practical constraints on the complexity and size of the code embedded in local controllers.

AFDD Software Deployed on Networked Workstations

AFDD software deployed on a BAS-connected workstation uses data collected by the BAS and, in some cases, data from other sensors (e.g., a separate, non-BAS wireless sensor system). The software usually resides on a computer that is part of a BAS or has access to stored data from a BAS. The BAS may serve one or several buildings (e.g., a campus). Generally, workstation-based software uses data collected or recorded at sampling intervals between one and five minutes. Data acquisition and analysis may be near real time or periodic over longer time intervals (e.g., daily) and depend on the specific application. Because the AFDD is implemented on a computer having significant computational resources, analytical methods and historical data can be processed with more complex algorithms than possible with handheld devices and local controllers. A key strength of workstation AFDD software is its

ability to detect system-level faults arising from interactions among components. For example, a rogue variable-air-volume (VAV) box controller may cause air-handling unit (AHU) fan power to exceed an expected level during an unoccupied period. In turn, if the VAV box controller has embedded AFDD, the workstation application will be able to report not only the fault at the AHU level, but also the underlying fault at the VAV box. Workstation AFDD software can require extensive effort for configuration before use. In particular, mapping points from the BAS to the AFDD tool can be cumbersome and depends on the number of measurement and control points used by the AFDD tool.

Web-Based AFDD Software. Web-based AFDD software is an extension of controller-embedded and workstation-based capabilities. It may obtain data from the BAS, independent data acquisition systems, and controller-embedded AFDD software, but uses the Internet to remotely acquire and display results. This feature allows gathering data for many buildings and supports enterprise-wide reporting. AFDD processing and analysis may be done locally at the building, with only results reported, or remotely. Updating software remotely is another advantage of web-based AFDD. A significant challenge for web-based AFDD is Internet security, which may require additional hardware and software administration, even if the access is periodic and not continuous.

Current State of AFDD in Buildings

During the 1990s, research and development on AFDD methods for HVAC&R systems grew significantly, yet few commercial AFDD products exist today. AFDD products available commercially are generally very specialized or are not fully automated. Reasons for the lack of widespread availability and use of AFDD systems may include lack of demand by the building O&M community, possibly as a result of insufficient information on the improvements and cost savings possible from them; lack of adequate sensors installed on building systems; the higher cost of reliable sensors; high perceived cost-to-benefit ratio for AFDD; lack of acceptable benchmarks to quantify the potential benefits; the difficulty of accessing real-time data for third-party AFDD software; and few AFDD capabilities built directly into building automation systems.

Furthermore, AFDD methods have generally been tested only in laboratories or special test environments (Breuker 1997; Breuker et al. 2000; Castro et al. 2003; Gomez et al. 1996; Li and Braun 2003). Some notable exceptions are reported by Braun et al. (2003), Castro et al. (2003), Dexter and Pakanen (2001), Downey and Proctor (2002), and Katipamula et al. (2003b). Many tools have not been adequately characterized with respect to detection sensitivity and the rate of occurrence of false alarms in real buildings.

Most AFDD methods developed to date work well when a single dominant fault is present in a system, but when multiple faults occur simultaneously or are already present when AFDD is initially applied, many of the methods fail to properly detect or diagnose the causes of the faults. Research in the last decade or so has begun to address detection and diagnosis of multiple simultaneous faults. For example, Braun et al. (2003) extended the previous work by Breuker and Braun (1998b) and Rossi and Braun (1997) to diagnose multiple simultaneous faults. This work has been extended by Li and Braun (2004a, 2004b, 2007a, 2007b, 2007c, 2007d, 2009a, 2009b, 2009c).

As with other software, AFDD tools require installation and, in some cases, input of configuration data before they are ready for use with building systems. Setup can include the installation of sensors dedicated to the AFDD tool or not present in existing monitoring and control systems. Configuration may require specifying the type and possibly even the model of equipment on which the AFDD will operate. It can also include specifying the kind of or basis for control (e.g., air-side economizers may be based on dry-bulb temperature or enthalpy; see the section on Air Handler Sequencing and Economizer Cooling in Chapter 42). Furthermore, fault detection and

diagnosis must be followed by evaluation of the fault and decision making regarding whether, when, and how to correct the faults identified.

Future for Automated Fault Detection and Diagnostics

The commercial availability of AFDD tools is increasing, although somewhat slowly, demonstrating some recognition of their value. As market penetration and experience in use increase, the need for improvements will accumulate. Key technical issues still to be completely addressed include the following (Katipamula and Brambley 2005b):

- Eliminating the need to handcraft and configure AFDD systems
- Automatic generation of AFDD systems
- Identifying the best AFDD method for each HVAC&R application
- Developing decision-support tools for using AFDD in operation and maintenance
- Developing prognostic tools to transform HVAC&R maintenance from corrective and preventive to predictive, condition-based maintenance
- Lowering the cost of obtaining data for AFDD and O&M support

Some AFDD tools require users to implement data collection from building automation systems, which is often difficult, costly, and beyond the capabilities of many end users. Other tools require the input of values or selections for many configuration parameters (e.g., the specific method used to control an economizer). Solutions for these problems include (1) developing AFDD tools that include databases sufficient to cover many equipment models, (2) delivering AFDD as part of equipment control packages, and (3) developing methods for automatically generating AFDD tools. The first approach was introduced in a hand tool for air-conditioning service providers more than a decade ago. The second approach of embedding AFDD onboard equipment controls has started to be used by some manufacturers of equipment and equipment controls (e.g., chillers). The third approach, involving rapid automatic generation of AFDD, requires research before it emerges in products.

Use of open communication standards for BAS (e.g., BACnet[®]) is increasing, and use of Internet and intranet technologies is pervasive. These developments make integration of third-party software with AFDD features that use BAS data easier, lowering the cost-to-benefit ratio of deploying AFDD systems. To benefit from these changes, facility managers, owners, operators, and energy service providers need the capabilities and resources to better manage this information and, as a result, their buildings and facilities.

2. SENSING AND ACTUATING SYSTEMS

Sensors

The typical sensors used in smart building systems are not far different from those used in all buildings. Smart building systems rely on sensors to measure quantities such as temperature, humidity, pressure, occupancy, electric power and energy use, fossil fuel energy use, light levels, air speeds, carbon dioxide, and electric harmonics. See Chapter 36, Measurement and Instruments, of the 2013 *ASHRAE Handbook—Fundamentals* for in-depth discussion of measurement techniques for such quantities.

Traditional sensors are connected to control systems via twisted pairs of wires, which conduct voltage or current signals. Sensor calibration (i.e., mapping from electronic signals back to measured physical quantities) can be complicated by nonlinear and/or time-varying functions, which are often implemented in software code by field engineers. The calibration process is time consuming and error prone. In practice, sensors are subject to various defects; therefore, sensor data should not be used without validation. Under

certain conditions, multiple physical sensors of different kinds should be used for reliable measure of a physical quantity. Truly smart buildings require pervasive use of smart sensors that possess intelligence and memory to identify, recalibrate, and repair defective sensors.

The intelligence of smart sensors can be described in four categories, discussed in the following paragraphs.

Local Intelligence. In local intelligence, the signal and data-processing capability reside at the local sensor node. For example, some fire detectors are equipped with multiple physical sensors to reduce false alarms and increase reliability, using complicated algorithms. Other sensors may be equipped with flash memory to store historical data. Another type of local intelligence is the ability to compute information based on raw sensor measurements. For instance, a photoresistor can be used to measure luminance, but the mapping from voltage across the resistor in the meter to luminance is not linear. A smart sensor is equipped with circuitry that calculates the desired quantity onboard, either through analog or digital approaches.

Networking Intelligence. Sensors with networking intelligence allow bidirectional communications via scalable, secure, and robust computer networks. Traditional sensors are connected to ports on panels via twisted pairs of wires. While implementing control sequences, engineers must embed the port number and detailed sensor characteristics to calculate the physical quantity of measurement from electronic signals. In practice, there is usually only one quantity that is measured by each sensor, and the direction of information flow is always in one direction from the sensor to control panels. As shown in Figure 3, smart sensors support bidirectional communications, are individually addressable, and form scalable, reliable, and robust networks. Networked sensors can be integrated by either wired or wireless approaches:

- **Wired sensors.** Some sensors are equipped with network ports and can be plugged directly into building control networks. They may support protocols including BACnet (ASHRAE Standard 135), LonWorks® (ISO 2012), Modbus® (Modbus 2012), etc.
- **Wireless sensors.** Wireless protocols, such as ZigBee® (ZigBee Alliance 2008), Z-Wave® (Z-Wave® Alliance 2014), and WirelessHART® (IEC Standard 62591) are designed for low-energy, low-data-rate sensors. Wi-Fi (IEEE Standard 802.11),

WiMax (IEEE Standard 802.16), Bluetooth® (Bluetooth SIG 2013), and GSM cellular protocols (Eberspächer et al. 2009) are also found in different types of sensors.

Data Object Intelligence. In this approach, structured data and commands are encapsulated within sensor data objects. Traditional sensors do not have computation capabilities to process high-level commands from control systems. For sensors with data object intelligence, sensor vendors ship sensors with detailed data sheets and sophisticated instructions on diagnostics. It is nontrivial work for field engineers to understand the detailed differences between hundreds of sensors and to implement proper sensor-handling logic in control systems; this type of intelligence automates those tasks. BACnet (ASHRAE Standard 135) and IEEE Standard 1451 are representative standards that support object models:

- **BACnet.** This protocol supports data objects in traditional system architectures. In addition to reading from sensors, a controller can send commands/messages to sensors. Note that commands are not sent to physical sensors, where information flow is always from sensor to panel. For example, the panel can receive a “who-is” query from other BACnet devices and respond accordingly to describe its attached sensors.
- **IEEE Standard 1451.** This smart sensor standard has been adopted by the automobile industry for test data acquisition. It features **transducer electronic data sheets (TEDS)**, which make plug-and-play operation feasible. Because sensor data, including calibration parameters, are embedded in TEDS, calibration can be conducted automatically. Numerous IEEE Standard 1451 vendors provide smart sensors for HVAC systems. However, the technology has not yet been widely adopted by the building industry, partially because of its high device cost.

Web Automation Intelligence. With this approach, sensor data objects are exposed as web services and integrated with web applications. Today, many sensors are connected to the Internet and expose web services via standard or proprietary application programming interfaces (APIs). These devices are often referred as the “Internet of things,” or IoT. For example, a personal weather station can measure and submit air quality data to the cloud, where the data are shared with the world through the Internet. Various vendors collect building performance data from customer sites via the Internet, process the raw data in the cloud, and expose results of business analysis to the web for applications of weather monitoring, lighting control, remote FDD, and IEQ monitoring. Some web data object standards including XML standards, such as Sensor Model Language (SensorML) (OGC® Standard 12-000), Transducer Markup Language—TransducerML (retired) (OGC® Standard 06-010r6), and numerous OASIS standards for smart grid and security.

The four levels of intelligence for smart sensors are interdependent. Local intelligence is the foundation for the entire architecture. Networking intelligence enables bidirectional data exchange and shields users from the detailed data transportation mechanism. Data object intelligence offers an abstracted and concise sensor data interface for effective software integration and serves as the enabling technology for plug-and-play sensors. As the result, engineers are liberated from tedious work such as manual sensor calibration. The web automation intelligence is the most advanced form of “smart” for sensors. Propelled by increasing applications in cloud computing, smart grid, and mobile devices, smart sensors with web automation intelligence could be widely used to enable smart building systems.

Actuators

The typical actuators used in smart buildings are similar to those used in all buildings. Smart buildings rely on actuators to, among other tasks, modify air flows through damper control and other

Fig. 3 Traditional Twisted-Pair Wired Sensing Architecture Transmitting Analog Signals (Left) versus Computer Network Architecture Capable of Exchanging Digital Information (Right)

means, modify chilled-water flow, adjust steam flows, shut off electrical devices, and adjust shading devices. Refer to Chapter 7 of the 2013 *ASHRAE Handbook—Fundamentals* for in-depth discussion of control actuation approaches for building systems.

A smart actuator is one that can correct itself and is possibly self powered. It can also have some sort of display showing the status of the actuator, either on the actuator itself, or on monitoring software having data sent to it directly from the actuator.

Smart actuators are relatively new and are still in the research phase. Not many commercially available smart actuator technologies are currently on the market. Research is ongoing to develop self-correcting HVAC actuators that detect soft faults (e.g., problems in computer software, incorrect set points) and automatically correct to the proper operating condition, as well as to develop ways to automatically correct hard faults (e.g., bent damper linkages) by adjusting actuator response to compensate for the faults (Fernandez et al. 2009; Siemens VAI 2008). Other efforts have pursued developing self-powered actuators that communicate using wireless mechanisms. These devices can control valves and dampers and are powered through harvested thermal or vibrational energy. Because actuators require more energy than sensors, power management is critical in such devices to ensure that they function as desired.

As smart actuators mature, the HVAC field could benefit from this new technology through potential energy savings (e.g., preventing energy waste from faulty actuators and by using self-powered actuators) and through potential maintenance cost savings (e.g., from automated calibration).

Sensor and Actuator Integration

To achieve truly smart buildings, smart sensors and actuators must take advantage of all data obtained throughout the building. Communication between devices is therefore critical. With the large number of sensing and actuating points, conventional sensor wiring may become impractical, especially when attempting to implement these systems on existing buildings. For these reasons, communication (via wireless means and power lines) is a vital technique to integrate smart devices to make a complete building network.

Chapter 40 provides an in-depth discussion of wireless technologies, suitable applications for wireless devices, and selection of wireless systems. For smart sensing and actuating, low-data-rate technologies are most appropriate, though radios based on IEEE *Standard* 802.11 could be used because of their large market. Although reliable communications are of paramount importance when considering wireless communications, low maintenance becomes critical when many devices are present in a building. One of the key maintenance concerns is the need to replace batteries, because many of these devices may not have convenient access to line power. Protocols for low-data-rate applications attempt to minimize energy consumption of these devices by taking steps such as putting the devices to sleep when they are not actively taking measurements, performing actions, or transmitting or receiving commands. IEEE *Standard* 802.15.4 is one such protocol that specifies the physical layers and media access control of radios appropriate for low-data-rate applications. This standard forms the basis of specifications such as ZigBee (ZigBee Alliance 2008), ISA *Standard* 100.11a, WirelessHART (IEC *Standard* 62591), and proprietary protocols, such as MiWi™, which add upper layers to IEEE *Standard* 802.15.4 to increase usability.

Reliability of Wireless Communications in Buildings. Attenuation of signals by building materials and interference from other devices make long-distance signal travel difficult. To overcome these problems, different network topologies can be implemented to make the network more robust. For example, a mesh network can allow each device to transmit and receive, communicating with other devices to relay messages through the network to their intended destinations or to enable direct communication between devices without

the need for central control equipment. The intelligence can, therefore, be moved down to specific portions of the building.

Wired Power Line Communications (PLC). Power line communication can also be used to reduce the cost and effort in deploying smart sensors and actuators throughout a building. In this type of communication, signals are sent over the same wires that carry alternating current (ac) electric power in a building. This approach reduces the need to run dedicated control system wiring and is especially useful in existing buildings. Some installation of wiring may still be needed to connect the sensor or actuator to the nearest electrical outlet. Modulated signals are typically sent at frequencies away from the common 50 to 60 Hz frequency of ac electricity. Bandwidth that is appropriate for streaming Internet traffic can be achieved, but noise on the lines and components of the electrical system (e.g., transformers) can make the signal unavailable in certain installations. IEEE *Standard* 1901 provides specifications for providing high-speed broadband networking over power lines using frequencies below 100 MHz. A variety of commercial protocols are available to provide a suite of products that can communicate with each other.

Physical integration of the sensors and actuators is not the final step in developing the components of a smart building; integrating the data streams seamlessly is a challenge, considering the potentially large number of devices. IEEE *Standard* 1451 provides guidance that aims to create plug-and-play devices that automatically report key operating parameters to other devices connected to them. Standards such as these will help to ease the burden in configuring sensing and actuating systems in buildings.

3. SMART GRID BASICS

This section provides the basis for understanding changes occurring in the electric grid infrastructure and how buildings now and in the future interact with the grid. Because this is a rapidly evolving topic area, readers are encouraged to seek additional information on the latest changes and future directions. For additional resources and information, refer to the U.S. Department of Energy's SmartGrid.gov (<http://smartgrid.gov>) and Energy.gov (<http://energy.gov/oe/technology-development/smart-grid/smart-grid-primer-smart-grid-books>) web pages.

Brief History of Electric Power Grid

In the early days of commercial electric power, direct current (dc) electricity was transmitted at the same voltage as end users (consumers) required, thus limiting the distance over which electricity could be transmitted. Direct current, however, could not easily be increased in voltage for long-distance transmission without incurring significant line losses. Different classes of loads (e.g., lighting, fixed motors, traction/railway systems) required different voltages, and so used different generators and transmission lines. This specialization of generation and transmission was inefficient for low-voltage, high-current circuits, because generators needed to be near their loads. Thus, the electric grid seemed to be developing into a distributed generation system, with large numbers of small generators located near their loads. However, as electricity use increased, it soon became apparent that using common generating plants and transmission networks for all loads yielded economies of scale that could lower costs and the overall capital investment required. This standardization of the grid also enabled more efficient use of all grid assets.

By allowing multiple generating plants to be interconnected over a wide area on a common network, the cost of electricity was reduced. The most cost-effective and efficient plants could supply electric power reliably to geographically distributed and temporally varying loads. Remote and low-cost sources of energy, such as hydroelectric power or mine-mouth coal, could be exploited to lower energy production cost.

Rapid industrialization in the early 20th century made electric power systems a critical part of the infrastructure in most industrialized nations. Interconnection of local generation plants and small distribution networks was driven by the needs of World War I, with large electric power plants built by governments to provide electricity to munitions factories. Later, these generating plants were used to supply civil loads through long-distance transmission lines. In the United States, an important part of developing the grid occurred with the passage of the Rural Electrification Act of 1936, which provided federal loans for installation of electrical distribution systems to serve rural areas of the United States. The funding was channeled through cooperative electric power companies, most of which still exist today. These member-owned cooperatives purchased power on a wholesale basis and distributed it using their own network of transmission and distribution lines. Because electricity must be produced at the exact rate at which it is consumed, the electric power grid is the largest and one of the most tightly controlled machines in the world today.

Electric Power Grid Operational Characteristics

The modern electric grid is modeled as three interconnected domains (Figure 4). The **generation system** produces electric energy. This domain contains a set of power stations and distributed energy generators (e.g., residential solar photovoltaic systems). The electricity generated is conditioned to reduce losses and is then transmitted over long distances across the **transmission system**. The transmission system typically consists of high-voltage wires that distribute electricity hundreds of miles. When needed to power loads within a region, the electricity is reconditioned (i.e., converted and/or stepped down in voltage) and distributed to customers over the **distribution system**. The distribution system is ordinarily a network of medium-voltage wires that distribute energy across a metropolitan area. The distribution system also includes electrical substations that transform the energy to the low voltages needed by customer loads and transmit it over the wires connected to the customer.

A **transmission grid** is a network of power stations, transmission lines, and substations. Electricity is usually transmitted within a grid as three-phase alternating current (ac). Single-phase ac is used only for distribution to end users, because it is not suitable for large, polyphase induction motors. In the 19th century, two-phase transmission was used but required either four wires or three wires with unequal currents. Higher-order-phase systems require more than three wires, but deliver marginal benefits.

In the United States, the transmission grid is divided into several regional operating units that manage overall electric transmission within their own territories and between regions (see Figure 5).

The capital cost of electric power stations is so high, and electric demand so variable, that it is often less expensive to import some portion of the needed power than to generate it locally. Because nearby loads are often correlated (e.g., hot weather in the Southwestern United States might cause many people to use air conditioners simultaneously), electricity often comes from distant sources. Because of the economics of load balancing, wide-area

transmission grids now span across countries and even large portions of continents. The web of interconnections between power producers and consumers ensures that power can flow, even when a few links are inoperative.

The unvarying (or slowly varying over many hours) portion of the total electric system demand is known as the **base load** and is generally served by large generation facilities (which are efficient for this purpose because of economies of scale) with low variable costs for fuel and operations. Such facilities might be nuclear, natural-gas, or coal-fired power stations or, in some locations, hydroelectric plants. Variable renewable energy sources, such as solar photovoltaics, wind, and wave power, because of their intermittency, are not considered base-load capable (unless firmed by storage) but can still add power to the grid. The remaining power demand is supplied by intermediate load-following plants and peaking-power plants, which are typically smaller, faster-responding, and higher-cost sources, such as combined-cycle or combustion turbine plants fueled by natural gas.

Subtransmission is part of an electric power transmission system that runs at relatively lower voltages. It is uneconomical to connect all distribution substations to the high main transmission voltage, because the equipment is larger and more expensive. Typically, only larger substations connect with this high voltage. The electric power is stepped down and sent to smaller substations in towns and neighborhoods. Subtransmission circuits are usually arranged in loops so that a single line failure does not cut off service to a large number of customers for more than a short time. Although subtransmission circuits are usually carried on overhead lines, buried cable is also used in urban areas.

The amount of power that can be sent over a transmission line is limited. These limits vary depending on the length of the line and can depend on the ambient temperature. For a short line, heating of conductors because of line losses sets a thermal limit. If too much current is drawn, conductors may sag too close to the ground or other obstructions (e.g., trees), or conductors and equipment may be damaged by overheating. For intermediate-length lines on the order of 62 mi, the limit is set by the voltage drop in the line. For longer ac lines, system stability limits the power that can be transferred.

Fig. 4 Electric Power Grid
U.S. Department of Energy (undated)

Fig. 5 Interconnections in Area of Responsibility of North American Electric Reliability Corporation (NERC)
NERC (2012)

Approximately, the power flowing over an ac line is proportional to the cosine of the phase angle of the voltage and current at the receiving and transmitting ends. This angle depends on system loading and generation, and it is undesirable for the angle to approach 90°. Very approximately, the allowable product of line length and maximum load is proportional to the square of the system voltage. Series capacitors or phase-shifting transformers are used on long lines to improve stability. High-voltage dc lines are restricted only by thermal and voltage drop limits, because the phase angle is not material to their operation.

To ensure safe and predictable operation, the components of the transmission system are controlled with generators, switches, circuit breakers, and even loads. The voltage, power, frequency, load factor, and reliability capabilities of the transmission system are designed to provide reliable, cost-effective performance for customers.

The transmission system provides for base- and peak-load capability, with safety and fault tolerance margins. The peak-load times vary by region largely because of differences in the industry mix. In very hot and very cold climates, home air-conditioning and heating loads can have a significant effect on the overall load at times. These loads are typically highest in the late afternoon in the hottest part of the year, and in mid-mornings and mid-evenings in the coldest part of the year. This variability makes the power requirements differ by season and the time of day. Distribution system designs take the base and peak loads into consideration.

Electricity produced by the generation system has to match the energy consumed by the loads, or the system becomes unstable. The transmission system usually does not have a large storage capability to match the varying energy consumed by loads. Thus, fast-acting balancing generation units (known as spinning reserves) are connected to the transmission system and kept matched to the load to prevent overloading failures of the generation equipment.

Typical Building Load Profile

Figure 6 depicts a typical commercial building load profile in relation to the utility system load profile. The profile reflects the building’s individual characteristics, including building use,

occupancy and equipment schedules, equipment characteristics, and building control strategies used. In contrast, the utility system load is the aggregate of all the individual loads, including commercial facilities, but also includes residential, industrial, and public facilities. Although individual commercial facility electric loads may have the same general shape as the utility system load, they may not have an identical shape and may peak at different times given the aggregation of the many loads that make up the system load. Understanding the relationship between the load profile of an individual facility and the overall system profile provides the basis for optimizing electricity use and costs to the mutual benefit of the grid and the customer.

Utility Demand Response Strategies

Demand response is the change in electric usage by end-use customers from their normal consumption patterns in response to changes in the price of electricity over time, or to incentive payments designed to induce lower electricity use at times of high wholesale market prices or when system reliability is jeopardized (DOE 2006).

Flexible load shape attempts to achieve a load shape composed of end-use services with varying degrees of reliability, allowing the utility the flexibility to control/adjust end-use demand in accordance with supply capability. In exchange for accepting a lower level of reliability, a customer receives some financial incentive. A flexible load shape may be achieved using interruptible loads, energy management systems, or individual customer load control devices imposing service constraints.

Peak shaving reduces the amount of energy purchased from a utility company during the peak. Many businesses pay for their electricity consumption on a time-of-use basis. Peak demand charges typically apply to electricity consumed within the peak hours, whereas lesser charges apply to the remainder of the day.

Direct load control involves the utility disabling and enabling consumer end uses. A communication system between the utility and the customer transmits control instructions to a receiver and control actuator on the customer’s premises that enables activation/

Fig. 6 Example Commercial Building Load Profile in Relation to Utility System Load
Adapted from Price (2010)

deactivation of customer loads. Many utilities use direct load control to reduce peaking requirements, and consider control only during the most probable days of the system peak. Other utilities use direct load control to reduce operating cost and dependence on critical fuels.

Valley filling involves increasing energy consumption in a time period when the electric system is under used. Valley filling may be particularly desirable where the long-run marginal cost of electricity is less than the average price of electricity. Properly priced off-peak load can decrease the average price for the customer and provide cost or capacity benefits to the utility. Valley filling can be accomplished in several ways, including using thermal energy storage (water or space heating or cooling).

Load shifting moves energy consumption to another time period, typically when prices are lower. Common options include storage water heating, storage space heating, cool storage, and time-of-use or other special rates. The shifting usually occurs within a 24 h period. The total energy used by a customer needs not be significantly affected by load shifting.

Strategic conservation is directed at reducing end-use consumption, often through increased efficiency. The change reflects a reduction in sales and a change in the use pattern. Examples include weatherization and appliance efficiency improvement.

Strategic load growth increases end-use consumption by increasing energy sales beyond the valley-filling strategy. The emphasis is often on increasing total sales without regard to the seasonal or daily timing of the load. Strategic load growth may involve area development, electrification, and increased market share of loads that are or can be served by competing fuels.

Utility Rate Options and Strategies

Public regulatory bodies provide incentives to drive customer behaviors using electric tariff design. To increase the reliability and use of existing generation assets or reduce the need for additional generation/transmission assets, there are two methods to reduce customer demand during peak consumption times. Utility customers can be induced to provide demand response either through **dynamic pricing tariffs**, retail electric rates that reflect short-term changes in wholesale electricity costs (e.g., hourly pricing or critical-peak pricing), or through **demand response programs** that offer customers payments in return for reducing consumption when called upon to mitigate high market prices or reserve shortfalls. Table 1 shows common types of demand response programs.

Modern Smart-Grid Strategy

The smart grid represents a modern grid concept that would replace dated infrastructure with currently available and future technologies that enable safe and secure two-way flows of electricity and information between customers and their electricity providers. In the typical grid configuration, energy predominately flows one way, from utilities to consumers, and information flows almost exclusively one-way, from consumers’ power meters to grid operators. However, with the smart grid, energy and information would flow easily from the grid to customers, and vice versa, in real time.

The vision for the modern electric grid is one that

- Motivates and includes the consumer
- Accommodates all generation and storage options
- Enables markets
- Provides power quality for 21st-century needs
- Resists attacks
- Self heals
- Optimizes assets and operates efficiently
- Provides less expensive electric power more cleanly

Two-way flows of energy and information would provide customers with valuable information about their electricity prices

and consumption patterns. This would enable customers to better manage their electricity use. On the utility side, the grid could be more accurately balanced, brownouts or blackouts could be avoided, and outages could be quickly mitigated. Advantages of the smart grid to the utility and to consumers are compared in Figure 7.

Investments in the smart grid are expected to yield the following four long-lasting effects (Lott et al. 2011):

- Next-generation electric power grid infrastructure that replaces the existing grid
- Substantial improvements in energy efficiency that bring financial and environmental benefits
- Greater use of renewable generation
- Widespread use of distributed generation

Table 1 Common Types of Demand Response (DR) Programs: Price Options and Incentive- or Event-Based Options

Price-Based DR Programs: Higher Prices Used to Induce Demand Reduction	
Time of use (TOU) rates	Rates with fixed price blocks that differ by time of day.
Critical peak pricing (CPP)	Rates include a prespecified, extra-high rate that is triggered by the utility and is in effect for a limited number of hours.
Real-time pricing (RTP)	Rates vary continually (typically hourly) in response to wholesale market prices.
Incentive- or Event-Based Programs: Incentives Provided to Induce Demand Reduction	
Direct load control	Customers receive incentive payments for allowing utility a degree of control over certain equipment.
Demand bidding/buyback programs	Customers offer bids to curtail load when wholesale market prices are high or identify how much they would be willing to curtail at posted prices.
Emergency demand response programs	Customers receive incentive payments for load reductions when needed to ensure reliability, but curtailments are voluntary.
Capacity market programs	Customers receive incentive payments or rate discounts/bill credits for providing load reductions as substitutes for system capacity.
Interruptible/curtailable programs	Customers receive a discounted rate or bill credit for agreeing to reduce load upon request. If participants do not curtail when requested, they can be penalized.
Ancillary services market programs	Customers receive payments from a grid for ancillary services provided. Require that customers are able to adjust load quickly.

Fig. 7 Benefits of Smart Grid as Viewed by Utilities and Customers

Lott et al. (2011)

This smart-grid strategy is intended to enable a new kind of load response, in which loads and generation are on an equal footing with equal visibility of the value of electricity in real time. It includes use of automation and other tools to enable even small customers to manage load in response to the real-time value of energy. It focuses on integrating renewables and higher reliability and resiliency, as well as distributed energy (customer-owned generation and storage) and advancing the regulatory framework to enable customers (and small generators) to manage the distributed energy resources and load in a variable-price environment.

Relevance to Building System Designers

As the modern grid develops, buildings will need grid communications to know the condition of the grid and to determine how to respond to it. Facilities can be operated in ways that support grid reliability while potentially lowering their costs of operation by managing loads and storage to contribute to balancing grid-wide demand and changes to the generation mix. An example is Open Automated Demand Response (OpenADR™), a research and standards development collaboration for power demand management. Typically, OpenADR is used to communicate data and signals that turn off powered devices when electrical demand is high. See OpenADR Alliance (undated) for more information.

Buildings and facilities should be designed for operation in an environment where electricity is valued in real time, varying throughout the day. Building owners, managers, and designers should consider incorporating automation to allow shifting and shedding loads, as well as planning to allow for thermal energy storage and renewable energy generation systems integration. Further, there should be some consideration of microgrid operations, with additional fossil-fuel-based distributed generation (fuel cells, diesel generators, etc.) and electrical storage capability on site.

In the future, not only will electricity costs become more dynamic, energy prices will continue to rise. Controlling energy costs begins with energy efficiency as the cornerstone of an overall energy management plan. Strategies for developing a site-specific plan can be found in EPA (undated).

The success of the smart grid depends on interoperability and communication between energy service providers and facility energy management systems to effectively manage supply and demand. Proposed ASHRAE Standard 201P, Facility Smart Grid Information Model (under development), would define an abstract, object-oriented information model to enable appliances and control systems in homes, industrial facilities, and other buildings to manage electrical loads and generation sources in response to communication with a smart electrical grid and to communicate information about those electrical loads to the utility and other electrical service providers. This model defines a comprehensive set of data objects and actions that support a wide range of energy management applications and electrical service provider interactions, including on-site generation, demand response, electrical storage, peak-demand management, direct load control, and other related energy management functions. This standard will become part of the Smart Grid Interoperability Panel (SGIP; <http://www.sgip.org>) catalog of standards recommended for adoption by utilities and energy service providers.

---	--

INDOORS, buildings should always be dry. When building interiors get damp and stay damp, problems often emerge for their occupants and for the building’s structure, material, and furnishings. Persistent indoor dampness has been associated with human health problems, increased risk to buildings’ structural fasteners and exterior enclosure, shortened useful life of furnishings, and reduced acceptability to occupants because of odors and stains. These and related problems can be costly and disruptive, as well as annoying to all concerned (ASHRAE 2013).

Human Health

The U.S. National Academy of Medicine and the World Health Organization determined that there is a clear association between damp buildings and negative health effects (NIM 2004). The U.S. Department of Energy’s Lawrence Berkeley National Laboratory estimated the cost of documented dampness-specific health effects to be more than \$3.5 billion each year (Mudari and Fisk 2007), and health hazard evaluations of buildings around the world have repeatedly shown that indoor dampness is neither normal nor desirable from a health perspective [e.g., NIOSH (2013)]. Although not all of the mechanisms are well understood at this time, cognizant public health authorities agree that damp buildings can lead to health problems.

Energy Conservation

Insulation can be compromised when rain and snow melt water leaks into roofs or exterior walls, and when indoor humidity condenses inside walls. When insulation gets wet, it allows more heat to pass through the building enclosure. The increased heat flow wastes energy, increases the difficulty of meeting energy reduction goals, and adds needless costs to building operation.

Sustainability

Damp buildings generate corrosion, rot, and mold, which damage structural fasteners (Zelinka 2013), materials, and finishes. Therefore, a building and its furnishings are not sustainable (because their useful lives are shortened) unless they are designed and constructed to prevent moisture accumulation.

Costs

Fixing a moisture problem after construction is roughly 10 times as expensive as correcting a drawing at the design stage, and remediating a mold problem is roughly 100 times as expensive as correcting that drawing. Thus, it is far more cost effective (and more sustainable) to avoid problems at the design stage than to repair problems caused by moisture-risky design.

Avoiding Litigation Risk

Humidity and moisture-related problems in buildings have been the single largest category of claims against the errors and omissions insurance of architects and engineers (84%). Also, moisture-related damage is the single most-litigated construction defect against contractors (NAIC 2008).

1. CAUSES

Based on investigations of problem buildings, dampness sufficient to cause problems seldom has a single cause. More often, a series of events, including decisions in many areas of professional and personal responsibility, combine in complex ways to cause a problem. Therefore, it is not appropriate to assign responsibility for building dryness to any single group, because it is not likely that any one group can prevent a problematic level of dampness, mold, or microbial growth by their actions alone.

The interactions that lead to the amount and duration of moisture accumulation that creates problems are similarly complex. Figure 1 shows an example: the classic and problematic practice of installing vinyl wallpaper on the indoor surfaces of exterior walls in a mechanically cooled building in hot, humid climate.

High-dew-point outdoor air infiltrates through exterior walls. Its moisture is then absorbed into hidden cool surfaces of interior gypsum wallboard. Because the vinyl wallpaper is relatively impervious to water vapor transport, moisture accumulates in the gypsum board, resulting in mold growth and eventually decay, rot, or corrosion of structural members or their fasteners.

Note that the problems illustrated by Figure 1 required more than one element: high outdoor dew point for many days or weeks, extensive humid air infiltration into the enclosure, chilled indoor surfaces, vinyl wallpaper, and untreated paper-faced gypsum board. If any one of those elements were absent, little or no mold growth might have occurred (Zelinka 2013). In this example,

- The owner or interior designer decided to install vinyl wall covering rather than a more permeable wall covering.
- The architectural designer designed and/or the contractor built a building that allows extensive humid air infiltration, and also selected untreated gypsum wall board for a location likely to experience high humidity in a climate where high humidity continues for many months.
- The HVAC system was apparently designed and/or installed such that it overcools wall surfaces. The toilet exhaust duct system was also either designed, installed, or operated such that it extracts air from building cavities as well as from the bathroom, thereby increasing humid air infiltration and leading to high relative humidity inside the cavities. High relative humidity inside cooled walls leads to moisture absorption and high water activity in vulnerable paper-based backing of the wall board.

The preparation of this chapter is assigned to TC 1.12, Moisture Management in Buildings.

Fig. 1 Mold Caused by Complex Combination of Factors

All of these factors combine to support mold growth, given enough time.

This example illustrates that risks from multiple decisions made by many different professionals usually act in combination to produce enough moisture accumulation in the wall cavities, for a long-enough period, to create a microbial growth problem.

Further, the risk of excess moisture accumulation can be either increased or reduced by occupants as they use the building. For example, if the occupants of an apartment generate a significant amount of moisture from cooking and cleaning activities without opening windows or using exhaust fans, excess moisture accumulation and mold growth may occur, most commonly on the inside surfaces of exterior walls during cold weather. A building is a complex and dynamic system, and the actions of its occupants are an integral and constantly changing component of that system.

Finally, with respect to health issues, people in the same building are often quite different in their individual sensitivities to airborne microbial contaminants. A low level of contamination that causes adverse health effects for one sensitive individual often causes no health effects for others.

Consequently, the prudent course of action is to keep all of the materials that make up a building and its HVAC systems as dry as possible, consistent with their normal functions. Building professionals and building occupants can reduce risks by

- Remembering that the risk factors for microbial contamination and corrosion are excessive long-term moisture accumulation in materials, repeated wetting, or catastrophic water damage.
- Making decisions and take actions to keep the building and its systems, furnishings, and finishes as dry as possible, given the function of the component in question and the available resources. To help establish threshold levels of concern for material dampness, microbiologists and building investigators observe that mold growth is rarely a problem when the water activity of interior building materials and furnishings is held consistently below 0.8 (below an equilibrium relative humidity of 80% rh in the surface layers of a material) (ASHRAE *Standard* 160).

- Being aware that, if adequate resources are not made available to keep the building, systems, and contents dry, then the risk of microbial growth including mold will increase.
- Addressing persistent dampness inside a building; constant, stagnant water in condensate drain pans; or constantly damp insulation, filters, or sound lining of HVAC systems.

2. MOISTURE TOLERANCE AND LOADS

Concrete, masonry, stone, and heavy wood timbers are much less moisture sensitive than untreated paper-faced gypsum board, light-gage steel studs, and carpet adhesives. That is why the traditional heavy construction assemblies typical of buildings built before the twentieth century sometimes tolerated rainwater loads and moisture accumulation in exterior walls with fewer problems than the lighter construction of most modern buildings.

Consequently, it is useful to recognize that not all buildings have the same risks, and each type responds differently to equal amounts of humidity and moisture accumulation. When building materials and finishes tolerate moisture exposure, as in the case of a ceramic tile-lined shower room, there is less risk of mold and microbial growth than if that same shower room were lined with painted gypsum wall board.

Similarly, not all exterior surfaces of the same building are subject to the same level of environmental moisture stress. Risks from rain exposure and moisture accumulation are quite different on each face of the building. Beginning with the matter of moisture loading, Figure 2 shows an example of the fact that the volume of rain often depends on the predominant direction of wind-driven rain. In Toronto, Canada, the majority of the rain comes from the east (Straube 2010). In other locations, most of the wind-driven rain can come from quite different directions, varying by season of the year.

Also, the drying potential of the building varies according to building orientation. For example, in the northern hemisphere, the northern side of a building is shaded from direct solar radiation,

Fig. 2 Rain Loads Versus Wind Speed and Direction (Straub 2010)

reducing the annual drying potential on the north wall to far less than on the south and west sides of the same building. In the northern hemisphere, the risks of equal amounts of rain are much higher on the north side than on the southern and western elevations.

Therefore, when designing any building enclosure, it is useful to recognize differences in moisture tolerance of materials and to remain aware of differences in moisture loading and drying potential both outside and inside the building. Chapter 44 outlines useful suggestions for architectural designers to limit the potential for problems in building enclosures.

The concern continues after construction is complete. An owner of an existing building should recognize that some types of construction and some systems and assemblies in a building are more subject to problems from moisture accumulation than others. Building operations become more economical and the building itself becomes more sustainable when designers avoid moisture-sensitive materials and assemblies in parts of the building where annual water exposure is high and drying potential low, rather than treating all parts of all buildings equally. In both design and operation, an appropriate hierarchy of concern will be based on how much water a given problem can potentially add to moisture-sensitive indoor materials and furnishings.

Architects should keep in mind that the side of the building that has the greatest annual wind and rain exposure needs the most water-resistant materials and the most effective building enclosure design details.

Engineers should remember that buildings in hot and humid climates experience thousands of hours at high outdoor dew points, so the ventilation and makeup air systems must be sure to dry incoming air with more certainty than buildings in dry climates.

Building owners and operators should remember that, no matter what the construction age or type, rainwater leaks are a bigger concern than high humidity, and plumbing leaks are a bigger concern than air leakage from ducts.

All of these problems can cause mold growth, but a simple rule applies to all circumstances: more moisture exposure means a higher potential for problems in a shorter amount of time. Therefore, designers and owners benefit from understanding some of the specific factors that have historically been most influential in dampness problems.

3. RISK FACTORS AND MITIGATION

Each area of professional and occupant activity involves decisions and actions that can either increase or reduce the risk of problems related to moisture, mold, and other microbial growth. In most cases, the individuals involved are not aware they are making fateful decisions. When reviewing these factors, it is important to remember that moisture and mold problems can develop for different reasons in cold and hot climates, and can also occur through mechanisms caused by regionally specific building designs, material selections, and construction practices in different parts of the world. Therefore, recommendations based on local conditions are often needed to avoid dampness-related problems.

Note also that these factors have seldom been responsible in isolation for moisture and microbial growth problems. More commonly, the risks have increased when more than one of these factors are present, or when an architectural risk factor is combined with risk factors associated with either HVAC systems or occupant activities.

3.1 HVAC SYSTEMS

Risk Factors

- Redistributing microbial air contaminants, including mold, from a contaminated space into occupied areas. Examples of contaminated spaces can include parts of the building under construction or renovation, hidden building assemblies (e.g., damp crawlspaces or attics), or spaces above dropped ceilings or below raised floors (Harriman and Lstiburek 2009).
- Failing to make air distribution components and joints in return plenums and supply and exhaust ducts sufficiently airtight. Joints and connections must be tight enough to prevent suction that otherwise pulls humid outdoor air into the building, and/or leakage that allows cold supply air to chill surfaces inside humid building cavities (Harriman and Lstiburek 2009; Harriman et al. 2001).
- Failing to keep the long-term average indoor air pressure positive with respect to the outdoors when the outdoor dew point is higher than indoor surface temperatures (Harriman et al. 2001).
- Failing to prevent dirt and dust accumulation on cooling coils and on duct surfaces and sound lining downstream of cooling coils. Accumulating a damp layer of dust can lead to microbial growth. Install access panels that allow inspection and cleaning of the condensate pans and areas upstream and downstream of cooling coils to ensure the condensate pan is not accumulating water, that coils are clean, and that upstream and downstream surfaces are clean and dry. Regular cleaning and ultraviolet lamps can reduce the impact of occasional lapses in filtration, but over time, effective filtration is the most important factor in preventing microbial growth in parts of the system likely to accumulate moisture during normal operation.
- Failing to keep air velocity through cooling coils low enough to prevent droplet carryover into downstream duct work and filters, leading to microbial growth in those locations (Harriman and Lstiburek 2000).
- Failing to install condensate drain traps deep enough to allow free-flowing drainage of normal cooling coil condensate, and failing to install traps and condensate drain lines with a diameter large enough to allow maintenance personnel to both observe clogs and clean out anything that obstructs free-flowing drainage (Harriman et al. 2001).
- Failing to install accessible cleanouts in condensate drain lines to allow periodic removal of algae and the particulate, feathers, sticks, and leaves that typically wash off the coil. Note also that copper piping has been effective in limiting biological accumulation in condensate drain lines (Harriman et al. 2001).

Fig. 3 Dehumidification Load Versus Peak Outdoor Dew Point Design and Peak Dry Bulb

- Failing to measure and limit the volume of ventilation and makeup air to the amount required for the current occupancy and that will in fact be dried by the system's dehumidification components. Ventilation without dehumidification during humid outdoor conditions has been responsible for major and widespread mold growth problems in hot and humid climates. Whenever any building in any climate is mechanically ventilated, the indoor dew point must remain low enough to keep the indoor surface relative humidity below 80%, even on hidden cool surfaces (Harriman and Lstiburek 2009).
- Failing to ensure that system operation during unoccupied periods keeps the indoor dew point low enough to maintain a water activity below 0.8 in building materials and furnishings (30-day average surface relative humidity below 80% in surfaces cooled by air-conditioning systems). Mold and microbial growth accelerates when the indoor dew point stays high while surfaces are intermittently chilled by cooling systems. Moisture accumulation and mold has often been observed in unoccupied schools, vacation homes, hotel rooms, institutional dormitories, and military barracks; this happens when there is no independent dehumidification that keeps indoor dew points low when cooling systems are reset to higher temperatures (Harriman and Lstiburek 2009).
- Failing to ensure that the temperature of chilled-water systems stays low enough, and water flow rates through the coils stay high enough, to effectively dry the air. Note that this problem is most common when a building or a system is not equipped with a separate dehumidifier (Harriman and Lstiburek 2009).

Risk Mitigation

- Ensure that all ventilation air is dried to a dew point below the dew point maintained inside the building when the building is being mechanically cooled (Harriman and Lstiburek 2009; Harriman et al. 2001).
- Design ventilation dehumidification components based on the humidity loads at peak outdoor dew point, rather than the loads at the peak outdoor dry-bulb temperature. Figure 3 shows the large difference between these conditions in Tampa, FL; Figure 5 provides more detailed examples in other climates (Harriman and Lstiburek 2009; Harriman et al. 2001).
- Ensure that all condensation inside HVAC components and air distribution ductwork is drained away to an appropriate sanitary drain or condensate collection system (Harriman et al. 2001).
- Ensure that indoor surfaces of both occupied and unoccupied spaces are not cooled to temperatures so low as to create an average surface relative humidity of over 80% lasting for more than

30 days, or surfaces cold enough to allow condensation (ASHRAE *Standard* 160).

- Note that the relative humidity of air measured in the occupied space or return air does not indicate the relative humidity in the thin boundary layer of air in contact with cool surfaces. Monitoring and controlling indoor dew point compared to indoor surface temperatures is the more useful metric for preventing persistent dampness. For example, in buildings that are mechanically cooled during hot or humid weather, keeping the indoor air dew point below 55°F nearly always ensures that surface relative humidity stays below 80% even on cool surfaces. In contrast, if the indoor air relative humidity were 55% at 78°F, any surface cooled below 66°F would have a relative humidity above 80% (Harriman and Lstiburek 2009).
- Keep the indoor dew point low enough to ensure that there is no condensation on the exposed surfaces of cool HVAC components or on moisture-sensitive building materials or furnishings. Note that the caution against condensation and long-term average surface relative humidity above 80% applies not only to visible surfaces in occupied spaces but also to any moisture-sensitive materials inside hidden building cavities and unconditioned spaces (Harriman et al. 2001).
- Ensure that large-capacity humidifiers are installed as multiple modular stages rather than a single large units, and controlled so they do not overload the air with humidity, reducing the risk of condensation inside air distribution systems or inside exterior walls and roofing assemblies (Harriman et al. 2001).
- Ensure that cold HVAC and plumbing components and systems such as chilled-water pipes and valves, supply air ducts, cold domestic water lines, and cold condensate drain piping are sufficiently insulated to keep the temperature of all of their surfaces at least 10°F above the dew point of the surrounding air. Note that pipes often pass through unconditioned spaces such as basements, crawlspaces, and attics. Any insulation on chilled piping must be continuous and complete, and also be equipped with an effective vapor retarder, or be itself a vapor retarder to limit high surface relative humidity on such cold pipes as they pass through high-dew-point spaces and building cavities (Harriman and Lstiburek 2009).

3.2 ARCHITECTURAL FACTORS

Risk Factors

- Vinyl wall covering on exterior and demising walls of buildings in hot and humid climates. Problems have frequently occurred

behind vinyl wall covering when the building lacks a continuous, sealed air barrier that effectively keeps humid outdoor air out of the cavities inside the exterior and interior walls (Harriman and Lstiburek 2009).

- Damp basements and crawl spaces (DOE 2005). In residences in cold climates, humid air from damp basements and crawlspaces is often carried upward into a cold attic by stack effect. The moisture condenses into the roof sheathing and supports mold growth. In hot climates, the water vapor may condense or be absorbed into the flooring of the first floor, because that surface has been cooled by air conditioning in the occupied space.
- Water accumulating next to or under the building's foundation, often because of exterior grading that has compacted inward towards the foundation after freeze/thaw cycles in cold climates, or because of decorative edging around shrubbery that creates a pond near the foundation (ASTM 2010; Rose 2005).
- Rain leaks through joints around windows, doors, or other wall penetrations such as through-wall air-conditioning units, electrical fixtures, exhaust ducts, or structural fasteners, or leakage through joints where different types of exterior cladding come together (Harriman and Lstiburek 2009).
- Absence of effective flashing around windows, doors, skylights, and other penetrations of the building's walls or roof (ASTM 2007).
- Absence of an effective, continuously sealed air barrier covering all six sides of the building envelope, allowing leakage of humid air from either indoors or outdoors into cool exterior walls, crawlspaces, roof assemblies, or attics (see Chapter 44) (ASHRAE *Standard* 90.1).
- Absorptive exterior cladding such as brick veneer, stucco, or masonry, which retains rainwater but is not backed by a free-draining and vented air gap in front of a water-resistant vapor barrier equipped with effective flashing (Derome and Saneinejad 2009).

Risk Mitigation

- Roof overhangs of at least 24 in. or more (CMHC 1998). In both tall and low-rise buildings, a roof overhang greatly reduces the volume of rainwater that ends up on the wall.
- Pan flashing under windows and doors to force any water leakage outward onto an effective water barrier and then out of the building wall (Harriman and Lstiburek 2009; ASTM *Standards* D7338, E2112; JLC 2007).
- Crawlspaces lined with water and vapor barriers that are sufficiently sealed to prevent infiltration into the building from surface water and moisture from the soil and humid air (DOE 2005).

3.3 BUILDING OPERATIONAL DECISIONS

Risk Factors

- Failing to effectively exhaust humid air from showers, spas, decorative water fountains, indoor landscaping irrigation, and swimming pools. When the weather is hot and humid, a related problem is failure to dry outdoor air brought into the building to replace exhaust air.
- In cold weather, humidifying indoor air to dew points high enough to create condensation or surface relative humidity above 80% or water activity above 0.8 at the surface of moisture-sensitive surfaces inside walls, above insulated ceilings, or in attics for extended periods (e.g., days, weeks).
- Failing to ensure that the temperature of chilled-water systems stays low enough, and that flow rates through the coils stay high enough, to effectively dry the air when the chilled-water systems are the only means of removing excess humidity from the building. This problem often occurs when chilled-water temperatures are reset to save energy when the building is unoccupied during

hot and humid weather; under these circumstances, a separate dehumidification system may be necessary to prevent problems associated with persistent dampness (Harriman et al. 2001).

Risk Mitigation

- Mop and dry up spilled liquids or wash water promptly, limiting the amount of water that soaks into walls, carpeting, or flooring materials.
- Repair plumbing leaks quickly, and dry up any water leakage that resulted from such leaks within 24 to 48 h.
- Keep irrigation spray heads aimed carefully away from the building, preventing the frequent soaking of exterior walls and foundation.
- Maintain the slope of exterior landscaping so that rainwater and irrigation spray flows away from the foundation rather than accumulating there.
- Keep rainwater runoff from the roof at least 3 ft away from the foundation.
- Prevent microbial growth in HVAC components and air distribution systems, and remove mold and other microbial contaminants from air flowing through HVAC systems, to prevent contaminants from being distributed throughout the building (ACGIH 1999; AIHA 2008; EPA 2001).

3.4 OCCUPANT DECISIONS

Risk Factors

- Failing to use either fans or window openings to effectively exhaust humid air from cooking or from baths and showers, especially in small homes or apartments with many people or long cooking operations that lead to a large percentage of hours per week or month at a high indoor dew point.
- Failing to effectively exhaust humid air from clothes driers or indoor drying racks. The problems associated with this error are especially severe during cold weather, when exterior walls and attics are cold, creating large condensing surfaces.
- Growing an unusually large number of live plants indoors, without exhausting or otherwise removing the humidity they respire. Problems created by this oversight can be especially severe in cold climates.
- In cold weather, humidifying the indoor air to dew points high enough to create condensation or surface relative humidity above 80% or surface water activity or materials inside cooled walls and attics for days or weeks at a time.
- Storing large amounts of documents, furniture, or cardboard boxes in damp basements or crawlspaces, or in contact with cool walls or foundations.

Risk Mitigation

- Keep shower or tub splash within the tub enclosure, limiting the amount of water that can soak the floor or walls.
- Mop and dry spilled liquids or wash water promptly, limiting the amount of water that soaks into walls, carpets, or flooring materials during cleaning operations, and dry any water that remains within 24 to 48 h.
- Repair plumbing leaks quickly, and dry any water accumulation within 24 to 48 h.
- Keep irrigation spray heads aimed carefully, preventing repeated soaking of exterior walls and foundation.
- Maintain the slope of the landscaping so that rainwater and irrigation runoff flows away from the foundation rather than accumulating there.
- Keep rainwater runoff from the roof at least 3 ft away from the foundation.
- Remove mold and other microbial contaminants from the residence promptly, using appropriate engineering controls such as

high-efficiency particulate air (HEPA) air filtration and temporary negative pressure containments to keep contaminants from becoming airborne and distributed throughout the building (ACGIH 1999; AIHA 2008; EPA 2001; IICRC *Standard S520*).

4. SOLUTIONS

4.1 ARCHITECTURE AND DESIGN

Suggestions in this section are traditionally within the control of the owner, architect, and general contractor. These can help accomplish three tasks that reduce the risk of indoor dampness: (1) keep rain off and away from the building envelope, (2) help materials drain water and resist its effects when leaks eventually occur, and (3) keep humid air from infiltrating into the building envelope (especially through the historically problematic large gaps in the long joints where the roof meets the walls).

Sill Pans and Flashing

To be effective, flashing must extend around the entire perimeter of windows and doors. It must be designed and installed so that any water leak above, beside, or through the window framing or door is caught by a watertight pan under the window or door, and redirected back out of the wall and onto the waterproof drainage plane.

The architectural designer (as opposed to the craftsperson installing the flashing) is in the best position to define how all the layers in the wall must be integrated with this flashing. For best results, the architectural plans should show the layer integration in isometric projection, with each layer and its installation sequence defined and illustrated. Most importantly, the architectural drawings need to clearly show how these layers all come together in the corners.

Many designers assume that flashing integration is a question of means and methods, and therefore a contractor responsibility. Depending on the contracts, this may sometimes be the case. But in most situations, designing and detailing the exterior walls with all their complex layers and corners is better left to the architectural designer. This is especially true of the complex inside and outside corner details. It is rarely sufficient to design the layers in section drawings and then hope that the contractor will be able to guess how they are supposed to meet in the corners and still be watertight. The three-dimensional integration of the flashing layers, especially the sill pan flashing, is usually the responsibility of an architectural designer.

When there are no drawings to show in three dimensions the sill pans, the window flashing at the head and jambs, and how all the layers go together in the corners, the architectural design of the flashing is effectively assigned to the installer. That may not always be the person who is best equipped to make complex decisions that involve both form and function as well as material compatibility, construction sequencing, economics, and long-term durability. Additionally, even very capable craftspeople are rarely compensated financially for absorbing responsibility for such design decisions.

Waterproof Drainage Plane

To further reduce risks, exterior walls can be designed with a three-part drainage plane behind the exterior cladding. An effective drainage plane consists of three components:

- Waterproof drainage layer with flashing at its base that forces any water leakage back out of the wall assembly.
- Air gap to allow smooth flow of any leakage water down the surface of that waterproof layer.
- Flashing that prevents water from entering the wall above and around penetrations (e.g., windows, doors, air-conditioning unit sleeves). The flashing is integrated with the waterproof layer such that any leakage water is eventually redirected back out of the wall to the weather side of the cladding.

In theory, exterior cladding can be designed as a barrier system, so that no water ever gets into the exterior wall. However, in practice, whether due to extreme weather or oversight during construction or aging of materials, some water usually gets in.

In some cases, the wraparound air barrier described in the following section can also act as the waterproof layer, if (1) both design and installation of the joinery are done carefully, and (2) the air barrier is adequately supported to minimize flexing. There is no inherent conflict between the functions of air barrier and water barrier; both are vapor permeable. However, keep in mind that an air barrier must be structurally strong enough to resist the full design wind load, and a waterproof membrane needs to remain waterproof. If an air barrier flexes and stretches over time under wind loading, its seams may not remain waterproof. Also, with sheets it is important to remember that the waterproof layers must overlap shingle style, so that each seam sheds water rather than traps it.

Combining the functions of water barrier and air barrier is especially doable when using spray-applied, vapor-permeable but waterproof membranes. However, when the sheets are assembled into a combined air barrier/waterproof layer, all joinery must resist wind loads over time, and it must be detailed to ensure that all its joints and seams shed water.

In addition to the air barrier and waterproof layer, buildings clad with brick, stone, or stucco need exterior vapor barriers because these materials act as moisture reservoirs: unless equipped with specialized coatings, they soak up rainwater. This is not always a problem for the material itself, but it often creates problems for more moisture-sensitive sheathing behind that cladding. Solar heat drives large amounts of hot water vapor out of the cladding and inwards into the sheathing. It is important to line the drainage gap for brick or stucco with a vapor barrier, and that layer may as well act as the waterproof layer and air barrier as well.

Keep in mind that although exterior waterproof layers and air barriers are needed in all buildings, vapor barriers are needed in a much smaller percentage of buildings and must be thoughtfully located to avoid problems. Walls must be able to dry, ideally both inwards and outwards. Exterior vapor barriers have often prevented this necessary drying. Except behind the claddings described above, it is usually best to avoid exterior vapor barriers in hot and mixed climates. In cold climates, if any vapor barrier is needed it should be located toward the inside surface of the wall, not its outside surface.

The basic goal is to keep humid air out of any cold wall. In the cold-climate situation, the humid air is on the inside, so a combination vapor barrier/air barrier is useful in that location. In the hot climate, an air barrier (not a vapor barrier) located near the outside of the wall is usually the best way to keep humid air out of exterior walls that are chilled by the indoor air conditioning. However, the optimal location for a vapor barrier is complex and depends on many other factors that are beyond the scope of this chapter. For more about the different functions and locations for vapor barriers, air barriers, and waterproof layers, see Chapter 26 of the 2013 *ASHRAE Handbook—Fundamentals* and Chapter 44 of this volume.

Wrap-Around Air Barrier

Continuous exterior air barriers reduce the risk of indoor moisture problems. Continuous air barriers should not leak air around windows, or through gaps around wall penetrations. Also, the air barrier must continue up the walls and connect with airtight integrity to the roof assembly's air barrier. In short, the ideal air barrier is continuously sealed around all penetrations and fasteners, and it must wrap around the entire building. A continuous air barrier reduces the risk of moisture problems and also saves energy.

If warm, humid air outdoor leaks into a building, its water vapor may condense on indoor assemblies and materials cooled by the air conditioning system. These cool surfaces absorb moisture from

infiltrating humid air, degrading materials and increasing the risk of corrosion and failure of structural fasteners. Also, leaking air imposes an additional load on the air-conditioning system, reducing its ability to keep the dew point low enough to prevent moisture-related problems.

Most air leakage occurs where the walls meet the roof. In traditional designs, this roof/wall joint was sometimes designed to leak (e.g., vented soffits). However, air leakage has proven highly problematic for humidity control, moisture control, and energy consumption. The state of the art is to design and construct buildings that do not leak air, as reflected in the guidance of ASHRAE *Standard* 90.1 and the requirements of building codes in Canada and standards for U.S. government buildings. From a moisture control perspective, pay special attention to air barrier continuity at the roof/wall joint, which is where major air leaks usually occur.

Mold-Resistant Gypsum Board

When gypsum board is used on or inside exterior walls, or installed over interior concrete or masonry walls, it is prudent to specify products certified by the manufacturer to be resistant to mold growth and moisture damage. Although cement board is generally the preferred material for the lining of showers and bathtubs, any additional gypsum wall board installed in the walls or ceilings of bathrooms, shower rooms, or laundry rooms should also be resistant to moisture and mold growth.

In addition, it is useful to specify that any masonry or concrete covered by gypsum board must be dried to the required moisture content specified by the gypsum board manufacturer. The logic for this suggestion is easily apparent: in parts of the building which can often be moist, it is wise to use moisture-tolerant and mold-resistant wall board. These products provide a useful degree of tolerance for common shortcomings of conventional construction, which begin with construction moisture. Excess construction moisture and plumbing leaks have been responsible for mold and moisture problems in buildings in all climates. In hot and humid regions, rain is a constant challenge on construction sites; in cold climates, the construction season is so short that the building must often be closed in before the concrete and block have had enough time to dry out with ambient air circulation alone.

Mold and moisture problems do not happen in the concrete or masonry block itself, because those materials are moisture tolerant. Problems arise when flooring adhesives are applied over damp concrete, or when untreated, paper-faced gypsum wall board covers damp masonry block.

Exterior walls also benefit from moisture-tolerant wall board. Water leakage and humid air infiltration are probable at some point during the life of the building, no matter how well built it is at the beginning.

Finally, beyond construction moisture and potential rainwater leakage into exterior walls, there are the usual problems with plumbing leaks and indoor water spills. In bathrooms, shower rooms, and laundry rooms, high humidity and water spills are unavoidable. So, to limit risks from these everyday low-level moisture accumulations, it is useful to install moisture-tolerant and mold-resistant products in parts of the building that are likely to become wet.

Permeable Interior Finish for Exterior Walls

To reduce risks of trapping moisture inside walls, specify that any paint or other wall finish for the indoor surface of an exterior wall must have a net value above 15 perm, including the effect of any adhesive.

Impermeable vinyl wall covering on the indoor surface of exterior walls has proven to be frequently problematic, especially in hot and humid climates. In tens of thousands of buildings, vinyl

wall covering has been largely responsible for massive mold growth inside exterior walls. The vinyl acts as a vapor barrier, preventing effective drying of moisture that often collects inside exterior walls. Moisture can accumulate through many mechanisms, including leaks in the drainage plane, aging of joints, or humid outdoor air infiltrating and condensing moisture in the material behind the vinyl. There is no practical way to prevent 100% of occasional episodes of moisture accumulation, so it is imperative that moisture not remain trapped inside the wall, as usually happens when vinyl wall covering is adhered to exterior walls.

The same problem can occur with certain types of paint, notably the epoxies and high-durability latex paints. So it is useful to require that any paint or wall covering must have a perm rating above 15 if it is installed on the indoor surface of the exterior wall.

In recent years, manufacturers have developed permeable or semipermeable vinyl wall covering. The actual permeability of these products varies considerably. Risks of moisture accumulation can be reduced by specifying that the system as a whole (wall covering plus its adhesive) must have a wet-cup perm value (ASTM *Standard* E96-00) above 15.

Roof Overhang

Ideally, the roof should project at least 2 ft beyond the walls all around the building. This greatly reduces the risks of water leakage, because much less rainwater ends up on the walls over the life of the building.

The baseline risk of mold and moisture problems depends on how much water contacts the exterior walls. More hours of contact and a higher volume of water generates more risk when gaps and cracks occur by design, or during construction, or over the building's lifetime. The further the roof extends beyond the walls, the less rainwater will flow down those walls to challenge every joint and seam.

A roof projection of about 2 ft is likely to cut the annual rain volume flowing down the walls and windows by roughly 50%. The exact reduction depends on many factors, but 50% is a reasonable approximation of the load reduction value of an overhang. Longer projections are even better because they reduce the rain volume still further. But studies of moisture problems in buildings indicate that even in very rainy climates, very few major moisture problems occur where the roof projection is at least 2 ft beyond the exterior walls (CMHC 1998). As a side benefit, the wider the overhang, the greater the reduction in cooling load, which reduces energy consumption in air-conditioned buildings.

A useful option for taller buildings is to increase the length of the overhang. Interestingly, in high-rise buildings, most of the annual rain load reaches the building as it blows in from the sides during periods of wind-driven rain; the building's 2 ft overhang catches the approaching wind and forces it to roll into a protective cylindrical air mass near the roof line. That rolling cylinder of air acts as a sort of dry protective bumper, moving most of the oncoming rain-laden wind up, over, and around. Consequently, most of the rainwater never reaches the surface of the building.

4.2 HVAC SYSTEMS

Suggestions provided here are traditionally under the control of the HVAC designer, installer, and the building operations staff. These steps can reduce risks by ensuring that the indoor dew point stays below the typical surface temperatures of an air-conditioned building and its HVAC components. They also save energy and reduce the risk of moisture accumulation by preventing cold air from escaping from ducts to chill indoor surfaces, and by avoiding the problems created when humid outdoor air is pulled through walls and through attics instead of through the HVAC system.

Dedicated Outdoor Air Systems (DOAS)

There are many reasons to separate a building's ventilation air system from its heating and cooling systems by using a DOAS, but from the perspective of reducing risk of moisture accumulation, the most important reason is to ensure that incoming outdoor air is always dried below the indoor dew point. Additionally, if the DOAS units are equipped with return air connections, they can act as effective whole-building dehumidifiers when the building is unoccupied or when the ventilation air flow requirement is reduced.

If incoming ventilation and makeup air is not dried out before it enters the building, it is very difficult to keep excess humidity from being absorbed into the building's interior finishes and building materials. Incoming ventilation and makeup air typically carries more than 80% of the building's annual dehumidification load; if this load is not intercepted and removed by a dedicated dehumidification component such as that typically included in a DOAS system, the cooling equipment will struggle to remove the humidity load and often overcools the building as a result. Overcooling leads to discomfort, energy waste, and cooler surfaces. Figure 4 illustrates the consequences in a building that was overcooled instead of dehumidified, resulting in moisture absorption by those cold surfaces and subsequent mold growth. (Note that this level of mold growth occurred in spite of hospital-grade, nonabsorptive epoxy wall paint.)

Maximum 55°F Indoor Dew Point for Mechanically Cooled Buildings in Hot or Humid Climates

Another way to reduce the risk of building moisture problem is to design the HVAC systems so they remove enough humidity to keep the indoor dew point below 55°F during both occupied and unoccupied periods.

Support for this maximum is documented in ASHRAE publications based on the collective experience and judgment of the authors and reviewers of those publications (Fischer and Bayer 2003; Harriman and Lstiburek 2009; Harriman et al. 2001; Spears and Judge 1997). Note, however, that the 55°F control level is not yet incorporated in an ASHRAE standard and has therefore not been subjected to public review. Consequently, each owner and designer must decide what indoor dew point maximum is prudent, given the climate, the needs of the building, and the risks for that building and its

Fig. 4 Mold Resulting from Humid Air Infiltration in Overcooled Health Clinic

occupants from any moisture or microbial growth problem. The following logic behind this control level should help readers use their own judgment about the prudent maximum dew point for different types of buildings, occupancies, and climates.

Keeping the dew point below 55°F protects the building from indoor condensation and excessive moisture absorption into cool surfaces. The 55°F dew point also allows comfort at higher dry-bulb temperatures, which reduces cooling energy consumption and provides comfort for a wider variety of activity levels and body types. At or below a 55°F dew point, occupants rarely need to overcool the space in order to achieve comfort (Fischer and Bayer 2003; Spears and Judge 1997).

Another reason for specifying a dew point maximum in place of a relative humidity maximum is that, in the past, guidance based on relative humidity has been ineffective in preventing moisture accumulation and the associated problems. A maximum 65% rh has been a traditional criterion, and some standards and codes still suggest that as a limit, but building failures have shown that this criterion is not always effective in preventing mold. Consequently, recent publications from ASHRAE, the U.S. Environmental Protection Agency (EPA), and U.S. General Services Administration (GSA) recommend a maximum dew point as a reasonable compromise between the competing goals of energy consumption, comfort, and mold avoidance during both occupied and unoccupied hours (EPA 2013; GSA 2014; Harriman and Lstiburek 2009; Harriman et al. 2001).

The basic problem with the 65% rh maximum is that it does not address what happens at the surface of cool materials, which is where problems occur. For example, consider 65% rh in an unoccupied office or day care center closed at night, or on weekends. The building's thermostat is often reset to 85°F to save energy. At that temperature, 65% means air has a dew point of 73°F. When the air-conditioning system begins to chill the building back down for occupied operation, any surface now cooled to 73°F has a surface relative humidity of 100%, not the 65% value shown by the HVAC control sensors (which measure the air). Air-conditioning systems' humidity sensors cannot measure the surface relative humidity on all of the cold surfaces on and behind the walls and above the ceilings.

Keeping the indoor air at or below a 55°F dew point avoids such confusion and provides an effective margin of safety for keeping building materials dry. At that dew point, the relative humidity at cool surfaces is very unlikely to rise to levels that promote the amount of mold growth shown in Figure 4.

Holding a building below a 55°F dew point is a conservative suggestion for standard operation, representing the collective experience of many who have investigated moisture problems in buildings. This limit will almost certainly reduce the risks of moisture problems caused by HVAC issues to a negligible level, and also reduce the risks of minor water leakage associated with architectural design and construction. Although the lower dew-point limit may also save energy, cost increases in terms of equipment and operating expense are possible. Many buildings all over the world have exceeded this criterion for a significant portion of their operating hours without any documented moisture or mold problems. Whether problems arise depends on many factors, including the sensitivity of the building material and of the furnishings and finishes, and (perhaps most importantly) the number of hours that interior surfaces are able to absorb moisture from the indoor air. The number of high-dew-point hours varies with climate, and often varies according to the design and operation of the HVAC system. More hours at high dew point increase risks, but do not guarantee failure.

Experience [e.g., Harriman and Lstiburek (2009); Harriman et al. (2001)] also shows that, at high indoor dew points, occupants are very likely to turn down the thermostat to gain comfort, which increases energy consumption. Again, these difficulties will be more problematic as the number of humid hours outdoors increases.

Climate. In cool climates or high-altitude locations with only a few hundred hours of outdoor dew points above 55°F and a few hundred hours of air conditioning, the risk of higher indoor dew points above may be relatively low. Any problems would usually take many years to develop, if they indeed ever happen. But in mixed or humid climates where there are many thousands of hours when the outdoor dew point is above 55°F and where the air-conditioning season (i.e., when building surfaces are chilled) is long, problems may develop in a few months or a few years.

Design for Dehumidification Based on Loads at Peak Outdoor Dew Point

Peak dehumidification loads occur when the outdoor dew point is at its highest level—not when the outdoor dry bulb temperature is at its peak. In absolute terms, the outdoor humidity is 30 to 35% higher at the peak dew point condition compared to the humidity load at the peak dry bulb condition.

Figure 5 shows the effect of this difference on the humidity loads of a medium-sized retail building that complies with the requirements of ASHRAE Standard 62.1-2010. When the humidity loads are calculated at peak outdoor dry-bulb temperature, the load calculation grossly understates the humidity load occurring when the outdoor air is at its local peak dew point. Note also that magnitude of this unexpected difference in humidity loads is usually greatest in continental climates (e.g., Beijing, Cincinnati) rather than coastal

climates (e.g., Miami, Hong Kong). To avoid the risk of major shortcomings in the design of the dehumidification components, the designer should use the peak dew point values for dehumidification load calculations. Peak dew-point design values for more than 6000 weather locations are provided in Chapter 14 of the 2013 *ASHRAE Handbook—Fundamentals* and on the CD accompanying that volume.

Mastic-Sealed Duct Connections

To reduce the risk of problems from humid air infiltration into the building and the risks of problems from chilling hidden surfaces in building cavities, specify that all air system connections and seams must be both mechanically fastened and covered with durable mastic. Such an air sealing requirement also logically extends to connections to air handlers and to air distribution components such as filter boxes, fans, cooling and heating coils, and variable-air-volume (VAV) boxes. Less obviously, the requirement to seal duct connections also extends to all joints in exhaust air duct work.

Air leakage into and out of duct connections has been responsible for many of the most expensive and difficult-to-repair mold problems in buildings. Leaking exhaust duct connections pull air from interstitial spaces, much of which is replaced by untreated outdoor air leaking in through construction joints in the exterior wall. The suction created by the exhaust fan ensures that this humid air infiltration is large, and in many cases, continuous. See Figure 1 for the results of this shortcoming in HVAC and architectural design.

The same thing happens when return air duct connections or plenums leak. The suction of the system creates local negative pressures, which lead to humid air infiltration and subsequent moisture absorption by cool indoor surfaces.

On the positive-pressure side of the fan, any leaks mean that cold air escapes the duct, cooling surfaces behind walls, under floors, and above ceilings. Those cold surfaces can either condense moisture from humid air, or absorb moisture because their surface relative humidity is very high. Both problems result in mold.

The other problem with leaking connections and plenums is that they waste energy. In theory, if the leak is inside the thermal boundary, all the cooling energy stays indoors; in fact, if the cooling capacity is where it is not needed (e.g., in the attic, above the ceiling), the air-conditioning system must work harder and longer to get the needed cooling to the occupied zones. Thus, any air leaks waste fan capacity, fan power, and compressor energy.

Duct tape has been used to satisfy a duct sealing requirement, but this material has often proven inadequate over time. Field experience does not usually match the expectations set by the warranty of duct tape. Durability warranties are only for “properly applied” material in “properly designed” and “properly installed” joints. Apparently, it is more difficult to properly apply the duct tape than might be expected, because over time duct tape has proven to be unreliable as an air seal. Connections that are mechanically fastened and sealed with mastic have not shown the same number or degree of problems.

According to measured data from field studies in California, Florida, New York, and Iowa, air leaks from duct connections waste between 25 and 40% of the annual energy needed to heat and cool the building (Cummings et al. 1996; Henderson et al. 2007; Wray 2006). Consequently, without airtight duct connections, the building is not likely to meet energy reduction targets no matter how efficient the heating and cooling equipment might appear from its ratings. Solving this problem is critical for reaching energy reduction targets: all air-side connections must be sealed with mastic, and unsealed plenums must not be used for either supply or return air systems.

Positive Building Pressure When Outdoor Dew Point Is Above 55°F

During the cooling season, risks of humid air infiltration can be reduced by providing more dry outdoor air to the building than

Fig. 5 Peak Dry-Bulb and Dew-Point Design: Retail Store Humidity Loads Based on ASHRAE Standard 62.1-2010

the sum of the exhaust air streams. To reduce the risk of moisture problems during hot and humid weather, it is better to have any air leaks going out of the building. By providing a slight excess of dry ventilation and makeup air, most of the leakage will be from indoors to outdoors, so that air inside the exterior walls will be dry instead of humid. This keeps the building's materials from absorbing moisture, and the slight outward flow of dry air helps dry out rain leakage that sometimes finds its way into exterior walls.

In most buildings, it is not necessary maintain a specific, defined pressure difference between indoors and outdoors to reduce risks of moisture problems. It is usually enough to design and commission the system so that more air enters the building than is being exhausted. In the real world, it is nearly impossible to maintain a defined pressure difference at all points across the exterior wall at all times. The wind outdoors changes pressures on the exterior wall many times per second, and any system attempting to maintain a fixed difference across an exterior wall is likely to waste cooling, dehumidification, and fan energy by keeping the building overpressurized much of the time.

The reason for the slight positive pressure is simply to keep most of the leakage going out rather than going in, most of the time. As long as that modest goal is achieved, and provided that the other risk reduction measures are installed, the exact amount of positive pressure does not really matter. Less is better, in this case: 10% more air makeup than the total exhaust air is a long-standing rule of thumb, but with modern airtight buildings and airtight duct connections, 5% excess outdoor air is often sufficient.

To minimize energy waste, modern designs sometimes reduce both exhaust and ventilation air streams according to occupancy. The preferred way to do this is to interlock the DOAS system with the exhaust fans. As the exhaust fans reduce speed or turn off, reduce the airflow through the DOAS system, keeping the total outdoor air higher than the total exhaust air. This is often a more practical method than using pressure control. With a very small pressure difference as the target, the system would be constantly hunting (i.e., running the fan speeds up and down, attempting to provide just the right pressure difference).

Winter weather presents a different problem. During the heating season, the humid air is now on the inside of the building rather than the outside. It can be counterproductive to keep blowing warm, humid indoor air outward through the cold exterior enclosure, where it is likely to condense and create problems. During the heating season, airflows should target neutral pressure. In cold climates, big moisture and mold problems happen when humid indoor air is pushed into cold exterior walls. Also, a great deal of energy is wasted by heating excess outdoor air to keep buildings under an arbitrary positive pressure during cold weather. There is no energy or mold risk reduction benefit to positive pressure during cold weather.

5. MEASURING BUILDING DAMPNES

The term *dampness* does not yet have an agreed-upon quantitative definition. This fact makes it difficult to assess the often discussed risks of damp buildings in a way that is comprehensive, repeatable and economically practical. The ASHRAE Board of Directors has called for research to develop a quantitative definition of building dampness that is relevant to health concerns, and to develop a companion assessment protocol that provides practical and repeatable results (ASHRAE 2013). Until such efforts are completed, the suggestions in this chapter will be confined to helping those who wish to understand the means of measuring the key factors that influence mold growth.

Contrary to popular impression, mold growth is not a direct function of humidity in the air, nor is it a function of the amount of air

circulation in a space or sunlight on a surface. These factors influence mold growth only indirectly, based on the extent that they allow moisture accumulation in a material that serves as a nutrient source. When the amount of moisture in its food source reaches a critical range, mold enzymes can begin to dissolve the nutrient material, creating a solution that is pulled into the mold's cell walls to sustain and encourage further growth. As long as all carbon-based building materials, coatings, and dusty surfaces are kept dry, mold cannot access the nutrients it needs to grow and reproduce (Harriman et al. 2001).

5.1 WATER ACTIVITY

When moisture in a material is loosely bound, then its moisture is more easily accessed by mold. Given equal temperature and nutrient value for any given mold type, the factor that most governs growth is not material moisture content, but rather how tightly that moisture is bound into the material's molecular structure. The concept of **water activity** provides a means of quantifying the biological growth potential of a damp material by measuring how tightly moisture is bound in a material. Consequently, it is the metric used by biophysicists and mycologists to define mold growth potential. It is the ratio of the water vapor pressure in the material to the water vapor pressure in the surrounding air, if that air were to be fully saturated at the same temperature as the material. (A useful engineering shorthand description is that water activity provides a measure of the bioavailability of water in a material. High values mean that water in the material is more easily accessible to bacteria and fungi. Lower water activity values mean that the material's moisture is more tightly bound and therefore less available to support fungal and bacterial growth.)

Water activity is measured most accurately by sealing the material in question into a small container, and then allowing the air inside that container to come into complete hygrothermal equilibrium with the material. The temperature of both air and material must be identical, and the air in the sealed container must have the same relative humidity as the air inside the pores of the material. After the hours or days necessary for both variables to reach simultaneous equilibrium, water activity of the material is measured by reading the relative humidity inside the sealed container. Water activity is reported as the decimal equivalent of the equilibrium relative humidity. For example, relative humidity measured at 80% after complete hygrothermal equilibrium inside the sealed container is reported as a material water activity of 0.80.

Water activity as low as 0.75 has allowed slow mold growth in an ideal laboratory environment of constant temperature and moisture, in an nutrient-rich and biologically accessible growth medium such as a Petri dish filled with malt extract agar. However, building materials are typically formulated to avoid mold growth. Also, in a building environment, damp areas usually benefit from a small amount of drying through normal HVAC system operation. Consequently, measured values of water activity below 0.75 usually indicate a low risk of mold growth even in the most nutrient-rich building materials and coatings.

Measuring water activity in buildings can never be identical to measurements in a sealed container in a lab environment, because nothing is ever at complete hygrothermal equilibrium in buildings. Materials are always gaining and losing small amounts of both heat and moisture, even when there is no excessive dampness. Also, it is not practical to seal up entire installed building components into a tightly sealed small container, much less wait the days, weeks, or months necessary for such a sealed container's air and the material to reach identical temperature and relative humidity. When water activity measurements are made in a building, they are more accurately described as the **near-equilibrium surface water activity** rather than as the biophysically defined term of water activity. Given

that water activity is abbreviated as A_w , to avoid confusion with the microbiological literature of the late twentieth century the building-relevant near-equilibrium surface water activity should be abbreviated as A_{ws} .

Surface water activity measurements are made in buildings by attaching a relative humidity sensor within a few millimetres of a target surface, and then covering both sensor and target location with a shield that isolates the two from direct contact with the surrounding air and any air movement. An ideal sensor attachment and shielding approximates the environment of the sealed container used in laboratory measurements while not impeding the lateral diffusion of heat and moisture within the material that occurs in any normal building environment.

5.2 MOISTURE CONTENT MEASUREMENT VARIATION

Although moisture content and water activity are not the same thing, it is often true that when a material has a high moisture content, it may also have a high water activity. When water activity measurements are not available, moisture content measurements can provide a potentially useful quantitative indicator of relative dampness. It is important to remember, however, that there is usually a wide variation between moisture content readings taken in nearly the same location. There are two principal causes of this variation: different exact measurement location and different scales and measurement technologies of moisture meters.

Different Measurement Locations

Figure 6 shows the variation in moisture content readings in the same material, in the same environment separated by a distance of less than 6 in. Mold growth is apparent where the moisture content reading is above 20% wood moisture equivalent (WME). Just a few millimetres away, the same meter shows the moisture content to be less than 15% WME, and in that location, no mold growth is visible. This figure illustrates two key points about moisture content measurements: they can and do vary widely within a few millimetres,

and small differences in measured moisture content can lead to big differences in mold growth rates.

Different Moisture Meters

Different types of moisture meters use different measurement principles, and each manufacturer generally chooses to scale the measured values differently. Therefore a moisture content reading of 26% has no useful meaning until both the meter model and the meter's scale are defined. Figure 7 shows why this issue is important in assigning any level of concern based on readings from undefined moisture meters. It shows that readings from different meters provide very different values when connected to the exact same electrodes planted in the same material at the exact same moment. This is not a matter of meter accuracy, but rather because each moisture meter manufacturer designed both the measurement principle and the scale for different purposes, and each different material has different electrical characteristics that affect the meter reading.

Similar variability is also typical of water activity measurements in buildings, because of different means of attaching sensors to building assemblies. Consequently, the investigator concerned with assessing the extent of moisture and dampness in a building is well advised to

- Note the date and time, and document the exact location of readings using a camera (Figure 8)
- Record the manufacturer, model number, and measurement scale of the instrument used to make the measurements

Building owners, investigators, and those who read their reports should consider that observations and measurements made at a single moment, at a single location in a building are rarely representative of that entire building's behavior over the extended time frame and variability of normal building operations. Also, different types of building materials, building construction, and environmental exposures present quite different risks with respect to dampness. Consequently it is usually helpful to make repeated visual observations, interview building occupants, and take measurements in all

Fig. 6 Variation in Moisture Content and Mold Growth Across Short Distances

Fig. 7 Variation in Moisture Meter Readings on Same Material

Fig. 8 Example of Documenting Both Values and Pattern of Moisture

suspect locations over a representative time frame of days or weeks to obtain the information to support robust conclusions about the causes and risks of dampness in a given building.

CHAPTER 63

CODES AND STANDARDS

THE codes and standards and other publications listed here represent practices, methods, or standard published by the organizations indicated. They are useful guides for the practicing engineer in determining test methods, ratings, performance requirements, and limits of HVAC&R equipment. Copies of these publications can be obtained from most of the organizations listed in the Publisher column, from Global Engineering Documents at global.ihc.com, or from Techstreet at techstreet.com. Addresses of the organizations are given at the end of the chapter. A comprehensive database with over 300,000 industry, government, and international standards is at www.nssn.org.

Selected Codes and Standards Published by Various Societies and Associations

	Tube Fittings for Flammable and Combustible Fluids, Refrigeration Service, and Marine Use	UL	ANSI/UL 109-1997
Plastic	Specification for Acrylonitrile-Butadiene-Styrene (ABS) Plastic Pipe, Schedules 40 and 80	ASTM	ASTM D1527-99 (2005)
	Specification for Poly (Vinyl Chloride) (PVC) Plastic Pipe, Schedules 40, 80, and 120	ASTM	ASTM D1785-12
	Test Method for Obtaining Hydrostatic Design Basis for Thermoplastic Pipe Materials or Pressure Design Basis for Thermoplastic Pipe Products	ASTM	ASTM D2837-13e1
	Specification for Perfluoroalkoxy (PFA)-Fluoropolymer Tubing	ASTM	ASTM D6867-03 (2014)
	Specification for Polyethylene Stay in Place Form System for End Walls for Drainage Pipe	ASTM	ASTM D7082-04 (2010)
	Specification for Chlorinated Poly (Vinyl Chloride) (CPVC) Plastic Pipe, Schedules 40 and 80	ASTM	ASTM F441/F441M-13e1
	Specification for Crosslinked Polyethylene/Aluminum/Crosslinked Polyethylene Tubing OD Controlled SDR9	ASTM	ASTM F2262-09
	Test Method for Evaluating the Oxidative Resistance of Polyethylene (PE) Pipe to Chlorinated Water	ASTM	ASTM F2263-14
	Specification for 12 to 60 in. [300 to 1500 mm] Annular Corrugated Profile-Wall Polyethylene (PE) Pipe and Fittings for Gravity-Flow Storm Sewer and Subsurface Drainage Applications	ASTM	ASTM F2306/F2306M-14
	Test Method for Determining Chemical Compatibility of Substances in Contact with Thermoplastic Pipe and Fittings Materials	ASTM	ASTM F2331-11
	Test Method for Determining Thermoplastic Pipe Wall Stiffness	ASTM	ASTM F2433-05 (2013)
	Specification for Steel Reinforced Polyethylene (PE) Corrugated Pipe	ASTM	ASTM F2435-12
	Electrical Polyvinyl Chloride (PVC) Tubing and Conduit	NEMA	NEMA TC 2-2013
	PVC Plastic Utilities Duct for Underground Installation	NEMA	NEMA TC 6 and 8-2013
	Smooth Wall Coilable Polyethylene Electrical Plastic Duct	NEMA	NEMA TC 7-2013
	Fittings for PVC Plastic Utilities Duct for Underground Installation	NEMA	NEMA TC 9-2004 (R2012)
	Electrical Nonmetallic Tubing (ENT)	NEMA	NEMA TC 13-2005
	Plastics Piping System Components and Related Materials	NSF	ANSI/NSF 14-2014
	Rubber Gasketed Fittings	UL	ANSI/UL 213-2008
Metal	Welded and Seamless Wrought Steel Pipe	ASME	ASME B36.10M-2004 (RA10)
	Stainless Steel Pipe	ASME	ASME B36.19M-2004 (RA10)
	Specification for Pipe, Steel, Black and Hot-Dipped, Zinc-Coated, Welded and Seamless	ASTM	ASTM A53/53M-12
	Specification for Seamless Carbon Steel Pipe for High-Temperature Service	ASTM	ASTM A106/A106M-14
	Specification for Steel Line Pipe, Black, Furnace-Butt-Welded	ASTM	ASTM A1037/A1037M-05 (2012)
	Specification for Composite Corrugated Steel Pipe for Sewers and Drains	ASTM	ASTM A1042/A1042M-04 (2009)
	Specification for Seamless Copper Pipe, Standard Sizes	ASTM	ASTM B42-10
	Specification for Seamless Copper Tube	ASTM	ASTM B75/B75M-11
	Specification for Seamless Copper Water Tube	ASTM	ASTM B88-14
	Specification for Seamless Copper Tube for Air Conditioning and Refrigeration Field Service	ASTM	ASTM B280-13
	Specification for Hand-Drawn Copper Capillary Tube for Restrictor Applications	ASTM	ASTM B360-09
	Specification for Welded Copper Tube for Air Conditioning and Refrigeration Service	ASTM	ASTM B640-12a
	Specification for Copper-Beryllium Seamless Tube UNS Nos. C17500 and C17510	ASTM	ASTM B937-04 (2010)
	Test Method for Rapid Determination of Corrosiveness to Copper from Petroleum Products Using a Disposable Copper Foil Strip	ASTM	ASTM D7095-04 (2014)
	Thickness Design of Ductile-Iron Pipe	AWWA	ANSI/AWWA C150/A21.50-14
	Fittings, Cast Metal Boxes, and Conduit Bodies for Conduit and Cable Assemblies	NEMA	NEMA FB 1-2012
	Polyvinyl-Chloride (PVC) Externally Coated Galvanized Rigid Steel Conduit and Intermediate Metal Conduit	NEMA	NEMA RN 1-2005 (R2013)
Plumbing	Backwater Valves	ASME	ASME A112.14.1-2003 (RA12)
	Plumbing Supply Fittings	ASME	ASME A112.18.1-2012
	Plumbing Waste Fittings	ASME	ASME A112.18.2-2011
	Performance Requirements for Backflow Protection Devices and Systems in Plumbing Fixture Fittings	ASME	ASME A112.18.3-2002 (RA12)
	Uniform Plumbing Code (2012) (with IAPMO Installation Standards)	IAPMO	IAPMO
	International Plumbing Code® (2015)	ICC	IPC
	International Private Sewage Disposal Code® (2015)	ICC	IPSDC

ASHRAE HANDBOOK

Additions and Corrections

This report includes additional information, and technical errors found between June 15, 2012, and April 1, 2015, in the inch-pound (I-P) editions of the 2012, 2013, and 2014 *ASHRAE Handbook* volumes. Occasional typographical errors and nonstandard symbol labels will be corrected in future volumes. The most current list of Handbook additions and corrections is on the ASHRAE web site (www.ashrae.org).

The authors and editor encourage you to notify them if you find other technical errors. Please send corrections to: Handbook Editor, ASHRAE, 1791 Tullie Circle NE, Atlanta, GA 30329, or e-mail mowen@ashrae.org.

2012 HVAC Systems and Equipment

- p. 25.1, Fig. 1. Point E was omitted. The correct figure appears below.
- p. 26.2, Eq. (2a). In the rightmost fraction, change m_s to m_e .
- p. 26.12, Example 2. Flow rate for ethylene glycol should be in gpm.

Fig. 1 Dehumidification Process Points
 (2012 HVAC Systems and Equipment, Ch. 25, p. 1)

- p. 26.12, Fig. 13. The corrected figure is given below.
- p. 41.3, Fig. 3. Replace parts B and C of the graphic with the horizontal polymer tube shown on p. A.2.
- p. 44.8, Table 1. In both equations for flow and head, change the minuses to equals signs.
- p. 51.24, Fig. 25. The bottom right line should have the discharge arrow pointing to the left, and the charge arrow pointing to the right. The corrected figure is shown on p. A.2.

2013 Fundamentals

- p. 1.13, 2nd col. Above Eq. (38), change “ $t_d(p, w)$ ” to “ $t_d(p, W)$.”
- p. 1.14, 1st col. In the table for Situation 2, 3rd line, Comments column, change “ t_d ” to “ t .”
- p. 4.21, Solution for Example 10, starting in 3rd para. Compute h_i using Eq. (T8.5a). Delete f_s and its value. Nu_d should be 248.3, and h_i should be 1248 Btu/h·ft²·°F. Compute h_o using Eq. (T9.10a). Change Ra to 74 574, Nu to 7.223, h_o to 3.643 Btu/h·ft²·°F, and the equation for h_{ot} to $0.643 + 0.757 = 1.400$ Btu/h·ft²·°F. Change the last paragraph in the example as follows:

Solving for d_o makes the left side of Equation (42) equal to the right side, and gives $d_o = 1.576$ in. Now, using the new value of 1.576 in. for the outer diameter, the new values of h_o and h_{ot} are 0.680 Btu/h·ft²·°F and 1.437 Btu/h·ft²·°F, respectively. The updated value of d_o is 1.857 in. Repeating the process several times results in a final value of $d_o = 1.733$ in. Thus, an outer diameter of 1.7874 in. (corresponding to an insulation radial thickness of 0.5 in.) keeps the outer surface temperature at 75.4°F, higher than the dew point. [Another method is to use Equation (42) to solve for t_o for values of d_o corresponding to available insulation thicknesses and using the insulation thickness that keeps t_o above the dew-point temperature.]

- p. 9.19, 1st col. For Eq. (71), remove the minus sign before “ $(t_{sk} - 93.2)$.” In the following definitions, add that t_{bset} should be

97.68°F. In Eq. (72), change the minus in the denominator to a plus.

Ch. 14, climate data table for Esbjerg, Denmark. Please use the 2009 data for this location.

p. 15.17, Eq. (13). The equals sign belongs after “SHGC(θ).”

p. 15.29, Example 6, Solution. The first equation should read $q_s = q_b + q_d$.

p. 15.32, Eq. (40). Change “ $\min(1.0, 0.02 \times \Omega)$ ” to “ $\min(1.2\Omega, 60)/60$.” Add Barnaby et al. (2009) to the list of sources cited below.

p. 16.24, Table 8. The corrected table appears above.

p. 16.24, Example 5. The house’s flow coefficient c should be 4370 cfm/(in. of water)ⁿ. In the Solution, C_s should be 0.001478 [(in. of water)/°F]ⁿ and C_w should be 0.001313 [(in. of water)/mph]ⁿ. Consequently, the second and third equations should be as follows:

$$Q_s = 4370(0.001478)[68 - (-2)]^{0.67} = 110 \text{ cfm}$$

$$Q_w = 4370(0.001313)(0.64 \times 8.9)^{1.34} = 59 \text{ cfm}$$

Q is thus 125 cfm = 7490 ft³/h, and the final equation should be

$$I = (7490 \text{ ft}^3/\text{h})/(12,000 \text{ ft}^3) = 0.62 \text{ ach}$$

pp. 16.24–25, Example 6. The house’s flow coefficient c should be 6890 cfm/(in. of water)ⁿ. In the Solution, C_s should be 0.00893 [(in. of water)/°F]ⁿ and C_w should be 0.001074 [(in. of water)/mph]ⁿ. Consequently, the second and third equations should be as follows:

$$Q_s = 6890(0.00893)(29)^{0.6} = 46 \text{ cfm}$$

Fig. 25 Typical Sensible Storage Connection Scheme
(2012 HVAC Systems and Equipment, Ch. 51, p. 24)

$$Q_w = 6890(0.001074)(0.50 \times 2.9)^{1.34} = 12 \text{ cfm}$$

Q is thus 48 cfm = 2880 ft³/h, and the final equation should be

$$I = (2880 \text{ ft}^3/\text{h})/(9000 \text{ ft}^3) = 0.32 \text{ ach}$$

p. 16.25, Example 7. The house’s flow coefficient c should be 8740 cfm/(in. of water)ⁿ. In the Solution, C_s should be 0.001791 [(in. of water)/°F]ⁿ and C_w should be 0.001295 [(in. of water)/mph]ⁿ. Consequently, the second and third equations should be as follows:

$$Q_s = 8740(0.001791)(9)^{0.67} = 68 \text{ cfm}$$

$$Q_w = 8740(0.001295)(0.43 \times 6.7)^{1.34} = 47 \text{ cfm}$$

Q is thus 83 cfm = 4960 ft³/h, and the final equation should be

$$I = (4960 \text{ ft}^3/\text{h})/(14,200 \text{ ft}^3) = 0.35 \text{ ach}$$

p. 17.12–13, Fig. 1. The corrected figure is shown on p. A.3.

p. 18.35, 2nd col. Just above the Plenums in Load Calculations heading, the citation for the *UFAD Design Guide* should be ASHRAE (2013).

p. 18.41, 1st col. In equation for q_{15} , the last term on the first line should be $c_{23}q_{i,16}$.

p. 18.49, References. Delete the Bauman and Daly 2013 source, and replace it with the following:

ASHRAE. 2013. *Underfloor air distribution (UFAD) design guide*, 2nd ed.

p. 20.1, 1st col. Immediately after the bulleted list, change the paragraph as follows: “As shown in Figure 1, local temperature concentration has a similar profile, although its rate usually differs. Carbon dioxide (CO₂) follows a similar pattern.”

pp. 21.7–8. Renumber Figure 10 (Diffuser Installation Suggestions) as Figure 9, and Figure 9 (Friction Chart) as Figure 10.

ASHRAE Research: Improving the Quality of Life

ASHRAE is the world's foremost technical society in the fields of heating, ventilation, air conditioning, and refrigeration. Its members worldwide are individuals who share ideas, identify needs, support research, and write the industry's standards for testing and practice. The result is that engineers are better able to keep indoor environments safe and productive while protecting and preserving the outdoors for generations to come.

One of the ways that ASHRAE supports its members' and industry's need for information is through ASHRAE Research. Thousands of individuals and companies support ASHRAE Research annually, enabling ASHRAE to report new data about material

properties and building physics and to promote the application of innovative technologies.

Chapters in the ASHRAE Handbook are updated through the experience of members of ASHRAE Technical Committees and through results of ASHRAE Research reported at ASHRAE conferences and published in ASHRAE special publications, *ASHRAE Transactions*, and ASHRAE's journal of archival research, *Science and Technology for the Built Environment*.

For information about ASHRAE Research or to become a member, contact ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329; telephone: 404-636-8400; www.ashrae.org.

Preface

The 2015 *ASHRAE Handbook—HVAC Applications* comprises more than 60 chapters covering a broad range of facilities and topics, written to help engineers design and use equipment and systems described in other Handbook volumes. Main sections cover comfort, industrial, energy-related, general applications, and building operations and management. ASHRAE Technical Committees in each subject area have reviewed all chapters and revised them as needed for current technology and design practice.

An accompanying CD-ROM contains all the volume's chapters in both I-P and SI units.

This edition includes two new chapters:

- Chapter 61, Smart Building Systems, covers smart systems and technologies for automated fault detection and diagnostics, sensors, and actuators, and the emerging modernized electric power grid and its relationship to buildings and facilities.
- Chapter 62, Moisture Management in Buildings, addresses avoiding or reducing risks associated with damp buildings, with suggestions for architectural and HVAC system design, operation, and occupancy.

Other selected highlights include the following:

- Chapter 1, Residences, has updated guidance on duct system design and communicating control systems.
- Chapter 4, Tall Buildings, has new content on supertall and megatall buildings; improved stack effect discussion and calculations; and new information on chilled beams, code references, split central plants, and elevator shaft pressurization.
- Chapter 7, Educational Facilities, provides new design criteria updated for current standards, a new section on energy measurement and verification, and a newly compiled list of case studies from *ASHRAE Journal*.
- Chapter 8, Health Care Facilities, has been extensively revised to ANSI/ASHRAE/ASHE *Standard 170-2013*, with new content on regulatory resources, hospital-acquired infections, sustainability, and operations, and expanded text on control measures, outpatient care, isolation and bronchoscopy rooms, plus research results from RP-1343 on heat gain from imaging systems.
- Chapter 16, Laboratories, includes updates on applying usage factors, pressurization control, and energy efficiency measures.
- Chapter 18, Clean Spaces, has extensive new content on demand control, computational fluid dynamics analysis, pharmaceutical manufacturing facilities, safety, environmental systems, installation and testing, and sustainability and energy conservation.
- Chapter 19, Data Centers and Telecommunication Facilities, has been completely rewritten for current best practices as in the ASHRAE Datacom Series.

- Chapter 33, Kitchen Ventilation, was updated for the latest revisions to relevant standards, with new sections added on commissioning and the design process (for the first-time designer), and the chapter content restructured to reflect the sequence of the design process.
- Chapter 34, Geothermal Energy, has significant new content and examples on ground-coupled heat pump systems design, hybrid ground-source heat pumps, piping, pressure considerations, purging, deep boreholes, central plants, open-loop/surface-water direct cooling, and simulation.
- Chapter 35, Solar Energy Use, has revised examples and figures, plus new content on solar-combi systems; design, control, and operation of solar cooling; and grid-connected photovoltaic systems.
- Chapter 49, Water Treatment, has major revisions on corrosion, deposition, microbiological growth and control, filtration and closed-loop systems, alternative water sources, Legionnaires' disease, thermal storage, and steam boiler systems.
- Chapter 50, Service Water Heating, describes new technologies for hot-water generation and distribution and reducing consumption at end-use fixtures.
- Chapter 53, Fire and Smoke Control, has been revised to align with ASHRAE's *Handbook of Smoke Control Engineering*, with many new figures and examples.

This volume is published, as a bound print volume and in electronic format on CD-ROM and online, in two editions: one using inch-pound (I-P) units of measurement, the other using the International System of Units (SI).

Corrections to the 2012, 2013, and 2014 Handbook volumes can be found on the ASHRAE web site at <http://www.ashrae.org> and in the Additions and Corrections section of this volume. Corrections for this volume will be listed in subsequent volumes and on the ASHRAE web site.

Reader comments are enthusiastically invited. To suggest improvements for a chapter, **please comment using the form on the ASHRAE web site** or, using the cutout page(s) at the end of this volume's index, write to Handbook Editor, ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329, or fax 678-539-2187, or e-mail mowen@ashrae.org.

Mark S. Owen

COMPOSITE INDEX

This index covers the current Handbook series published by ASHRAE. The four volumes in the series are identified as follows:

- S = 2012 HVAC Systems and Equipment
- F = 2013 Fundamentals
- R = 2014 Refrigeration
- A = 2015 HVAC Applications

Alphabetization of the index is letter by letter; for example, **H**eaters precedes **H**eat exchangers, and **F**loors precedes **F**loor slabs.

The page reference for an index entry includes the book letter and the chapter number, which may be followed by a decimal point and the beginning page in the chapter. For example, the page number S31.4 means the information may be found in the 2012 HVAC Systems and Equipment volume, Chapter 31, beginning on page 4.

Each Handbook volume is revised and updated on a four-year cycle. Because technology and the interests of ASHRAE members change, some topics are not included in the current Handbook series but may be found in the earlier Handbook editions cited in the index
